Medical Cannabis Registry

PETITION TO ADD A DEBILITATING MEDICAL CONDITION IN 2020

Instructions

1. ALL items on the form MUST be completed.
2. Petitions and any supporting documents may be submitted as follows:
 - a. Email to: medicalmarijuana@doh.hawaii.gov before the close of business (4:30PM) on **Thursday, April 30, 2020**. Please use the subject line: Petition to Add New Condition. Note that the DOH will not make public any information that is protected pursuant to Chapter 92F, HRS, the Uniform Information Practices Act.
 - b. Postal mail to: 4348 Waialea Avenue, #648, Honolulu, Hawaii 96816. Mailed petitions must be received by **Thursday, April 30, 2020**.
 - c. Hand delivered to: Kinau Hale at 1250 Punchbowl Street, Honolulu, Hawaii 96813 before the close of business (4:30PM) on **Thursday, April 30, 2020**. Hand delivered petitions must be left with the security guard and addressed to the Medical Cannabis Registry Program **ATTN: Petition to Add New Condition**.
3. For best results, complete and thorough petitions that include substantiated and reputable research have the best chance of succeeding. DOH recommends that you do the following for items #2- #8 on the petition form:
 - a. Please cite research, published evidence, or findings using the standard American Medical Association (AMA) format for each piece of research, published evidence, or findings that you reference in your submittal or at a minimum the following:
 Author's Name; Title of Article; Name of Publication; Date of Publication; Volume/Section/Chapter/Page/Line as applicable; and URL (if applicable).
 - b. Please attach a PDF copy of the cited material to your submittal. These documents will NOT be returned.
 - c. Please be sure to indicate the specific section, page(s), lines, etc., of the attachment that you want reviewed/considered as evidence.
4. To view a list of current conditions click here: [Current Debilitating Medical Conditions](#)

Petitioner

Name [REDACTED]

- I am a
- Physician/APRN
 - Potentially qualifying patient (a person who has been diagnosed with the medical condition for which the petition is being made)

Street Address [REDACTED]

City [REDACTED]

State [REDACTED]

Email [REDACTED]

I prefer the following and give my consent for all notifications about my petition to be by:

- Mailing address
- Email address
- Both mailing and email addresses

If I have indicated communication via email, and if for any reason email communication is not successful (i.e. email provided bounces or is kicked back to DOH), then I further understand that communication will be by regular U.S. postal service to the mailing address that I have provided. I also take full responsibility for any inaccurate email or U.S. postal mail address provided.

Petitioner Content

(1) State the specific medical condition or its treatment for which the petition is being made.

Anxiety

(2) State the reason(s) why the medical condition or its treatment should be added to the list of qualifying debilitating medical conditions for which medical cannabis may be used. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

This petition includes new published evidence and scientific research findings supporting the request to add "Anxiety" as a qualifying condition that were not present in the "General Anxiety Disorder" petition. This petition should be reviewed and not rejected for its similarity to an earlier petition due to the new evidence published by the Minnesota Department of Health, the Massachusetts Department of Health and other peer-reviewed medical research attached and included.

The number one condition that medical cannabis patients report that cannabis alleviates symptoms is Anxiety. Cannabis helps patients with Anxiety more than it helps alleviate chronic pain. It is for this reason and the reasons below that Anxiety should be added to the list of qualifying debilitating medical conditions for which medical cannabis may be used. Anxiety is a debilitating condition that affects the whole person, including treatment of other conditions.

<https://www.mass.gov/report/massachusetts-department-of-public-health-marijuana-research>
(REF #77) <https://www.mass.gov/files/documents/2019/07/09/MBHS-full-report-final.pdf>
The Marijuana Baseline Health Study (MBHS)

A legislative mandate required the Massachusetts [Department of Public Health \(DPH\)](#) to conduct a baseline study to investigate marijuana use in Massachusetts. The report published confirms the consensus that marijuana use improves mood and or mental health for a large percentage of people.

Page 148:

Results from this survey suggest that respondents appear to be treating a wide range of medical conditions, and often more than one at a time. **The top 5 medical conditions being treated were anxiety (60% or all respondents)**, chronic pain (46%), insomnia (43%), depression (42%), and stress (41%), and the average number of conditions being treated by medical marijuana is 4.7.

In the 1999 National Academy of Sciences Institute of Medicine report on marijuana, the National Academy of Science found that thorough medical research shows that marijuana reduces anxiety for "many people".

(REF #99) <https://www.nap.edu/catalog/6376/marijuana-and-medicine-assessing-the-science-base>

(REF #99) <https://www.nap.edu/download/6376>

page 165

The movement disorders most often considered for marijuana or cannabinoid therapy are dystonia, Huntington's disease, Parkinson's disease, and Tourette's syndrome.

Movement disorders are often transiently exacerbated by stress and activity and

improved by factors that reduce stress. **This is of particular interest because for many people marijuana reduces anxiety.**

In a study of medical marijuana patients in Arizona, many patients reported significant relief levels of anxiety.

(REF #13) <https://www.ncbi.nlm.nih.gov/pubmed/26317379>

367 medical marijuana patients in Arizona were surveyed.

181 patients reported using medical marijuana to experience relief from Anxiety
General relief from Anxiety symptoms was 82.9% with medical marijuana,

Relief by medical marijuana compared to other medications was 79.3% for Anxiety
Less frequent use of other medications was 85.9% for Anxiety

Patients who suffer from Post Traumatic Stress Disorder find relief of anxiety with medical cannabis. PTSD is a qualifying condition in Hawaii and other states. It makes logical sense to allow people who do not have PTSD to gain relief of anxiety by adding anxiety to the list of qualifying conditions.

In a small percentage of people, medical cannabis can aggravate their anxiety. For the majority of people, cannabis reduces anxiety. This contraindication is similar to other anti-anxiety prescriptions, for whom a small percentage, their anxiety can be aggravated. This is not a reason to reject a qualifying condition, merely a reality of using any medication. Some epilepsy medicines make seizures worse or more frequent for example.

Marijuana is safer than all prescription medications and most of OTC medications. Cannabis has less side effects, and no severe, toxic or dangerous side effects compared to all of the prescription medications used to treat Anxiety.

<https://www.nimh.nih.gov/health/topics/mental-health-medications/index.shtml>

For example Benzodiazepines commonly used as anti anxiety medications, are responsible for hundreds of deaths each year in the United States.

A safety profile of Medical Marijuana can be found in the first year report of the Minnesota medical marijuana program. The Minnesota Department of Health surveyed 1500+ medical marijuana patients enrolled in the program.

(REF #98) <https://www.health.state.mn.us/people/cannabis/about/firstyearreport.html>

Adverse Side Effects: At this point, the safety profile of the medical cannabis products available through the Minnesota program seems quite favorable. Approximately 20-25% of enrolled patients report negative physical or mental side effects of some kind, with the majority – around 60% - reporting only one and 90% reporting three or fewer. The vast majority of adverse side effects, around 90%, are mild to moderate in severity. An assessment of the 30 patients reporting severe side effects, meaning “interrupts usual daily activities,” found no apparent pattern of patient age, medical condition, or type of medical cannabis used. The most common adverse side effects are dry mouth, drowsiness, and fatigue. Fortunately, up to the present no serious adverse events (life threatening or requiring hospitalization) have been reported.

Medical Marijuana's mild to moderate side effects of dry mouth, drowsiness and fatigue are easily tolerated by the vast majority of patients.

The Mayo Clinic website has assembled dosage information on Medical Marijuana.

<http://www.mayoclinic.org/drugs-supplements/marijuana/dosing/hrb-20059701>

In the latest petition to add Anxiety to Ohio's medical marijuana program, the New Jersey Department of Health's final decision on a petition to add anxiety in New Jersey was included.

(REF 96) [https://med.ohio.gov/Portals/0/Publications/Medical%20Marijuana%20Petitions%202019/0133%20-%20Anxiety%20\[Rosenberger\].pdf?ver=2020-01-28-104750-247](https://med.ohio.gov/Portals/0/Publications/Medical%20Marijuana%20Petitions%202019/0133%20-%20Anxiety%20[Rosenberger].pdf?ver=2020-01-28-104750-247)

(REF 97)

https://www.nj.gov/health/medicalmarijuana/documents/agency_decision_letters/MMP_FAD_conditions_012319.pdf

New Jersey's medical cannabis program is similar to Hawaii's medical cannabis program. With similar requirements for petitions to meet.

On July 5, 2016, the Department published the Request for Petitions in the New Jersey Register advising that from August 1, 2016 to August 31, 2016, it was accepting petitions to establish additional medical conditions as "debilitating" under the MMP. 43 NJR. 1395(a). The Request for Petitions stated that the Department was seeking petitions in accordance with the Act, which authorizes the Department to include additional debilitating medical conditions under the MMP.

In the Request for Petitions, the public was advised that submitted petitions were required to include the following information, pursuant to N.J.A.C. 8:64-53:

- (1) The extent to which the condition is generally accepted by the medical community and other experts as a valid, existing medical condition;
- (2) If one or more treatments of the condition, rather than the condition itself, are alleged to be the cause of the patient's suffering, the extent to which the treatments causing suffering are generally accepted by the medical community and other experts as valid treatments for the condition;
- (3) The extent to which the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting, or otherwise severely impair the patient's ability to carry on activities of daily living;
- (4) The availability of conventional medical therapies other than those that cause suffering to alleviate suffering caused by the condition and/or the treatment thereof;
- (5) The extent to which evidence that is generally accepted among the medical community and other experts supports a finding that the use of marijuana alleviates suffering caused by the condition and/or the treatment thereof; and
- (6) Letters of support from physicians or other licensed health care professionals knowledgeable about the condition.

New Jersey found that Anxiety met the requirements and accepted Anxiety as a qualifying condition.

Anxiety

Based upon my independent review of the petitions, I am granting those seeking to add anxiety to the MMP. In coming to this conclusion, I reviewed these petitions against the six regulatory criteria cited above and found that the condition meets the requirements for inclusion in the MMP.

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that anxiety satisfies this criteria.

Specifically, the American Psychiatric Association defines anxiety and anxiety disorders as conditions characterized by excessive fear and behavioral disturbances. Anxiety results from anticipation of a future threat and may be associated with symptoms of muscle tension, vigilance in preparation for future danger, and overly cautious or avoidant behaviors. Additionally, there are multiple ICD-10-CM codes for anxiety disorders. Because anxiety maintains a common definition in the medical community and has ICD-10-CM codes, I find that anxiety is a valid and recognized medical condition.

Under the second factor, I must consider whether the treatments for the condition, rather than the condition itself, are causing the patient's suffering and the extent to which the treatments causing the patient suffering are

generally accepted by the medical community and other experts as valid treatments for the condition. From my review of this condition, the generally accepted treatments for anxiety are dependent on the symptoms and the severity of the particular disorder.

Mild and moderate forms of anxiety may not require a pharmacologic intervention, but may necessitate other forms of treatment, such as meditation, mindfulness, breathing techniques as well as psychotherapy (counseling) or cognitive therapy.⁴⁸ The most common classes of medications used to combat anxiety disorders are antidepressants, anti-anxiety drugs, and beta-blockers.⁴⁹ Antidepressants are safe and effective but they may be risky for children, teens, and young adults.⁵⁰ Antidepressants also come with a "black box" warning — the FDA's strongest warning — advising that some people may have suicidal thoughts or make suicide attempts while taking the medication.⁵¹ The most common anti-anxiety medications are called benzodiazepines.

As noted by the Panel, the common side effects of benzodiazepines include headache, confusion, tiredness, and in some cases nightmares and memory impairments.⁵² And, benzodiazepines carry a risk of dependence and addiction.⁵³ Furthermore, the FDA notes that the number of patients who were prescribed both an opioid analgesic and benzodiazepine increased by 41% between 2002 and 2014.⁵⁴ As a result, the FDA requires black box warnings and patient-focused Medication Guides for prescription opioid analgesics, opioid-containing cough products, and benzodiazepines to inform the patient about the serious risks associated with using these medications at the same time.⁵⁵ Thus, I find that the treatments for anxiety are recognized and accepted by the medical community as the treatments for this condition and relate to the suffering of the patient.

As for the third factor, which is whether the condition itself and for the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that both the anxiety condition itself as well as the treatments for this condition cause severe suffering for patients. Specifically, anxiety may lead to problems that negatively impact an individual's activities of daily living and quality of life and may lead to suicide and depression. Anxiety disorders can also cause significant distress or interfere with social, occupational, and other areas of functioning. In fact, an estimated 31.1% of U.S. adults experience an anxiety disorder at some time in their lives.⁵⁶ Medications, in some instances, may exacerbate the symptoms and are associated with debilitating side effects that can prevent a patient from engaging in activities of daily living, thereby diminishing one's quality of life. Accordingly, I find that both the condition of anxiety as well as the therapies to treat it cause severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and or the treatment thereof. As discussed above, mild and moderate forms of anxiety may be treated with meditation, mindfulness, breathing techniques as well as counseling or cognitive therapy that can be effective. Progression to medication therapy may be initiated; however, in both instances, one must consider the therapeutic response. Failure to respond to therapies or side effects associated with treatments may result in significant impacts on quality of life. As such, I find that there is an absence of medically-accepted, alternative medical therapies to the conventional therapies currently prescribed for migraine that cause suffering.

Regarding the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I find that cannabis is generally accepted as an effective treatment for anxiety.

The Panel discussed medical evidence that cannabis may exacerbate anxiety symptoms or that an effect related to cannabis may be associated with anxiety, such as dependence and cravings. Literature suggests that individuals with anxiety sensitivity may be more likely to turn to cannabis as a mechanism for coping with stress, which may in turn lead to problematic use behaviors.⁵⁷ However, the Panel further discussed a review published by the National Academies of Sciences, Engineering, and Medicine in 2017, which found that there is limited evidence that cannabidiol is an effective treatment for the improvement of anxiety symptoms, which was assessed by a public speaking test utilizing individuals with social anxiety disorders.⁵⁸

On balance, the Panel recommended adding anxiety as an allowable condition under the MMP as research suggests that it could be helpful to some patients with this condition. I agree. While marijuana may not be effective for all anxiety sufferers, there is research evidencing that it may be helpful to some, especially those with social anxiety disorders. Thus, I find that there is acceptance in the medical community that marijuana is

likely to relieve the suffering associated with some anxiety conditions. However, like any medical condition, the use of medical marijuana to treat anxiety must be explored by the medical professional treating the patient to determine whether it is the best and most appropriate course of treatment for the patient.

As for the final factor, which is whether there were letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of anxiety under the MMP, I find that the petitions were submitted with support from medical professionals.

Based upon the above analysis, I find that the condition of anxiety is “debilitating” and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the debilitating effect of this condition. As such, I find that anxiety should be added to the MMP.

In a previous qualifying condition petition for Generalized Anxiety Disorder, the Director of Health at the Hawaii Department of Health rejected adding the condition to the medical marijuana program. The main reason being that there is a lack of peer-reviewed scientific evidence showing beneficial use to treat GAD. This idea that peer-reviewed scientific evidence needs to conclusively show medical benefit or else no other qualifying conditions could be approved is wrong; due to the political nature of marijuana. Please allow me to explain.

The Hawaii medical cannabis law was created based on medical and anecdotal evidence. Anecdotal evidence was accepted because there is a lack of scientific research on the benefits of marijuana. Due to cannabis’s placement in schedule 1 of controlled substances in both state and federal laws. Quoting from the Hawaii Medical Cannabis Law:

https://www.capitol.hawaii.gov/session2000/acts/Act228_SB862_HD1_.htm

There is sufficient medical and **anecdotal evidence** to support the proposition that these diseases and conditions may respond favorably to a medically controlled use of marijuana.

This lack of research is due to the funding of marijuana research being regulated by NIDA, the National Institute of Drug Abuse. NIDA’s purpose is investigating the abuse potential of drugs, including cannabis, with focus solely on trying to prove the negatives of marijuana use. Since NIDA funds negative effects of marijuana research, research is granted on the flimsiest of theories and has corrupted and biased science. Forcing researchers to chase more NIDA grants for research to ensure they continue to have jobs.

Negative research findings are promoted wildly by NIDA when they are published. Even if the methodology of the study is flawed beyond belief. Even when other researchers try to duplicate the results and fail, NIDA continues to promote the flawed study as though it still has merit. An example of this can be found on NIDA's website

<https://www.drugabuse.gov/news-events/nida-notes/2016/08/study-questions-role-marijuana-in-teen-users-iq-decline>

This finding suggests that the twins’ IQ was affected by factors that twins share in their genes or family background, rather than factors in which they differed (e.g., drug use). A further analysis, comparing the impact of marijuana use on fraternal versus identical twins, suggested that family-wide environmental influences are more decisive than genes for determining IQ trajectory.

NIDA, without any evidence to back up the statement, goes on:

These findings contrast but are not entirely inconsistent with those of an earlier study that linked teen-onset regular marijuana use to IQ deficits in the fourth decade of life (see Early-Onset, Regular Cannabis Use Is Linked to IQ Decline). The researchers say that although their evidence indicates that marijuana exposure does not cause persistent loss of intellectual function up to age 20, **prolonged regular exposure for decades might do so.**

NIDA contradicts itself often, and continues to promote failed theories that bear no relationship to reality. Especially trying to say that marijuana is a gateway drug.

<https://www.drugabuse.gov/publications/research-reports/marijuana/marijuana-gateway-drug>

These findings are consistent with the idea of marijuana as a "gateway drug." However, the majority of people who use marijuana do not go on to use other, "harder" substances.

A more sinister theory promoted by NIDA, the DEA, and even physicians is that marijuana use increases the risk of Schizophrenia. This is so unbelievable that it is a slap in the face of science. Simply looking at reality, the larger numbers of people using, or admitting to use of marijuana, the large number of registered medical cannabis patients in the USA (roughly 1,000,000 to 2,000,000) and the flat schizophrenia rates as reported by the NIH and WHO completely invalidate all peer-reviewed published research on the topic of marijuana causing schizophrenia.

<https://www.nimh.nih.gov/health/statistics/schizophrenia.shtml>

<https://www.who.int/news-room/fact-sheets/detail/schizophrenia>

In fact, a percentage of people diagnosed with schizophrenia use marijuana to reduce anxiety and help with symptoms. People with more severe schizophrenia use more marijuana, this is the basis for the theory that marijuana causes more severe symptoms of schizophrenia. Similar thinking is used against patients who have more severe pain, that marijuana somehow makes pain worse for patients and they have to use more marijuana to gain pain relief. Instead of the observable theory that people with more severe pain use more marijuana to treat their more severe pain than people who have less severe pain. No one makes the theory that aspirin makes pain worse, because people with more pain use more aspirin. Bad science.

The whole point of a state medical marijuana law is that the federal government has engineered a catch-22 circular logic loop about marijuana. States, mostly via people's ballot initiatives have sideswiped the FDA in approving a medicine. This is because the FDA has adopted a policy of only endorsing and approving of monotherapies, e.g. one or two isolated and specific chemicals per approved medicine. There is another policy to reject crude botanical medicines due to variations from plant to plant. These comments by the FDA are found in the DEA response to a petition to reschedule marijuana to schedule 2 and in congressional testimony. Even if a company submitted an IND to the FDA to study marijuana for the treatment of a disease, it would be rejected by the FDA on both of those policies.

The catch-22 comes when patients, nurses, physicians, governors, senators and representatives suggest that marijuana be investigated as a medicine. In congressional testimony, the FDA says we need more research before endorsing that. NIDA says we need more research before utilizing marijuana as a medicine. The DEA says we need more research before marijuana could be considered a medicine. So, if everyone agrees we need more research, where exactly is the research?

Individual physicians have attempted to research the benefits of marijuana within universities. What happens is that, at every turn, approval to study is blocked, delayed and rejected. See for example the 10 years of trying to study medical marijuana for treatment of PTSD in veterans.

<https://www.stripes.com/marijuana-ptsd-study-concludes-after-10-years-of-planning-research-1.570986>

Sisley and her team had to gain approval and support from the U.S. Food and Drug Administration, the Drug Enforcement Administration and the National Institute on Drug Abuse to initiate the research – a process that lasted years.

One study took several years just to begin. After NIDA provided marijuana for research that was full of seeds, stems and mold.

<https://health.hawaii.gov/medicalcannabisregistry/files/2017/08/Generalized-Anxiety-Disorder-08.09.17-Redacted.pdf>

The GAD petition submitted in 2017 included anecdotal evidence, peer-reviewed patient surveys, marijuana use reports and other information. It was rejected by the director due to not having enough peer-reviewed scientific research. One reason given for the rejection was that there was "no specific evidence to GAD". This is why exact specific conditions and waiting for peer-reviewed medical research will never work as an administrative rule for reviewing qualifying condition petitions. There will never be medical marijuana research that specifically mentions each of the hundreds of conditions that include anxiety as a symptom. Research studies are done with one drug and one condition. A rejection for not having a specific condition mentioned seems more like a pedantic nitpick and less like a legitimate reason when both GAD and anxiety share anxiety as the core symptom.

This GAD petition rejection uses the same reason the federal government does not approve of medical marijuana. If this requirement barrier of peer-reviewed research was erected, no state would have a medical marijuana program. Due to the federal policies which are a de facto prohibition on research for medical marijuana benefits. These state medical marijuana programs were created because the federal government failed to do research, and continues to prohibit new research. While the reality is that cannabis is a non toxic medicine, has always been a medicine and always will be a

medicine.

Anxiety was also included with a bill in the Hawaii legislature to add qualifying conditions. The Department of Health testified, and in opposing the bill, the DOH stated it would rather include conditions via the petition process. The HDOH also gave another reason, that the dept wanted to delay adding the condition until dispensaries were active. Try naming another medication that is delayed and kept illegal because the department was waiting for a pharmacy to open. The DOH needs to stop these petty games played with sick people's lives.

(REF #95) https://www.capitol.hawaii.gov/session2018/testimony/SB174_TESTIMONY_CPH_02-08-17.pdf

This is another wrong-headed approach to the process, and ignores why and what the medical marijuana law does. Allow me to explain the purpose of the law and the role of the DOH in it.

From the Hawaii medical cannabis law:

The legislature is aware of the legal problems associated with the legal acquisition of marijuana for medical use. However, the legislature believes that medical scientific evidence on the medicinal benefits of marijuana should be recognized.

...

Therefore, the purpose of this Act is to ensure that seriously ill people are not penalized by the State for the use of marijuana for strictly medical purposes when the patient's treating physician provides a professional opinion that the benefits of medical use of marijuana would likely outweigh the health risks for the qualifying patient.

The whole point of the medical marijuana program is not to endorse, nor recommend medical marijuana to patients. The purpose of the law is to NOT PENALIZE patients using medical marijuana with recommendations from their physicians. To protect patients from the laws prohibiting the use of marijuana.

Said another way, it is not the Department of Health's role to become the FDA and research medical marijuana. It is not the DOH's role to judge if medical marijuana is a medicine or not. It is not the DOH's role to decide which conditions marijuana is beneficial for either. That role is solely for a patient to decide if medical marijuana works for their conditions or not. Physicians have a role to make sure the patient's health is first priority over any medication.

The DOH's only role in the petition process is to protect medical marijuana patients from arrest.

People are currently illegally using marijuana to treat their conditions, specifically anxiety. The DOH has the power to protect these patients by adding qualifying conditions. Instead, the DOH has assumed the role of the FDA, denying petitions and opposing adding conditions legislatively. Waiting for peer-reviewed medical evidence that by all accounts is not coming within the next two decades.

This delay and denial of the reality of medical marijuana patients conditions needs to stop.

- (3) Describe the **extent to which** the medical condition is generally accepted by the medical community as a valid, existing medical condition. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Anxiety is accepted by the medical community as a valid existing medical condition affecting millions of Americans each year. The CDC, NIH and Veterans Affairs all have in-depth websites dedicated to anxiety and treatment.

<https://www.nimh.nih.gov/health/statistics/any-anxiety-disorder.shtml>

The wide variety of anxiety disorders differ by the objects or situations that induce them, but share features of excessive anxiety and related behavioral disturbances. Anxiety disorders can interfere with daily activities such as job performance, school work, and relationships.

Based on diagnostic interview data from the National Comorbidity Study Replication (NCS-R), Figure 1 shows past year prevalence of any anxiety disorder among U.S. adults aged 18 or older.¹

An estimated 19.1% of U.S. adults had any anxiety disorder in the past year.

Past year prevalence of any anxiety disorder was higher for females (23.4%) than for males (14.3%).

An estimated 31.1% of U.S. adults experience any anxiety disorder at some time in their lives.

Anxiety affects a large portion of the people in the United States, costing billions of dollars in medical treatment costs.

<https://www.cdc.gov/mentalhealth/basics/burden.htm>

Anxiety:

- Anxiety disorders, which include panic disorder, generalized anxiety disorder, post-traumatic stress disorder, phobias, and separation anxiety disorder, are the most common class of mental disorders present in the general population.
- The estimated lifetime prevalence of any anxiety disorder is over 15%, while the 12-month prevalence is more than 10%.
- Prevalence estimates of anxiety disorders are generally higher in developed countries than in developing countries.
- Most anxiety disorders are more prevalent in women than in men.
- One study estimated the annual cost of anxiety disorders in the United States to be approximately \$42.3 billion in the 1990s, a majority of which was due to non-psychiatric medical treatment costs. This estimate focused on short-term effects and did not include the effect of outcomes such as the increased risk of other disorders.

Veterans suffer from Anxiety and related disorders.

<https://pubmed.ncbi.nlm.nih.gov/15127904/>

Results: Veterans of the first Gulf War reported a markedly higher prevalence of current anxiety disorders than nondeployed military personnel (5.9% vs. 2.8%; odds ratio = 2.1; 95% confidence interval = 1.3-3.1), and their anxiety disorders are associated with co-occurring psychiatric disorders. Posttraumatic stress disorder, panic disorder, and generalized anxiety disorder were each present at rates nearly twice expected. In our multivariate model, predeployment psychiatric treatment and predeployment diagnoses (posttraumatic stress disorder, depression, or anxiety) were independently associated with current anxiety disorder. Participation in Gulf War combat was independently associated with current posttraumatic stress disorder, panic disorder, and generalized anxiety disorder.

(4) Describe the symptoms and other physiological or psychological effects experienced by an individual suffering from the medical condition or its treatment and **the extent to which** these symptoms and physiological or psychological effects are debilitating. Note: "Debilitating" generally means impairing the ability of a person to accomplish activities of daily living. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Anxiety can cause a person to withdrawal from talking to other people or even going outside. Anxiety can diminish or completely debilitate a person from interviewing for a job, making day to day decisions, making personal relationships or thriving.

Instead of dealing and treating anxiety, the world instead decided to call anxiety being an introvert. An "introvert" is a "shy, reticent person". In other words, a person who has so much anxiety that they would rather hide than speak to someone else. Shyness is anxiety.

<https://www.nimh.nih.gov/health/publications/social-anxiety-disorder-more-than-just-shyness/index.shtml>

The reason this petition is for "Anxiety" and not "social anxiety disorder" is because each year there seems to be a newly named disorder with the core symptom being anxiety. Panic Disorder, Generalized Anxiety Disorder, Social Anxiety Disorder, Seasonal Affective disorder, PTSD. Anxiety is the common condition.

<https://www.nimh.nih.gov/health/statistics/any-anxiety-disorder.shtml>

Any Anxiety Disorder with Impairment Among Adults

Of adults with any anxiety disorder in the past year, degree of impairment ranged from mild to severe, as shown in Figure 2. Impairment was determined by scores on the Sheehan Disability Scale.

Among adults with any anxiety disorder, an estimated 22.8% had serious impairment, and 33.7% had moderate impairment.¹

A majority of people with any anxiety disorder experienced mild impairment (43.5%).¹

1. Harvard Medical School, 2007. National Comorbidity Survey (NCS). (2017, August 21). Retrieved from <https://www.hcp.med.harvard.edu/ncs/index.php>. Data Table 2: 12-month prevalence DSM-IV/WMH-CIDI disorders by sex and cohort.

<https://www.ncbi.nlm.nih.gov/pmc/articles/PMC181171/>

Although the principal symptoms of anxiety disorders include fear, excessive worry, nervousness, and obsessions, a multitude of physical symptoms also may be present. These somatic symptoms—which include heart palpitations, gastrointestinal problems, sweating, fainting, and chronic pain—can confound the diagnosis and resist all forms of medical management, unless the underlying anxiety source is identified and treated. Delays in diagnosis and treatment can be expensive for the patient, physician, and society: unnecessary tests and ineffective treatments increase medical costs, and **anxiety symptoms may lead to loss of income and productivity, financial dependence, and even suicide.**

11 Signs and Symptoms of Anxiety Disorders

Many people experience anxiety at some point in their lives.

In fact, anxiety is a very normal response to stressful life events like moving, changing jobs or having financial troubles.

However, when symptoms of anxiety become larger than the events that triggered them and begin to interfere with your life, they could be signs of an anxiety disorder.

Anxiety disorders can be debilitating, but they can be managed with proper help from a medical professional. Recognizing the symptoms is the first step.

Here are 11 common symptoms of an anxiety disorder, as well as how to reduce anxiety naturally and when to seek professional help.

1. Excessive Worrying

One of the most common symptoms of an anxiety disorder is excessive worrying.

The worrying associated with anxiety disorders is disproportionate to the events that trigger it and typically occurs in response to normal, everyday situations ([1Trusted Source](#)).

To be considered a sign of generalized anxiety disorder, the worrying must occur on most days for at least six months and be difficult to control ([2Trusted Source](#)).

The worrying must also be severe and intrusive, making it difficult to concentrate and accomplish daily tasks.

People under the age of 65 are at the highest risk of generalized anxiety disorder, especially those who are single, have a lower socioeconomic status and have many life stressors ([3Trusted Source](#)).

2. Feeling Agitated

When someone is feeling anxious, part of their sympathetic nervous system goes into overdrive.

This kicks off a cascade of effects throughout the body, such as a racing pulse, sweaty palms, shaky hands and dry mouth (4).

These symptoms occur because your brain believes you have sensed danger, and it is preparing your body to react to the threat.

Your body shunts blood away from your digestive system and toward your muscles in case you need to run or fight. It also increases your heart rate and heightens your senses (5Trusted Source).

While these effects would be helpful in the case of a true threat, they can be debilitating if the fear is all in your head.

Some research even suggests that people with anxiety disorders are not able to reduce their arousal as quickly as people without anxiety disorders, which means they may feel the effects of anxiety for a longer period of time (6Trusted Source, 7Trusted Source).

3. Restlessness

Restlessness is another common symptom of anxiety, especially in children and teens.

When someone is experiencing restlessness, they often describe it as feeling “on edge” or having an “uncomfortable urge to move.”

One study in 128 children diagnosed with anxiety disorders found that 74% reported restlessness as one of their main anxiety symptoms (8Trusted Source).

While restlessness does not occur in all people with anxiety, it is one of the red flags doctors frequently look for when making a diagnosis.

If you experience restlessness on the majority of days for more than six months, it may be a sign of an anxiety disorder (9Trusted Source).

4. Fatigue

Becoming easily fatigued is another potential symptom of generalized anxiety disorder.

This symptom can be surprising to some, as anxiety is commonly associated with hyperactivity or arousal.

For some, fatigue can follow an anxiety attack, while for others, the fatigue can be chronic.

It's unclear whether this fatigue is due to other common symptoms of anxiety, such as insomnia or muscle tension, or whether it may be related to the hormonal effects of chronic anxiety (10Trusted Source).

However, it is important to note that fatigue can also be a sign of depression or other medical conditions, so fatigue alone is not enough to diagnose an anxiety disorder (11Trusted Source).

5. Difficulty Concentrating

Many people with anxiety report having difficulty concentrating.

One study including 157 children and teens with generalized anxiety disorder found that more than two-thirds had difficulty concentrating (12Trusted Source).

Another study in 175 adults with the same disorder found that almost 90% reported having difficulty concentrating. The worse their anxiety was, the more trouble they had (13Trusted Source).

Some studies show that anxiety can interrupt working memory, a type of memory responsible for holding short-term information. This may help explain the dramatic decrease in performance people often experience during periods of high anxiety ([14Trusted Source](#), [15Trusted Source](#)).

However, difficulty concentrating can also be a symptom of other medical conditions, such as an attention deficit disorder or depression, so it is not enough evidence to diagnose an anxiety disorder.

6. Irritability

Most people with anxiety disorders also experience excessive irritability.

According to one recent study including over 6,000 adults, more than 90% of those with generalized anxiety disorder reported feeling highly irritable during periods when their anxiety disorder was at its worst ([16Trusted Source](#)).

Compared to self-reported worriers, young and middle-aged adults with generalized anxiety disorder reported more than twice as much irritability in their day-to-day lives ([17Trusted Source](#)).

Given that anxiety is associated with high arousal and excessive worrying, it is not surprising that irritability is a common symptom.

7. Tense Muscles

Having tense muscles on most days of the week is another frequent symptom of anxiety.

While tense muscles may be common, it's not fully understood why they're associated with anxiety.

It is possible that muscle tenseness itself increases feelings of anxiety, but it is also possible that anxiety leads to increased muscle tenseness, or that a third factor causes both.

Interestingly, treating muscle tension with muscle relaxation therapy has been shown to reduce worry in people with generalized anxiety disorder. Some studies even show it to be as effective as cognitive behavioral therapy ([18Trusted Source](#), [19Trusted Source](#)).

8. Trouble Falling or Staying Asleep

Sleep disturbances are strongly associated with anxiety disorders ([20Trusted Source](#), [21Trusted Source](#), [22Trusted Source](#), [23Trusted Source](#)).

Waking up in the middle of the night and having trouble falling asleep are the two most commonly reported problems ([24Trusted Source](#)).

Some research suggests that having insomnia during childhood may even be linked to developing anxiety later in life ([25Trusted Source](#)).

A study following nearly 1,000 children over 20 years found that having insomnia in childhood was linked to a 60% increased risk of developing an anxiety disorder by age 26 ([26Trusted Source](#)).

While insomnia and anxiety are strongly linked, it is unclear whether insomnia contributes to anxiety, if anxiety contributes to insomnia, or both ([27Trusted Source](#), [28Trusted Source](#)).

What is known is that when the underlying anxiety disorder is treated, insomnia often improves as well ([29Trusted Source](#)).

9. Panic Attacks

One type of anxiety disorder called panic disorder is associated with recurring panic attacks.

Panic attacks produce an intense, overwhelming sensation of fear that can be debilitating.

This extreme fear is typically accompanied by rapid heartbeat, sweating, shaking, shortness of breath, chest tightness, nausea and fear of dying or losing control ([30Trusted Source](#)).

Panic attacks can happen in isolation, but if they occur frequently and unexpectedly, they may be a sign of panic disorder.

An estimated 22% of American adults will experience a panic attack at some point in their lives, but only about 3% experience them frequently enough to meet the criteria for panic disorder ([31Trusted Source](#)).

10. Avoiding Social Situations

You may be exhibiting signs of social anxiety disorder if you find yourself:

- Feeling anxious or fearful about upcoming social situations
- Worried that you may be judged or scrutinized by others
- Fearful of being embarrassed or humiliated in front of others
- Avoiding certain social events because of these fears

Social anxiety disorder is very common, affecting roughly 12% of American adults at some point in their lives ([32Trusted Source](#)).

Social anxiety tends to develop early in life. In fact, about 50% of those who have it are diagnosed by age 11, while 80% are diagnosed by age 20 ([33Trusted Source](#)).

People with social anxiety may appear extremely shy and quiet in groups or when meeting new people. While they may not appear distressed on the outside, inside they feel extreme fear and anxiety.

This aloofness can sometimes make people with social anxiety appear snobby or standoffish, but the disorder is associated with low self-esteem, high self-criticism and depression ([34Trusted Source](#)).

11. Irrational Fears

Extreme fears about specific things, such as spiders, enclosed spaces or heights, could be a sign of a phobia.

A phobia is defined as extreme anxiety or fear about a specific object or situation. The feeling is severe enough that it interferes with your ability to function normally.

Some common phobias include:

- **Animal phobias:** Fear of specific animals or insects
- **Natural environment phobias:** Fear of natural events like hurricanes or floods
- **Blood-injection-injury phobias:** Fear of blood, injections, needles or injuries
- **Situational phobias:** Fear of certain situations like an airplane or elevator ride

Agoraphobia is another phobia that involves fear of at least two of the following:

- Using public transportation
- Being in open spaces
- Being in enclosed spaces
- Standing in line or being in a crowd
- Being outside of the home alone

Phobias affect 12.5% of Americans at some point in their lives. They tend to develop in childhood or the teenage years and are more common in women than men ([35Trusted Source](#), [36Trusted Source](#)).

(5) If one or more treatments for the medical condition, rather than the condition itself, are alleged to be the cause of a person's suffering, describe **the extent to which the treatments causing suffering are generally accepted by the medical community as valid treatments for the medical condition.** For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions

This petition is for the medical condition of anxiety. Not the treatment of anxiety. Anti-anxiety medications are a valid treatment generally accepted by the medical community and can cause serious side effects and death.

https://www.medicinenet.com/sertraline_zoloft_vs_venlafaxine_effexor/article.htm

What are the side effects of sertraline and venlafaxine?

Sertraline

The most common side effects of sertraline are:

- Sleepiness
- Nervousness
- Insomnia
- Dizziness
- Nausea
- Tremor
- Skin rash
- Constipation
- Upset stomach
- Loss of appetite
- Headache
- Diarrhea
- Abnormal ejaculation
- Decreased interest in sexual activity
- Dry mouth
- Increase in sweating, known as diaphoresis
- Weight loss

Possible serious side effects of sertraline include:

- Irregular heartbeats
- Serious allergic reactions
- Worsening of depression
- Serotonin syndrome
- Hyponatremia
- Abnormal bleeding
- Priapism (prolonged erection)
- Decreased liver function
- Suicidality
- Activation of mania in patients with bipolar disorder

Important side effects are irregular heartbeats, allergic reactions and activation of mania in patients with bipolar disorder.

If sertraline is discontinued abruptly, some patients experience side effects such as:

- Abdominal cramps
- Fatigue
- Nausea
- Vomiting
- Diarrhea
- Headaches
- Lightheadedness

- Dizziness
- Diminished appetite
- Flu-like symptoms
- Sweating
- Chills
- Sleep disturbances
- Memory impairment

A gradual dose reduction of sertraline is recommended when therapy is discontinued.

Venlafaxine

WARNING

- Antidepressants increase the risk of suicidal thinking and behavior (suicidality) in short-term studies in children, adolescents, and young adults with depression and other psychiatric disorders. Anyone considering the use of venlafaxine or any other antidepressant in a child or adolescent must balance this risk with the clinical need. Patients who are started on therapy should be closely observed for clinical worsening, suicidality, or unusual changes in behavior.

Venlafaxine, like most antidepressants, can cause:

- Nausea
- Headaches
- Anxiety
- Insomnia
- Drowsiness
- Loss of appetite

Other side effects that can occur are:

- Dizziness
- Ejaculation disorder
- Sweating
- Dry mouth
- Weight loss

Increased blood pressure can occur, and blood pressure should be monitored.

Seizures have been reported.

(6) Describe the availability of conventional medical therapies other than those that cause suffering to alleviate symptoms caused by the medical condition or its treatment. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

(7) Describe the extent to which evidence supports a finding that the use of cannabis alleviates symptoms caused by the medical condition or its treatment. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Selected quotes and transcribed tables are taken from the following research and presented below.

1. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3998228/>

Ninety-seven per cent of respondents used cannabis primarily for chronic pain. Average pain improvement on a 0–10 pain scale was 5.0 (from 7.8 to 2.8), which translates to a 64% relative decrease in average pain. Half of all respondents also noted relief from stress/anxiety, and nearly half (45%) reported relief from insomnia. Most patients (71%) reported no adverse effects, while 6% reported a cough or throat irritation and 5% feared arrest even though medical cannabis is legal in Hawai'i. No serious adverse effects were reported.

These results suggest that Cannabis is an extremely safe and effective medication for many chronic pain patients. Cannabis appears to alleviate pain, insomnia, and may be helpful in relieving anxiety. Cannabis has shown extreme promise in the treatment of numerous medical problems and deserves to be released from the current Schedule I

federal prohibition against research and prescription.

2. <https://harmreductionjournal.biomedcentral.com/articles/10.1186/1477-7517-2-18>

Approximately three quarters of participants (71%) claimed to have experienced a return of their symptoms or condition on stopping cannabis, especially: pain (53% of those who claimed a return of symptoms), depression or anxiety (30%), insomnia (11%), spasm (10%) and nausea/vomiting or lack of appetite (9%).

3. <https://doi.org/10.1016/j.jpain.2007.09.002>

A randomized, double-blind, placebo-controlled trial was conducted to determine the benefit of nabilone in pain management and quality of life improvement in 40 patients with fibromyalgia.

There were significant decreases in the VAS, FIQ, and anxiety in the nabilone treated group at 4 weeks. There were no significant improvements in the placebo group. The treatment group experienced more side effects per person at 2 and 4 weeks, respectively. Nabilone appears to be a beneficial, well-tolerated treatment option for fibromyalgia patients, with significant benefits in pain relief and functional improvement.

4. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2683812/>

Thematic analysis revealed that these teens differentiated themselves from recreational users and positioned their use of marijuana for relief by emphasizing their inability to find other ways to deal with their health problems, the sophisticated ways in which they titrated their intake, and the benefits that they experienced. These teens used marijuana to gain relief from difficult feelings (including depression, anxiety and stress), sleep difficulties, problems with concentration and physical pain.

5. <https://doi.org/10.1080/02791072.2011.587700>

Of 1,746 patients, 37.8% self-reported therapeutic benefits from medical marijuana for anxiety.

16.9% of patients self-reported therapeutic benefits from medical marijuana for panic attacks.

6. <https://www.ncbi.nlm.nih.gov/pubmed/6117575>

The results of the study showed a dramatic improvement in anxiety in the nabilone group when compared with placebo (P less than 0.001). Side effects reported were dry mouth, dry eyes, and drowsiness. Patients did not report any of the subjective "altered state" experience of marijuana.

7. <https://www.ncbi.nlm.nih.gov/pubmed/15857739>

Following Ethics Committee approval, HIV-positive individuals attending a large clinic were recruited into an anonymous cross-sectional questionnaire study. Up to one-third (27%, 143/523) reported using cannabis for treating symptoms. Patients reported improved appetite (97%), muscle pain (94%), nausea (93%), **anxiety (93%)**, nerve pain (90%), depression (86%), and paresthesia (85%).

8. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5101100/>

Cannabidiol oil, an increasingly popular treatment of anxiety and sleep issues, has been documented as being an effective alternative to pharmaceutical medications. This case study provides clinical data that support the use of cannabidiol oil as a safe treatment for reducing anxiety and improving sleep in a young girl with posttraumatic stress disorder.

9. <https://www.ncbi.nlm.nih.gov/pubmed/24095000>

Patients reported using cannabis to treat multiple symptoms, with sleep, pain, and anxiety being the most common. Cannabis was perceived to provide effective symptoms relief across medical conditions. Patterns of use were also consistent across medical conditions. Notable differences were observed with regard to modes of access.

10. <https://www.ncbi.nlm.nih.gov/pubmed/15184623/>

Of 21 patients reporting stress, 20 said medical marijuana helped moderate-complete relief.

Of 16 patients reporting mood, all 16 said medical marijuana helped moderate-complete relief.

The symptoms reported by medical cannabis users to be most effectively relieved were stress, sleep, mood,

stiffness/spasm, and pain.

11. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5312634/>

Finally, preliminary clinical trials suggest that high-dose oral CBD (150–600 mg per day) may exert a therapeutic effect for epilepsy, insomnia, and social anxiety disorder. Nonetheless, such doses of CBD have also been shown to cause sedation.

12. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5165161/>

In addition, we have assessed the role of the cannabinoid system and marijuana constituents in neuroprotection as well as considered other beneficial effects of marijuana. Marijuana has been shown to improve nonmotor symptoms of PD such as depression, pain, sleep, and anxiety.

Moreover, components of cannabis have been demonstrated to have neuroprotective effect due to their anti-inflammatory, antioxidative, and antiexcitotoxic properties.

13. <https://www.ncbi.nlm.nih.gov/pubmed/26317379>

367 medical marijuana patients in Arizona were surveyed.

181 patients reported using medical marijuana to experience relief from Anxiety

164 patients reported using medical marijuana to experience relief from Stress.

General relief from Anxiety symptoms was 82.9% and 87.2% for Stress,

Relief by medical marijuana compared to other medications was 79.3% for Anxiety and 91.6 for Stress.

Less frequent use of other medications was 85.9% for Anxiety and 79.1% for Stress.

14. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3285527/>

One Hundred Canadian medical marijuana patients were surveyed in 2007-2008. 60.2% said they used medical marijuana to reduce anxiety.

15. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1262744/>

This exploratory study examined the patterns of medicinal cannabis use among a sample of 128 Australian adults who responded to media stories about this issue.

Nearly one in ten (8%) reported no effect on depression or anxiety. More than one in ten (14%) specified that while cannabis could ease their symptoms and enabled them to cope, they realised that it could not cure their underlying condition.

Approximately three quarters of participants (71%) claimed to have experienced a return of their symptoms or condition on stopping cannabis, especially: pain (53% of those who claimed a return of symptoms), depression or anxiety (30%), insomnia (11%), spasm (10%) and nausea/vomiting or lack of appetite (9%).

Almost two thirds (62%) of respondents claimed that they decreased or discontinued their use of other medicines when they started using cannabis medicinally. This was more common in males (65% vs. 58% of females) and older participants (aged 50 years +) (70% vs. 59% among younger participants). For some people this was a substantial change, representing a shift away from chronic, high-dose medication use.

Perhaps not surprisingly, cannabis was typically perceived as superior to other medications in terms of undesirable effects, and the extent of relief provided. Thus, cannabis was rated to produce equivalent (8%) or worse side effects (3%) by a minority of therapeutic users. It was considered to work "a bit" or "much better" than other medicines, or to be the only source of relief, by more than three quarters (82%).

16. <https://www.ncbi.nlm.nih.gov/pubmed/28189912>

In regards to conditions, pain-related conditions were the most common, reported by 53% of participants (n = 144; chronic pain 36%; (n = 98), arthritis 12% (n = 32), headache 5% (n = 14)). The second most prominent class was mental health (eating disorder, PTSD & psychiatric disorder), reported by 15% (n = 41). Other prominent conditions included gastrointestinal disorders (11%, n = 29), insomnia (7%, n = 18) and multiple sclerosis (4%, n = 11). In regards to symptoms; the most highly endorsed were chronic pain (73%, n = 197), stress (60%,n=162), insomnia (57%, n =

155), depression (46%, n = 126) and headache (32%, n = 87). gastrointestinal (GI) issues also featured prominently, with 29% (n = 79) citing appetite loss and another 29% (n = 79) nausea. Cannabis was perceived to be very effective at symptom relief, with 95% (n = 257) reporting that it “often” or “always” helped alleviate their symptoms.

17. <https://doi.org/10.1111/dar.12323>

Participants presented with the range of conditions that is generally consistent with surveys of CTP users, the most prominent conditions being pain (32%), mood (i.e. anxiety and depression (18%), arthritis (15%), HIV (10%), gastrointestinal disorder (7%)

18. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5422566/>

We previously reported in an earlier survey that of 1,429 respondents, 61% reported using cannabis for managing pain, 58% reported using cannabis for anxiety and 50% reported using cannabis for depression. In the current analysis, these same conditions were also the most commonly reported conditions by respondents. Of the 1,040 participants reporting pain and/or intractable pain, 619 (59.52%) reported depression and anxiety as comorbidities. As such, the odds of reporting substituting cannabis for prescription drugs were more than one and a half times greater (OR, 1.66; 95% CI, 1.27–2.16) among those reporting using it to manage pain, anxiety and depression than among those using it to manage only one of the three conditions.

This team previously reported that in a survey of 1,429 medical cannabis users, 61% reported cannabis use for pain, 58% reported cannabis use for anxiety and 50% reported using cannabis to manage depression. In 2016, Dale and Stacey reported that those using cannabis for pain were more likely to be substituting for prescription drugs. In 2017, Walsh et al published a review of medical cannabis and mental health to try to better understand how medical cannabis use may impact areas of potential concern for clinicians. “Relaxation and relief of anxiety” and “relief of negative mood” or depression were among the most widely reported conditions in 60 publications included in their analysis. Because it is common for chronic pain patients to be prescribed combinatorial pharmacotherapy to address comorbidity with depression and/or anxiety, it is largely unknown how often patients may be discontinuing prescription medications when initiating cannabis use.

Taken with preclinical data on the role of the endocannabinoid system in stress, pain processing and immune homeostasis, it is clear that future investigation is warranted using controlled trials with human subjects to better understand the role that cannabis may play in treating pain, anxiety, depression and other conditions.

19. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4277530/>

Most of the respondents (from the clinic and online groups) reported that cannabis improved their mood, pain, muscle spasms, and sleep.

20. <https://www.ncbi.nlm.nih.gov/pubmed/11210205>

Of 628 Canadian medical marijuana patients:

463 patients reported using medical marijuana to treat anxiety.

This article reports on an exploratory study of medical cannabis users. Interviews were completed with 50 self-identified medical cannabis users recruited through notices in newspapers and on bulletin boards. They reported using cannabis for a variety of conditions including HIV-AIDS-related problems, chronic pain, depression, anxiety, menstrual cramps, migraine, narcotic addiction as well as everyday aches, pains, stresses and sleeping difficulties.

However, cannabis was also used to treat menstrual cramps, anorexia, narcotic addiction, migraine, Tourette's Syndrome, lupus, Grave's Disease, epilepsy, retinitis, chemotherapy-induced loss of appetite, Crohn's Disease, arthritis and everyday aches, pains, stresses and sleeping difficulties.

Many reported benefits of cannabis were consistent with those reported elsewhere. Cannabis was typically used for its sedative, analgesic, antispasmodic, appetite stimulating, anticonvulsant and euphoric properties. These properties were well known in the past century when cannabis was used to treat conditions that required medications with these properties.

Although scientific evidence in favor of medical cannabis is limited (Gurley, Aranow & Katz 1998), self-treatment with cannabis could become popular as more users publicize their own experiences. This is especially so if the everyday aches and pains and psychological problems are promoted as medical reasons for using cannabis.

21. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2683812/>

The use of marijuana to manage stress and anxiety was described by 12 teens in our sample. Dealing with bullying at school, heavy demands of school work, taxing shifts at work, and just "giving as much as you can" along side difficult relationships with parents or guardians, and receiving threats from neighbors all took its toll on these youth. For some, these experiences contributed to high levels of stress and anxiety, and for others uncomfortable levels of anger – both were difficult to manage. Although some had friends they could turn to, marijuana provided an additional source of stress relief that was ready at hand.

"Lots of people know me, know I do pot and they think that I'm a pot head but really the thing they don't realize is that I have a reason for it. It's for my stress and an antidepressant. I get really upset. It [pot] helps me feel better about myself, because you know people don't do that [help me], like my friend [name] can, but nobody else can." [Female, 14 years, non-daily use]

There was general agreement among the teens that marijuana calmed them down, and helped them feel "not so nervous" and "not so uptight about everything." One teen recognized, however, that despite the fact that marijuana could be a very effective stress reliever, it might not work for everyone:

"Well as far as pot goes, the good thing is that it's definitely a stress reliever, hands down. I know lots of people who would be just a complete wreck if they weren't smoking pot but then there's also people who are a complete wreck because they do smoke pot, so it's kind of a hard thing." [Male, 16 years, non-daily use]

22. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3691841/>

While the controversies surrounding cannabis are far from subdued (and are often permeated and masked by conflicting ideological credos), standardized studies on cannabinoids have highlighted that the psychological and behavioral outcomes of this substance are highly variable and range from relaxation, euthymia and heightened sociability to panic, paranoid ideation and psychosis [112 - 116]. A corollary of this observation is that the high comorbidity rate between cannabis use disorders and psychiatric conditions [100 - 105] may indicate that cannabis consumption is either a concurring cause or a "self-therapeutic" strategy for anxiety and mood disorders [117 - 123]. The latter interpretation is supported by the observation that anxiety-spectrum disturbances and traumas in early developmental stages are a strong predictor for later cannabis use disorders [124 - 127]; furthermore, several lines of evidence suggest that the anxiolytic effects of THC may partially account for the high prevalence of cannabis use in patients affected by PTSD [128 - 131] and OCD [132]. Accordingly, recent clinical studies have shown that THC elicits therapeutic effects in OCD [133] and trichotillomania, an impulse-control disorder characterized by compulsive hair-pulling [134].

23. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4604171/>

Overall, current evidence indicates CBD has considerable potential as a treatment for multiple anxiety disorders, with need for further study of chronic and therapeutic effects in relevant clinical populations.

24. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4604174/>

Although clinical studies in this area are difficult to do, even in countries where the use of cannabis has been allowed for years, there is a clear role for cannabis products in symptom management for these difficult conditions.

25. <https://www.ncbi.nlm.nih.gov/pubmed/22729452>

RESULTS:

Studies using animal models of anxiety and involving healthy volunteers clearly suggest an anxiolytic-like effect of CBD. Moreover, CBD was shown to reduce anxiety in patients with social anxiety disorder.

CONCLUSION:

Future clinical trials involving patients with different anxiety disorders are warranted, especially of panic disorder, obsessive-compulsive disorder, social anxiety disorder, and post-traumatic stress disorders. The adequate therapeutic window of CBD and the precise mechanisms involved in its anxiolytic action remain to be determined.

26. <https://doi.org/10.2202/1941-2851.1017>

1655 Patients reported using medical marijuana for these conditions:
Anxiety disorders 18.7% of patients

Applicants most frequently reported using medical marijuana for pain relief (82.6%), improved sleep (70.6%), and relaxation (55.6%). The next most frequently reported benefits included relief of muscle spasms (41.3%), headache (40.8%), relief of anxiety (38.1%), improved appetite (38.0%), relief of nausea and vomiting (27.7%), and relief of depression (26.1%). Half the applicants (50.8%) reported using marijuana as a substitute for prescription medication and 13.2% reported using marijuana as a substitute for alcohol.

27. <https://doi.org/10.1176/appi.ajp.2007.07061016>

Hence, it can be speculated that the anti-obsessive effect observed in our patients may have been a consequence of the glutamate modulation of the cannabinoid dronabinol.

28. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4349825/>

The findings from the study indicate that cannabis use is associated with a subsequent change in positive affect, depressive symptoms and manic symptoms over the course of daily life. No evidence for the use of cannabis to self-medicate minor fluctuations in negative affect or BD symptoms was revealed. Participants in the study were currently well and out of episode. Future research should explore whether the self-medication hypothesis is more relevant to individuals that are in the acute stages of depression or mania. This would be consistent with the broader self-medication hypothesis in BD where individuals have reported finding cannabis useful in the management of their symptoms.

29. <https://www.ncbi.nlm.nih.gov/pubmed/9692379>

The authors present case histories indicating that a number of patients find cannabis (marijuana) useful in the treatment of their bipolar disorder. Some used it to treat mania, depression, or both. They stated that it was more effective than conventional drugs, or helped relieve the side effects of those drugs. One woman found that cannabis curbed her manic rages; she and her husband have worked to make it legally available as a medicine.

Others described the use of cannabis as a supplement to lithium (allowing reduced consumption) or for relief of lithium's side effects. Another case illustrates the fact that medical cannabis users are in danger of arrest, especially when children are encouraged to inform on parents by some drug prevention programs. An analogy is drawn between the status of cannabis today and that of lithium in the early 1950s, when its effect on mania had been discovered but there were no controlled studies. In the case of cannabis, the law has made such studies almost impossible, and the only available evidence is anecdotal. The potential for cannabis as a treatment for bipolar disorder unfortunately can not be fully explored in the present social circumstances.

30. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4898690/>

Findings suggest that for some bipolar patients, marijuana may result in partial alleviation of clinical symptoms. Moreover, this improvement is not at the expense of additional cognitive impairment.

31. <https://www.ncbi.nlm.nih.gov/pubmed/17703715>

Subjective reports by patients suggest an overall positive effect, but these may be unreliable. We herein report a case in which mood data was prospectively collected over two years of total substance abstinence and two years of extreme marijuana use. Marijuana use did not alter the total number of days of abnormal mood, however, marijuana was associated with an increase in the number of hypomanic days and a decrease in the number of depressed days. While not conclusive, the data suggest that marijuana may indeed have an effect on mood in bipolar patients that needs to be systematically examined.

32. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5652027/>

Cannabis use diminishes some of the adverse effects of neurological and psychiatric disorders.

33. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4323143/>

These results suggest that cannabis use has clinical implications for the early course of BD (Bipolar Disorder) by increasing mood level.

34. <https://doi.org/10.1111/j.1368-5031.2005.00271.x>

Medicinal cannabis use was Reported by patients with chronic pain(25%), multiple sclerosis and depression (22% each), arthritis (21%) and neuropathy (19%).

(8) Provide any information, studies, or research reports regarding any beneficial or adverse effects from the use of cannabis in patients with the medical condition. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Minnesota has undertaken the most comprehensive research on the medical cannabis patients in its medical cannabis program in the United States. Including surveys by both the patients and their physicians. Tracking which medical cannabis products they purchase, use and continue using to treat each qualifying condition.

The Minnesota Department of Health publishes reports of the medical cannabis patients and how medical marijuana helps them with anxiety.

In its first year of reports, the Minnesota DOH published patient comments about the beneficial effects of the medical marijuana.

(REF #98) <https://www.health.state.mn.us/people/cannabis/about/firstyearreport.html>

(REF #94) <https://www.health.state.mn.us/people/cannabis/docs/about/appendixa.pdf>

Many such comments are found within the above report.

Further reports in the following years also track which patients under each condition report benefits of medical marijuana on anxiety.

<https://www.health.state.mn.us/people/cannabis/about/omcreport.html>

<https://www.health.state.mn.us/people/cannabis/about/cohort.html>

(REF #93) https://www.health.state.mn.us/people/cannabis/docs/about/cohort/2015_2016_benefitspse.pdf

The patient self-evaluation is required for patients to complete prior to each medical cannabis purchase. It includes questions to assess symptom severity, some of which are administered to all patients (standard set of 8 symptom measures) and some of which are tailored to symptoms for a given condition (condition-specific symptom measures). Since symptom data is collected prior to each patient's first medical cannabis purchase, symptom changes can be assessed over time and compared to baseline (baseline = patient responses to symptom questions just prior to their first medical cannabis purchase)

These reports are useful to show that medical marijuana patients find a greater than 30% reduction in anxiety symptoms, and a large percentage of patients continue to maintain that reduction of anxiety for 4 months.

(REF #92) https://www.health.state.mn.us/people/cannabis/docs/about/cohort/2016_2017_benefitspse.pdf

(REF #91) https://www.health.state.mn.us/people/cannabis/docs/about/cohort/c2015_2017_benefitspse.pdf

MDOH publishes Adverse Side Effects reports which show a very small percentage of people experience a worsening of anxiety symptoms. I urge you to read them all as it shows how small the number of adverse anxiety reports are.

<https://www.health.state.mn.us/people/cannabis/about/cohort.html>

(REF #90)

https://www.health.state.mn.us/people/cannabis/docs/about/cohort/appendix_c_2015_2016_patientreportednegativeeffects.pdf

Although the comments mention anxiety as a side effect, sometimes it is not the cannabis's fault, but prohibition's fault, as this comment rated at score level 4 shows:

I have more anxiety that police may take me for a blood test of charge me with DUI if they know I'm a patient at dispensary. I also had a Warning of illegal drug use in a urine test from the so called pain clinic I'm required to go to by [CLINIC]By my now ex primary Dr of 20 years. I told the pain clinic when I signed contract not to use illegal drugs that I took cannabis by prescription in medical form thru Dept of Health etc. The Dr said OK, as long as it wasn't in organic form for smoking! He said I was the 1st patient at [CLINIC]to be on legal cannabis. I advised him, I maybe to 1st but surely not the last patient. They said this will be resolved ok but I still was warned for illegal THC drug use, which is upsetting but it will be straightened out. Thank u!

Massachusetts published a report on its medical marijuana patients and their benefits.

<https://www.mass.gov/report/massachusetts-department-of-public-health-marijuana-research>
(REF #77) <https://www.mass.gov/files/documents/2019/07/09/MBHS-full-report-final.pdf>

The Marijuana Baseline Health Study (MBHS)

A legislative mandate required the Massachusetts [Department of Public Health \(DPH\)](#) to conduct a baseline study to investigate marijuana use in Massachusetts. The report published confirms the consensus that marijuana use improves mood and or mental health for a large percentage of people.

Page 10:

Among all respondents, **78% reported positive changes in their mood or mental health**, and 67% reported improved physical health. In addition, 83% of respondents reported no negative outcomes/consequences related to their marijuana use.

Page 148:

Results from this survey suggest that respondents appear to be treating a wide range of medical conditions, and often more than one at a time. **The top 5 medical conditions being treated were anxiety (60% or all respondents), chronic pain (46%), insomnia (43%), depression (42%), and stress (41%), and the average number of conditions being treated by medical marijuana is 4.7.**

5/25/20

To whom it may concern:

I am writing this letter in support of [REDACTED] three petitions submitted to the Hawaii Department of Health, which adds depression, anxiety, and insomnia to the medical qualifications permitted for medical cannabis certification.

The mind and body are connected. The effects of insomnia, depression, and anxiety upon the physical well-being of an individual are significant and well documented. Current pharmaceutical interventions for these conditions can have severe side effects and risks. There is scientific evidence to support the use of medical cannabis for these disorders—a medicine with far less potential for addiction or abuse.

After witnessing the knee jerk, draconian response to the opioid crisis, I am concerned for that moment in time when someone realizes that a severe hypnotics problem also exists. I need to know that when severe restrictions are placed on hypnotics, my patients will have a safe and legal alternative. Medical cannabis is that alternative.

I have learned that if you close one door for a patient to escape their pain—they will find another. If you close or restrict the pharmaceutical options, they WILL find other ways to relieve their suffering. The inclusion of the three diagnoses recommended by [REDACTED] for the use of medical cannabis will provide a far safer option for these vulnerable patients.

May 26, 2020

Aloha,

My name is Marghee Maupin and I am a board certified family Nurse Practitioner in Hawaii with over 30 years of experience. In the course of my practice, I have treated patients who utilize medical cannabis as an alternative treatment option for multiple health conditions. I have observed, (per patient report), that medical cannabis reduces the symptoms and severity of anxiety, insomnia and depression.

These three diagnosis present commonly as the top conditions that my patient's report medical cannabis has helped them with.

I have discussed, observed and documented the side effects of medical cannabis with my patient's and I have compared the side effects with traditional pharmaceuticals. Generally, I have found medical cannabis to have fewer and more manageable side effects than pharmaceutical formulations.

I am writing this letter as a letter of support to add Anxiety, Insomnia and Depression into the Hawaii Medical Cannabis program.

Please contact me at my office if you require any information.

Sincerely,

Margaret Maupin, APRN

Telephone: (808) 242-5856 • Fax (808) 242-5949

Email: hawaiiendoc@yahoo.com

Aloha,

I am licensed medical doctor on Maui, board certified in both Internal Medicine and Endocrinology. I have been in practice for over thirty years, 25 in Hawaii. I am writing this letter of support of three petitions submitted to the Hawaii Department of Health which adds depression, anxiety and insomnia to the medical qualification permitted for medical cannabis certification.

A few years ago, the list of medical qualifications was expanded to recognized Post Traumatic Stress Disorder (PTSD). Note that PTSD is a disorder that can manifest with anxiety, depression and sleeplessness. There are many conditions that cannabis is helpful for, but there are three conditions that cannabis is especially helpful for, yet even after twenty years of the program, depression, anxiety and insomnia remain off the list of qualifying conditions.

██████████ has laid out in detail, from various evidence-based scientific sources and studies giving evidence that cannabis is helpful for these three ailments. I want to support his petition. I have been evaluating patients for their 329 cards for over 3 years and have done hundreds of renewals. Virtually 100% of patients have been helped. All use cannabis for the indications they listed but have also found that coincidentally medical marijuana helps with anxiety, depression and insomnia.

In fact, I believe that because of the better safety profile cannabis should be the first-line drug for these conditions. Most anxiolytics are habit forming. Anti-depressants have a warning: "May Cause Suicide". Hypnotics, like Ambien, are also habit forming and are used in combination with alcohol to simulate Rohypnol ("roofie") by rapists. Using cannabis as a safe first-line option will be a paradigm shift for many health care providers, but the approval of these conditions by the DOH will go a long way to legitimizing this point of view.

So far, in my decades as a physician, I have much more harm done with alcohol, hypnotics, opiates and anti-depressants and anxiolytics than with cannabis. In fact, as an urgent care, ER, hospital and ICU physician (before starting my Endocrine practice), I have never attended a single patient due to cannabis.

Please recognize these patient's needs and add depression, anxiety and insomnia onto the list of recognized qualifications for medical cannabis certification. Please call if you have any questions, 808-242-5856.

Thank you for your kind attention,

Till Hansen, M.D.

Hawaii Endocrine Associates, Inc.

James Berg, MD
PO Box 371
Hawi, HI 96719
808-889-1822
Barefootmd@gmail.com

Aloha,

I am licensed medical doctor from the Big Island of Hawaii, board certified in both Family Medicine and Integrative Medicine. I have been in practice for over thirty years treating my clients with a reasonable balance between medical and natural approaches to healing. I co-direct a school of natural medicine called the *Barefoot Doctors' Academy*, a nonprofit organization operating continuously since 1983, devoted to natural approaches to community medicine. In my career, I have been on the clinical teaching faculty of two medical schools, three traditional oriental medical colleges, two massage schools, and lecturer on scientifically oriented natural medicine. I am writing this letter of support to [REDACTED] three petitions submitted to the Hawaii Department of Health which adds depression, anxiety and insomnia to the medical qualification permitted for medical cannabis certification.

According to my records, I have taken care of over 6,000 patients in Hawaii who have used cannabis legally. I have taken their testimony, examined them, and followed up with many of them at least annually for the past 15 years. I have seen the medical cannabis program go through many changes, and would especially like to thank the Department of Health for their kind and skillful transformation of the Medical Cannabis Program since they took the helm from the Narcotics Enforcement Division. They have worked out many of the administrative kinks and have sincerely honored the clinical necessity of cannabis. A few years ago, they expanded the list of medical qualifications, and recognized Post Traumatic Stress Disorder as a qualification. That was the first psychological condition allowed to that date.

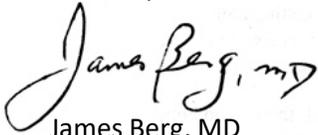

There are many conditions that cannabis is helpful for, but there are three conditions that cannabis is especially helpful for, yet even after twenty years of the program, depression, anxiety and insomnia remain off the qualification list. Cannabis has been labeled in the past as an "euphoric agent" because it relaxes people and helps them feel good. These days we call these kinds of medicines, "antidepressants" and "anti-anxiety medicines". Let me say emphatically, that I recognize that cannabis can cause the very same negative effects in some people. In my experience, at least 90% of my clients already know how cannabis helps their condition. They come and explain to me, their doctor, how it has helped them, and they seek certification so they can use this medicine legally. I want to testify that of all the conditions I have heard the greatest praise for the benefits of cannabis from my clients over the past fifteen years, it has been for this medicine's help with sleep, anxiety and depression. Keeping them off the list seems medically ethical at this point.

[REDACTED] has laid out in detail, various scientific studies giving evidence beyond my anecdotal testimony for these three ailments. I want to support his petition. As a Medical Cannabis Specialist, I witness the answers to these studies every day in my practice. I believe that depression, anxiety and insomnia are the conditions *most helped* by cannabis. I hear, patient after patient, testifying to me how they can finally sleep the night through simply by sucking on a medicated lozenge; How one puff can avert a panic attack; How they finally feel bright spirited and motivated. Cannabis has been a true blessing for many of my patients with insomnia, anxiety or depression, who have been qualified by another condition that the state recognizes. Unfortunately, that list excludes those without severe pain, nausea, muscle spasms, etc.

Yet they still have a severe problem that they know is helped by cannabis. That is self-evident in their experience. We do not need more studies to prove to them that they slept the night through, or didn't escalate into a panic attack, or that they actually feel happy for the first time in a long time. They know it helps with minimal side effects and that is proof enough to them.

In this case, science and politics needs to catch up with the clinical experience. As a practicing physician, I have seen medical cannabis be used far more safely than any pharmaceutical anti-depressant, anti-anxiety med, or sleeping pill commonly prescribed for insomnia, depression and anxiety. One day, I predict that cannabis, or an analogue, will be the medical standard for the first line of attack for mild to moderate depression, anxiety and insomnia. I speak for these sincere patients who already know that cannabis helps them. Please recognize these patient's needs and add depression, anxiety and insomnia onto the list of recognized qualifications for medical cannabis certification.

Sincerely,

A handwritten signature in black ink that reads "James Berg, MD". The signature is written in a cursive, flowing style.

ASSOCIATION OF CANNABIS SPECIALISTS
SCIENCE. EDUCATION. REGULATION. COMPASSION.

May 27, 2020

Dear Madam/Sir:

I write to you to support the petitions before you to include anxiety, depression, and insomnia as qualifying conditions for medical cannabis treatment in Hawai'i.

I am a cannabis medicine specialist. I went to Harvard Medical School and trained in Internal Medicine at the Brigham & Women's Hospital in Boston. I have been in practice for over 25 years, the last nearly decade exclusively focused on cannabis medicine. I am president of the Association of Cannabis Specialists – an international professional organization, and I am an Instructor of Medicine at Harvard Medical School.

In Massachusetts, where I live and practice, we do not have qualifying conditions per se. We are afforded the freedom to treat patients who have any condition that is medically appropriate to treat with cannabis. I think this is an ideal approach that returns the ability and responsibility to follow the science and medical best practices to the physicians who are best able to judge that medical necessity.

The literature on medical cannabis specifically for the indications of anxiety, depression, and insomnia is clear. These studies have been presented by the petitioner and I would be happy to address any questions about these that you may have. Cannabis can be very effectively used to treat all three of these problems.

Dosing is the critical element dividing success or failure, particularly for these specific conditions. As with any medication, cannabis can be used successfully or it can be misused. Cannabis can be used in conjunction with many conventional medications to achieve better benefit than with either alone. I have personally treated thousands of patients with these specific illnesses, and the results are impressive.

As a practical matter, to improve the outcomes for patients in HI, I would suggest greater requirement of clinicians to be specific about dosing and delivery methods, and absolute adherence by the dispensary agents to a clinician's treatment plan.

777 Concord Ave. Ste 104
Cambridge, MA 02138

800-645-0807
www.cannabis-specialists.org

Please refer to the Association of Cannabis Specialists' website and the document entitled [A Federal Framework of Regulation for Medical Cannabis Use](#) which can equally well be applied to states' programs.

I, and the medical literature, strongly support the addition of anxiety, depression, and insomnia to the list of conditions clinicians are able to treat with medical cannabis in HI. I urge you to add these conditions to the approved list.

Sincerely,

Jordan Tishler MD
President, CMO inhaleMD
President, Association of Cannabis Specialists
Instructor of Medicine, Harvard Medical School

**VII. The Potential of Cannabinoid
Derived Therapy in Anxiety,
Spasticity, and Epilepsy**

The Efficacy and Safety of Nabilone (A Synthetic Cannabinoid) in the Treatment of Anxiety

LOUIS F. FABRE, M.D., Ph.D., and DAVID McLENDON, Ph.D. Houston, Tex.

Abstract: The anxiolytic properties of nabilone, a synthetic cannabinoid resembling the natural cannabinoids, were studied in 25 outpatients suffering from anxiety. The drug was compared with a placebo in a double-blind manner over a 28-day treatment period. Patients were seen weekly by the physician and were rated by the Hamilton Rating Scale for Anxiety and the Patient's Global Evaluation as well as by patient-rated evaluations. The results of the study showed a dramatic improvement in anxiety in the nabilone group when compared with placebo ($P < 0.001$). Side effects reported were dry mouth, dry eyes, and drowsiness. Patients did not report any of the subjective "altered state" experience of marihuana.

THE marihuana plant has been used by man for various ailments and for pleasure for thousands of years. As recently as 40 years ago, cannabis was a recognized drug in the *United States Pharmacopeia*. It then fell into therapeutic disuse. Recent research has indicated that cannabis (Δ^9 -tetrahydrocannabinol, THC) and cannabinoid-like compounds may represent a class of compounds that are of potential therapeutic value.¹⁻³ Marihuana is now considered to be useful in the treatment of glaucoma and the nausea associated with cancer chemotherapy.

Nabilone* is a synthetic cannabinoid which resembles the cannabinoids but is not a tetrahydrocannabinol. Preclinical research indicates that nabilone has anal-

gesic, antianxiety, and antipsychotic properties and is a drug with a wide margin of safety.⁴

More recent research found nabilone to be active in single doses of 1 to 5 mg, with 1- and 2.5-mg doses inducing relaxant and sedative effects in all of six subjects. Euphoria, dry mouth, tachycardia, or postural hypotension were not seen in 1-mg doses although slight effects were noted at 2.5 mg and marked effects at 5 mg. Tolerance developed to the side effects of the drug after two days.⁵ No significant tachycardia developed at any dose. This research indicated that nabilone may have utility in the treatment of psychoneurotic anxiety.

Our research group set out to systematically study the anxiolytic effects of nabilone. Three studies were planned: first, a dose-rising open-label study to assess the proper dose range of nabilone; second, a double-blind study against placebo to assess the efficacy of nabilone.⁶ Finally, the third study was a double-blind study of nabilone against placebo and diazepam to assess the relative efficacy of nabilone to a standard anxiolytic. The first and second studies were performed and are discussed.

From Research Testing, Inc., and the Fabre Clinic, Houston, Tex. 77004.

* Eli Lilly and Company.

The third study was begun but canceled before any data could be gathered. The sponsor had experienced side effects in their ongoing cancer antiemetic studies which they felt made nabilone not a proper anxiolytic candidate.

Methods

Patients

Twenty-five patients of a private psychiatric clinic (The Fabre Clinic) participated in the two studies. In order to be admitted to the study, each patient had to be 18 to 60 years of age and be a male, or female who would not become pregnant during the study. Each had to be suffering from anxiety for a sufficient time to indicate that spontaneous remission would not occur during the study. Patients could not participate if they were psychotic, had organic CNS diseases, had alcoholism or drug addiction, had significant cardiovascular, hepatic, renal or hematopoietic disease, or had a history of adverse drug reactions or severe plant allergies. The use of psychotropic drugs was prohibited during the study, and the patients were warned against the use of alcohol. Patients participating in the open-label study were required to have a third party to transport them to and from the clinic.

Procedure

Open-Label Study. Five patients suffering from psychoneurotic anxiety participated. Duration of treatment was 28 days preceded by a four-day washout period. No patients were started on active drug until the laboratory results were found to be within the normal range. The dosage was started at 1 mg b.i.d. and adjusted at the discretion of the investigator, but it was not to exceed 10 mg per 24 hours. Dosage was adjusted until anxiety was controlled. The patients visited the clinic at screen and at days 1, 4, 8, 11, 14, 18, 22, 25, and 32. At baseline and on days 8, 11, 18, and 32, the following measures of efficacy were com-

pleted: Self-Rating Symptom Scale, Hamilton Anxiety Rating Scale, Patient's Global Impressions, and Physician's Global Impressions. A physical examination and ECG were completed at baseline and at day 32. Laboratory evaluation (including complete blood count with differential, SMA-12, and urinalysis) was completed at baseline and at days 11, 18, 25, and 32. Standing and supine blood pressures and pulse rates were recorded at each clinic visit.

Double-Blind Study. Twenty patients suffering from psychoneurotic anxiety participated. Duration of treatment was 28 days preceded by a four-day washout period. The dosage of nabilone used was based on information gained in the open-label portion of the study. The patient was administered either nabilone or placebo in a double-blind manner. Half of the patients were on each treatment. Safety and efficacy evaluations were made according to the same schedule as the open-label study.

Results

Open-Label Study

All five patients completed the entire 28 days of the study. The five participants were Caucasian males ages 22 to 35 years (mean 29.4 years). The dosage was adjusted throughout the study for each patient and ranged from 2 to 8 mg a day. The average dose at the end of the study was 2.8 mg a day. All five patients reported side effects, the most common being dry mouth reported by all five patients. Also reported were drowsiness (one patient), feeling slowed down (three patients), feeling spaced out (one patient), headaches (one patient), and dry eyes (one patient). None of the side effects was rated as severe. None of the patients reported euphoria, and apparently none enjoyed a drug "high" from the medication. All patients asked to have their dosage lowered when they began to experience side effects.

An after-before comparison was used to

test for possible changes in the efficacy parameters. The baseline value for each patient was subtracted from the last visit value (visit 8). Using this method, nabilone was found to significantly reduce anxiety as measured by the Hamilton Anxiety Scale total score ($P < 0.001$). Both the somatic anxiety and the psychic anxiety factors of the Hamilton Anxiety Rating Scale were significantly reduced ($P < 0.001$). Examination of the Clinical Global Impressions indicated that all five patients improved on the Global Improvement item and three of the five patients improved on the severity-of-illness item. No statistical tests were performed because of the small sample size.

In addition to the physician's ratings, the patients themselves rated improvement in almost all areas. There was a reduction of most of the items of the 56-item symptom checklist (SCL-56). For the patients' Global Impressions, four of the five rated themselves as improved since they started receiving medication; and, when comparing each visit with the previous visit, four out of five felt an improvement by the fifth visit. No significant changes were found in the before-after analysis of the blood pressure. However, there seemed to be a slight decrease during the first three visits, after which time the blood pressure tended to return to normal levels.

Double-Blind Study

Twenty patients were enrolled. All of the patients on nabilone completed the study. Of the ten patients receiving placebo, five dropped out before completing the study due to lack of relief of their anxiety symptoms. Significantly more people dropped out from the placebo group than from the nabilone group ($P < 0.03$). Nineteen of the patients were Caucasian; one was Black. There were 15 males and five females participating in the study. The patients' ages ranged from 19 to 41 years, with a mean of 29.0 years. This portion of the study utilized

a fixed dose of nabilone which was 1 mg t.i.d., and matching placebo capsules. One patient on nabilone deviated from this dosing regimen and reduced the dosage to 1 mg per day.

The most common side effect reported was dry mouth. Five patients reported this side effect of mild intensity on 19 occasions, nine reported it of moderate intensity on 28 occasions, and four reported it of severe intensity on seven occasions. Dry eyes of mild to moderate intensity was reported by five patients four times. Moderate to severe drowsiness was reported by three patients seven times. One patient reported moderate to severe headaches and one, moderate to severe insomnia. Other side effects reported infrequently were a lump in the throat, nausea, tingling in the toes, red eyes, diarrhea, constipation, and feeling slowed down. In the placebo group, one patient reported muscle weakness, and one reported vascular dilation around the eyes.

Several efficacy parameters were analyzed by analysis of variance. In each case, the baseline measure was subtracted from the subsequent measurements before the analysis was performed. Almost all the efficacy parameters showed nabilone to be significantly superior to placebo. Figure 1 shows the results for the Hamilton Anxiety Scale. This measure showed dramatic improvement as a result of nabilone treatment. The overall score showed nabilone significantly more effective than placebo ($P < 0.001$), the same result pertaining to the factors of somatic anxiety ($P < 0.001$) and psychic anxiety ($P < 0.001$). It can be seen from Fig. 1 that both treatment groups started at about the same baseline ratings on the Hamilton Scale. On the seventh day of the treatment, the nabilone group showed a 50 per cent reduction in anxiety symptomatology, and this reduction persisted throughout the treatment period. The placebo group showed only a slight and insignificant reduction in anxiety.

The efficacy index of the Physician's Global Impressions showed significant

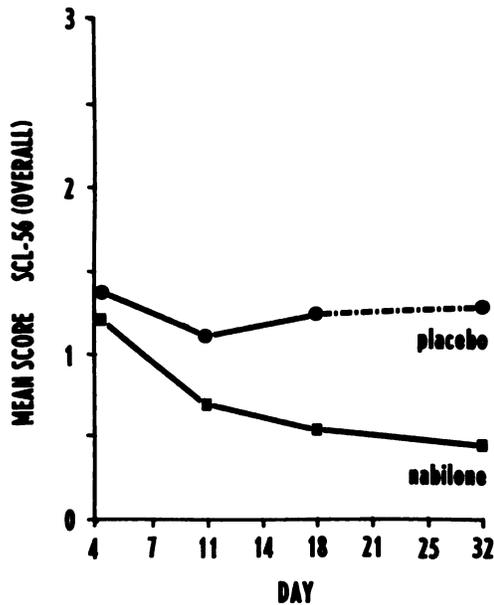

Fig. 1. Effects of nabilone and placebo in the Hamilton Anxiety Rating Scale over a 32-day period. The points on the dashed portion of the placebo curve are mean values of the five placebo-treated patients who did not drop out of the study. All other points are the mean values for ten patients.

improvement for the nabilone group at the $P = 0.002$ level. Overall, there was a downward trend in the severity of symptoms across the duration of the study for the nabilone group but not the placebo group. Alleviation of anxiety occurred quickly, and the patients reported dramatic improvement by day 3.

The results of the patients' self-ratings were consistent with those of the physician. The symptom checklist of 56 items has proved to be a difficult scale with which to measure drug effects on psychiatric symptomatology. However, in this study the difference in efficacy between placebo and nabilone was easily measured. Figure 2 shows the results of the mean score for the anxiety factor of the SCL-56. Anxiety symptoms were greatly reduced by day 11, with a continued decline throughout the treatment period. Here it can be seen that the placebo group showed no decline in

anxiety symptomatology. Figure 3 shows the results of the mean score of the depression factor of the SCL-56. Again the same pattern can be seen: improvement in depression symptomatology by day 11 for the nabilone group and no improvement in depression ratings in the placebo group. Figure 4 shows the results of the overall SCL-56 scores. The trend is the same. A large reduction in overall symptomatology can be seen by day 11 in the nabilone group, and the reduction continued until the end of treatment. The placebo group showed a slight decrease by day 11, with a return to pre-treatment symptomatology after this rating period and continuing throughout the study. Also, individual items of the SCL-56 were improved such as somatization ($P = 0.087$) and interpersonal sensitivity ($P = 0.065$). In fact, changes in all of the items on the SCL-56 were either significant or approaching significance.

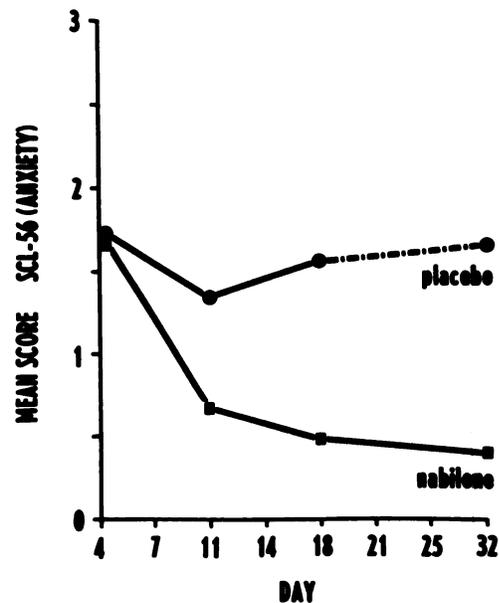

Fig. 2. Effects of nabilone and placebo on the anxiety factor of the 56-item symptom checklist over a 32-day treatment period. The points on the dashed portion of the placebo curve are mean values of the five placebo-treated patients who did not drop out of the study. All other points are the mean values for ten patients.

NABILONE ON ANXIETY

There was a slight but statistically insignificant decrease in blood pressure for the nabilone group during the first few visits, and later this tended to rise to baseline levels. Compared to predrug values, the nabilone group showed a decrease in the systolic blood pressure ($P=0.060$). No changes were noted in the placebo group. There were no other observable effects on the parameters of the physical examination, and nabilone did not alter any value in the clinical chemistry battery.

Discussion

Anecdotal reports support the idea that marihuana is an anxiolytic. It is likely that many users of marihuana use it for its anxiolytic effects. However, research studying the effects of marihuana or THC have not supported this concept.^{7B} These studies have generally shown that THC or marihuana has the effect of accentuating exist-

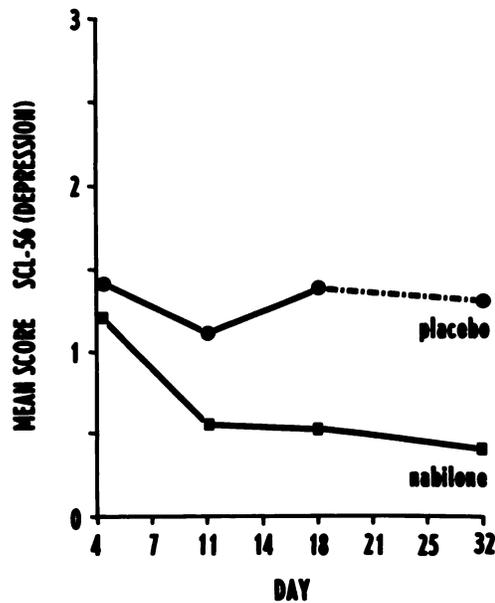

Fig. 3. Effects of nabilone and placebo on the depression factor of the 56-item symptom checklist over a 32-day treatment period. The points on the dashed portion of the placebo curve are mean values of the five placebo-treated patients who did not drop out of the study.

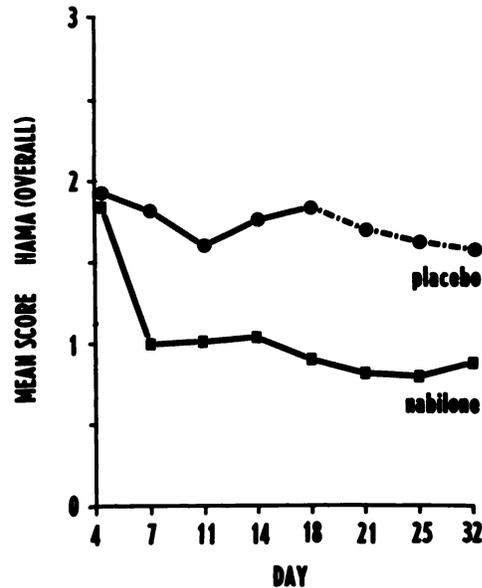

Fig. 4. Effects of nabilone and placebo on the total score of the 56-item symptom checklist over a 32-day treatment period. The points on the dashed portion of the placebo curves are mean values of the five placebo-treated patients who did not drop out of the study. All other points are the mean values for ten patients.

ing feelings and that no relief of anxiety is produced.

Recently, cannabinoid research has focused on the development of synthetic compounds which separate beneficial effects of marihuana from undesirable effects. Nabilone represents one of the first of this class of compounds. Preclinical research indicated that nabilone had anti-anxiety activity.⁴ The results of the studies presented here confirm that nabilone does in fact have anxiolytic activity in man. Our results have in turn been confirmed by Ilaria and Fann working in a Veterans Administration Hospital setting.⁹

Two groups have studied the acute effects of nabilone: one on human subjects with experimentally induced anxiety,¹⁰ and the other on anxious volunteers.¹¹ Both have found that in single doses nabilone is either ineffective or only mildly effective in reducing anxiety. The difference in these results and our own indicate that nabilone takes

some time to develop its anxiolytic effects. It also suggests that nabilone may have a different mechanism of action than the benzodiazepines.

The anxiolytic program with nabilone was terminated by the sponsor after several cases of hallucinosis were reported in cancer patients being treated with nabilone for antiemesis. No hallucinations were reported in our studies.

We feel that at a dose of 1 mg two or three times a day, nabilone is a very effective anxiolytic deserving of further study.

Abstract

*Despite the major benefits of antiretroviral therapy on survival during HIV infection, there is an increasing need to manage symptoms and side effects during long-term drug therapy. Cannabis has been reported anecdotally as being beneficial for a number of common symptoms and complications in HIV infections, for example, poor appetite and neuropathy. This study aimed to investigate symptom management with cannabis. Following Ethics Committee approval, HIV-positive individuals attending a large clinic were recruited into an anonymous cross-sectional questionnaire study. Up to one-third (27%, 143/523) reported using cannabis for treating symptoms. Patients reported improved appetite (97%), muscle pain (94%), nausea (93%), anxiety (93%), nerve pain (90%), depression (86%), and paresthesia (85%). Many cannabis users (47%) reported associated memory deterioration. Symptom control using cannabis is widespread in HIV outpatients. A large number of patients reported that cannabis improved symptom control. *J Pain Symptom Manage* 2005;29:358–367. © 2005 U.S. Cancer Pain Relief Committee. Published by Elsevier Inc. Cannabis, HIV, pain, symptoms

Introduction

HIV or AIDS affects over 40 million people in the world¹ and more than 49,500 in the UK.² Although there is still no cure available for this disease, remarkable improvements in the survival of HIV-infected individuals have been achieved.³ This survival has led to an increasing prevalence of individuals with HIV infection, many on long-term treatment with combinations

of antiretroviral therapies. This has increased the clinical focus on the management of chronic symptoms associated with both HIV and the side effects of antiretroviral medication. Recently, in small sample studies of HIV patients, the medicinal use of cannabis has been documented as a treatment for varied symptoms.^{4–7}

Symptoms associated with HIV occur as both direct and indirect consequences of the disease process and as a side effect of the antiretroviral drugs used in the treatment of the disease. These symptoms include nausea and vomiting, pain (e.g., in a nerve distribution), reduced appetite, weight loss, headaches, diarrhea, constipation, anxiety, and depression. Flu-like symptoms and severe myalgia can result directly

from seroconversion early in the disease. Central pain and peripheral neuropathy can occur as a result of viral-mediated neurotoxicity, secondary to either mitochondrial damage, demyelination, or low B₁₂ levels, all of which have been observed in patients with HIV. The inflammation that occurs as a result of the mitochondrial damage can result in HIV-related encephalopathy or HIV-related colitis. Symptoms may also occur secondary to infections or tumors, which have resulted from HIV-related immunosuppression. Examples of this include nausea and dysphagia from esophageal candida, or pain from a gastrointestinal lymphoma. Symptoms commonly occurring as a side effect of HIV treatment include renal colic from nephrolithiasis associated with the protease inhibitor, indinavir; painful peripheral neuropathy from use of stavudine, a nucleoside analogue; or sleep disturbances from the non-nucleoside inhibitor, efavirenz. Thus, a wide range of symptoms can significantly affect the quality of life of individuals living with HIV as a long-term chronic infection.^{8,9}

It has been recognized that cannabinoids such as delta-9-tetrahydrocannabinol (THC), which is now available as a licensed pharmaceutical preparation, can improve appetite and relieve nausea and vomiting.¹⁰ Cannabis plant material not only contains THC but also other cannabinoids, such as cannabidiol (CBD), that may mitigate psychotic mood effects of THC.¹¹

The aim of this study was to measure the patterns and prevalence of cannabis use in patients presenting at a large HIV clinic and to evaluate its beneficial or detrimental effect on symptom control.

Methods

Subjects

Following Ethics Committee approval, HIV-positive patients were recruited into an anonymous cross-sectional questionnaire survey using a single center. The outpatient clinic provided a walk-in service as well as pre-arranged appointments, including pharmacy and phlebotomy sections. All patients entering the clinic were asked to verbally consent to participate in the study. Written consent was not obtained in order to protect patient anonymity. The number of patients who refused to take part

was recorded. Many patients were regular clinic users, had discussed their symptoms with HIV and pain specialists, and were able to distinguish between the various types of pain described on the questionnaire. A researcher was available to answer questions (e.g., on the interpretation of words). Patients completed the questionnaire while waiting and confidentiality was maintained by enumerating the papers without patient identification.

Questionnaire

The questionnaire was piloted to refine its content, word use, and format and then issued to patients attending the clinic. The questionnaire (see Appendix) was designed to contain close-ended questions with defined yes/no or categorical responses. It was divided into sections. The first included demographics (age, sex, number of years with HIV) and a validated scale to measure degree of disability described by Sharrack and Hughes.¹² The second had specific questions concerning the patient's use of cannabis medically to treat symptoms of HIV. These symptoms included those directly related to HIV plus those resulting from their medication. Those who did not use cannabis for medicinal purposes, including those who used it solely for recreation, were not required to continue completing the questionnaire, although their demographic details were recorded. The next section included questions relating to frequency, patterns, and reasons for cannabis use. Then in tabular form, a range of symptoms were listed (Table 1), and against

Table 1
Order of Symptom List in Questionnaire as Scored by Patients for Benefit or Detriment

Lack of appetite
Feeling sick (i.e., nausea)
Tremor
Depression
Anxiety
Weight loss
Weakness
Tiredness
Vision dimness
Slurred speech
Memory loss
Constipation
Headaches
Diarrhea
Pain in muscles
Nerve pain
Tingling
Numbness

each one, the patient was invited to score benefit or detriment as 'much better,' 'little better,' 'unchanged,' 'a little worse,' and 'much worse'. For the symptoms of pain and sensory changes, the questionnaire also contained 'body diagrams', that is, pain maps, so that the patients could mark where they identified their nerve or muscle pain, tingling and numbness.

Analysis

Data from the questionnaires were entered into an Access database (Windows 98 version) and analyzed using the Statistical Package for Social Sciences (SPSS 11.5, SPSS Inc., Chicago). Categorical data comparing the sex differences between the two groups and symptom severity were analyzed using the Fisher's exact test. Because the distribution of age and the number of years with HIV were not normal and had some outliers, the differences in these variables between the two groups were analyzed using the Mann-Whitney U test. Both simple frequency analysis and the sign test were used in assessing the percentage improvement or deterioration in symptoms.

Results

A total of 523 questionnaires were completed from 565 patients approached. This was a 93% response rate. Of those who completed the study, 143 (27%) used cannabis to treat symptoms associated with HIV.

Physical Data

The sex, age, years with HIV, disability, and cannabis user status are shown in Tables 2 and 3.

About 1 in 10 patients were female and few were severely disabled in this outpatient setting. Compared with females, males were statistically significantly likely to be cannabis users ($P < 0.01$) and those who had the disease for longer and were more disabled were also more likely to be users ($P < 0.01$).

When nerve pain was reported on the pain map, it was experienced mainly in the legs, and less in the feet and hands (27, 19, and 15 patients, respectively). Muscle pain was predominantly localized to the legs, but also to the lower back, shoulders and neck (46, 19, and 19 patients, respectively). Tingling and numbness was experienced in the periphery, with the hands and feet being affected (34 and 26 patients, respectively).

Patient Choice of Route and Timing for Symptom Control

Of the 143 patients who had used cannabis to treat HIV symptoms, 107 (75%) were current users. Within the whole group, smoking was the single route of administration in 101 (71%), and was combined with eating and drinking the plant in 39 (27%); ingestion was the only route in 3 (2%). On a day that cannabis was used, 50 patients (36%) would take it once, 33 (23%) twice, 23 (16%) three times, and 35 (24%) four or more times. Most patients (79/143 [55%]) were daily users and 15 (11%) used it weekly. Others reported intermittent administration during the week. Thus, all patients reported using cannabis at least once a week to relieve symptoms.

Throughout the day, the majority of patients (91/143 [64%]) took cannabis after 6 p.m. and

before midnight. However, an overlapping group (66/143 [46%]) also reported use at any time if necessary. The reasons for taking the cannabis at these times were reported in a structured format, as detailed in Table 4. A number of reasons related to the time of administration, not least of which was recreational use together with medicinal use. Relief of symptoms of anxiety and depression was common, as was general symptom relief. The reported use for relaxation may reflect the time at which it was taken, namely, during the evening.

Effect on Symptoms

A lack of appetite was the most frequent symptom reported (Table 5) and 97% experienced improvement with cannabis use. Pain was the next most frequent, being present in 45% of patients and improved in 94% of them. The collective results demonstrated statistically significant improvement in half or more patients in symptoms of nausea, anxiety, nerve pain, depression, tingling, numbness, weight loss, headaches, tremor, constipation, and tiredness. Symptoms that were not improved included weakness and slurred speech, and statistically significant memory deterioration was recorded in 47% of users.

Discussion

The demographic characteristics of our cohort of patients (male:female, 11.2:1) is comparable with the UK population of HIV-positive

patients, which has a male:female ratio of 11.5:1. In addition, their ages and duration of HIV disease were comparable with the general UK data for such patients.¹³ Our sample of 523 patients has the highest response rate and is the largest study of its kind. It compares with previous studies, which have had samples ranging from 72 subjects⁷ to 442.⁶ This detailed report of cannabis use for symptom control in a clinically significantly large group of patients can form the basis for more extensive investigations using purified and standardized cannabis extracts.

Despite the fact that cannabis is still illegal, its use for medical purposes appears to be quite widespread. A report from the British Medical Association¹⁴ stated “many normally law abiding citizens—probably many thousands in the developed world” use cannabis illegally for therapy. Wesner¹⁵ reported from an anonymous mail survey of 123 HIV-positive patients in Honolulu that 36.9% of them used cannabis for therapeutic reasons. Approximately one-quarter of 228 HIV-positive men in the Sydney Men and Sexual Health study reported therapeutic use of cannabis.¹⁶ Thirty-two percent (32%) of 72 patients at a clinic in Alabama reported the medical use of marijuana.⁷ These results are comparable to a more recent study carried out in Northern California, in which 33.3% of HIV-positive patients who responded to an anonymous mailed questionnaire used cannabis to treat symptoms associated with their disease.⁶ Our study expanded these findings in a large city clinic population by focusing on the patient’s perceived improvement or worsening of symptoms for which cannabis was considered the origin.

The large number of patients using cannabis as medicinal therapy for symptoms related to HIV raises a number of issues. First, patients are being left with no alternative but to use a non-medical source of supply, which has the

potential for heterogeneity of active cannabinoids, toxic contaminants, inappropriate dose, and drug misuse. Second, if part of the plant material has therapeutic efficacy, the source of this material should be standardized and subjected to clinical trials so that safe and effective use is advocated. Third, the patient is unlikely to divulge cannabis use to their medical team, so that potential drug interactions with prescribed antiretroviral medications may be occurring. In addition, in this study, the number of purely recreational users was not determined so that the overall incidence of drug interactions may be far greater. The type of drug interactions to be considered include loss of cognitive function because it is well-recognized that this is an effect of both cannabis¹⁷ and antiretroviral drugs such as efavirenz.¹⁸ Certainly, the loss of memory reported by these patients is of clinical significance, particularly in the methodological design of clinical trials, and if it is the result of combining preparations, this may be investigated using known standardized cannabinoid therapies. This approach may be one way to reduce additive effects and prevent patients being subject to the effects of unpredictable concentrations of illicit drugs.

The positive responses to symptom control recorded in this study, as exemplified in Table 5, suggest that it is highly probable that cannabinoid medications have a medicinal role in this condition for a number of reasons. First, they

are reported by patients to improve appetite, reduce weight loss, and alleviate nausea.^{19–23} These effects have been recognized and synthetic THC (dronabinol) is licensed for use in the U.S. for this indication. However, no direct comparison has been attempted with a cannabis plant extract that will contain not only THC but also other cannabinoids, of which CBD is reputed to reduce the adverse effects of THC.²⁴ Secondly, pain relief appears to be significant in cannabis users, thereby suggesting a potential target for investigation in the use of cannabinoids as analgesics in HIV patients.

Patients have reported various forms of pain with HIV, such as muscular and neuropathic pain, and these were characterized in the pain maps drawn by the patients. Currently available analgesic drugs have limited efficacy, particularly for neuropathic pain.²⁵ Clearly, there is a need to develop alternative analgesic agents, such as cannabinoids, to improve the choice of therapies. There is animal evidence that cannabinoids have analgesic effects that operate in models of hyperalgesia and allodynia, both indicators of neuropathic pain states,^{26,27} and the discovery of the endogenous cannabinoid system has led scientists to explore the role of endocannabinoids in chronic pain models.^{28,29} However, in clinical practice the choice of natural or synthetic phyto- or endo-cannabinoids for clinical trials is very limited. There have been several anecdotal and clinical trial reports that

cannabis plant extract and synthetic THC and related analogues produce pain relief in humans.^{30–33} For this present select group of HIV patients, given the reported symptoms experienced using cannabis plant material, there is a strong concern from the medical community managing these patients to limit adverse side effects from self-administered drugs and to provide cannabinoids in a formulation and dosing schedule that avoids harm to the patient. For example, there is strong evidence that the smoking route of administration of cannabis is not safe long-term because of the carcinogenic properties of a cannabis cigarette.³⁴

A pattern of cannabis use emerges from this study that is regular, ongoing, and treats the symptoms of HIV patients to their satisfaction. Given the sedative properties of cannabis, it is important to assess whether evening dosing for cannabinoid therapies is more useful or appropriate. Its sedative effects may be helpful at this time but none were reported as predominant. Presumably there is tolerance to these types of effects.²⁹ More importantly, reduction of pain, anxiety, and gastrointestinal upset appears to be the constellation of symptom control sought by these HIV patients, as shown in Tables 4 and 5.

In relation to HIV, there have been anecdotal reports³⁵ of patients who were already recreational users of cannabis reporting that it improved certain symptoms, such as loss of appetite and nausea, as well as pain and general well being. A small, uncontrolled study of 10 symptomatic AIDS patients reported that dronabinol might be effective in reducing nausea and increasing appetite.¹⁰ Where patients are also medicating with antiretroviral agents, the combination of cannabis and protease inhibitors may be detrimental by altering viral loads. Thus, the effect of smoking on the viral load of HIV-infected patients was investigated by a short-term randomized placebo controlled trial.³⁶ No adverse effects of either therapy were measured with respect to RNA levels, CD4⁺ and CD8⁺ cell counts, or protease inhibitor levels. This brief trial suggests that there are no obvious harmful effects, but these need to be determined using an appropriate route of drug administration and a longer-term study.

There is accumulating evidence that suggests that cannabinoids have therapeutic applications in a variety of neurodegenerative diseases,

such as multiple sclerosis,^{37,38} Huntington's disease,³⁹ and brain injury.⁴⁰ So far, in terms of HIV, the evidence for therapeutic efficacy of cannabinoids is still mainly anecdotal. We have sought to establish if an improvement from cannabis use, albeit self-administered and not standardized, is seen in symptoms such as pain, appetite, and nausea in a large sample of HIV patients. To do this, we expanded on previous research by determining specifically the variety and groups of symptoms that patients select to modify by their use of cannabis. We also secured a therapeutic timetable in order to predict the frequency of drug administration for the patient's selected symptoms. These results will be important in the design of a randomized, placebo-controlled clinical trial comparing conventional treatments to cannabis for symptoms of HIV.

Appendix
Questionnaire

HIV Symptoms and the Use of Cannabis

This questionnaire is designed to establish the current use of cannabis for the management of symptoms from HIV in our patients. We would be grateful for some personal details (but not details of identification) and your past and present experiences (if any) with cannabis.

Please complete the following:

General Details:

Sex: MALE/FEMALE (encircle as necessary)

Age:years

Number of years with HIV:

Degree of Disability

Please choose ONE of the following statements which best describes how severely you are affected by the HIV disease, and how it affects your activities of daily living:

- None
- Mild symptoms
- Moderate symptoms—not requiring help from others
- Moderate symptoms—requiring help from others
- Severe symptoms—almost total loss of function
- Total loss of function

Cannabis use

Have you ever used cannabis to relieve your symptoms (as listed below) of HIV? Y/N

If “NO” we thank you for answering this questionnaire and you are not required to complete any more of the questionnaire.

If “YES” please complete the following details:

How do you take the cannabis?

- Smoke Y/N
- Drink Y/N
- Eat Y/N
- Other (state).....

How many years have you used cannabis relieve some of your symptoms?.....years

How many times a day do you use cannabis?.....

How many days a week do you take cannabis?.....

When do you take cannabis: [*Please choose only ONE*]

After 6 pm and before midnight	Y/N
Between 6 am and midday	Y/N
Midday to 6 pm	Y/N
At any time when necessary	Y/N
Just before going to bed	Y/N
At regular intervals during the day	Y/N

Do you take cannabis to: [*You may choose MORE THAN ONE*]

Relieve symptoms	Y/N
Aid relaxation	Y/N
Relieve anxiety	Y/N
Relieve depression	Y/N
Reduce symptom frequency	Y/N
Obtain energy	Y/N
To get a 'high' / Recreational	Y/N

For each symptom in the left-hand column state if the symptom is now present. Then mark for each symptom, whether past or present, its response to cannabis use, i.e., better or worse. Diagrams are provided below for the question relating to sites of pain, etc.

Symptom (past or present)	Present	Response to cannabis <i>[Please tick ONE box]</i>				
	Y/N	Much better	Little better	Not changed	Little worse	Much worse
Lack of appetite						
Feeling sick, i.e., Nausea						
Anxiety						
Depression						
Tremor						
Headaches						
Weight loss						
Weakness						
Tiredness						
Vision dimness						
Slurred speech						
Tremor						
Memory loss						
Constipation						
Diarrhea						
Muscle pain (please mark on Diagram 1 where you are affected by this)						
Nerve pain (please mark on Diagram 2 where in your body this is)						
Tingling (draw on Diagram 3 where this is)						
Numbness (draw on Diagram 4 where this is)						
Others (please state)						

N.B. Please do not forget to fill in the body diagrams on the next page if you suffer from MUSCLE PAIN, NERVE PAIN, TINGLING OR NUMBNESS.

Once completed please hand over this questionnaire to the reception desk.

THANK YOU.

Effectiveness of Cannabidiol Oil for Pediatric Anxiety and Insomnia as Part of Posttraumatic Stress Disorder: A Case Report

Scott Shannon, MD, ABIHM; Janet Opila-Lehman, ND

Perm J 2016 Fall;20(4):16-005

E-pub: 10/12/2016

<http://dx.doi.org/10.7812/TPP/16-005>

ABSTRACT

Introduction: Anxiety and sleep disorders are often the result of posttraumatic stress disorder and can contribute to an impaired ability to focus and to demonstration of oppositional behaviors.

Case Presentation: These symptoms were present in our patient, a ten-year-old girl who was sexually abused and had minimal parental supervision as a young child under the age of five. Pharmaceutical medications provided partial relief, but results were not long-lasting, and there were major side effects. A trial of cannabidiol oil resulted in a maintained decrease in anxiety and a steady improvement in the quality and quantity of the patient's sleep.

Discussion: Cannabidiol oil, an increasingly popular treatment of anxiety and sleep issues, has been documented as being an effective alternative to pharmaceutical medications. This case study provides clinical data that support the use of cannabidiol oil as a safe treatment for reducing anxiety and improving sleep in a young girl with posttraumatic stress disorder.

INTRODUCTION

Cannabidiol (CBD) oil is a naturally occurring constituent of industrial hemp and marijuana, which are collectively called cannabis. CBD oil is 1 of at least 85 cannabinoid compounds found in cannabis and is popular for its medicinal benefits. After tetrahydrocannabinol (THC), CBD oil is the second-most-abundant component of cannabis. Other names for CBD oil include CBD-rich hemp oil, hemp-derived CBD oil, or CBD-rich cannabis oil. Considered to be generally safe, CBD has been used medicinally for decades. However, CBD is not medical marijuana and should be distinguished from high-CBD strains

of medical marijuana, which do contain THC, such as “Charlotte’s Web.”

The most abundant compound in cannabis, THC is also a cannabinoid. The THC component induces the psychoactive effect, “high.” A cannabis plant has different amounts of CBD and THC depending on the strain and thus provides different recreational or medicinal effects. The cannabinoid profile of industrial hemp or medical marijuana is ideal for people looking for the medical benefits of CBD without the “high” of the THC.

The mechanism of action of CBD is multifold.¹⁻³ Two cannabinoid receptors are known to exist in the human body: CB1 and CB2 receptors. The CB1 receptors are located mainly in the brain and modulate neurotransmitter release in a manner that prevents excessive neuronal activity (thus calming and decreasing anxiety), as well as reduces pain, reduces inflammation, regulates movement and posture control, and regulates sensory perception, memory, and cognitive function.^{4,2} An endogenous ligand, anandamide, which occurs naturally in our bodies, binds to the CB1 receptors through the G-protein coupling system. CBD has an indirect effect on the CB1 receptors by stopping the enzymatic breakdown of anandamide, allowing it to stay in the system longer and provide medical benefits.⁴ CBD has a mild effect on the CB2 receptors, which are located in the periphery in lymphoid tissue. CBD helps to mediate the release of cytokines from the immune cells in a manner that helps to reduce inflammation and pain.²

Other mechanisms of action of CBD include stimulation of vanilloid pain receptors (TRPV-1 receptor), which are known to mediate pain perception, inflammation, and body temperature.⁵ In addition, CBD may exert its anti-anxiety effect by

activating adenosine receptors which play a significant role in cardiovascular function and cause a broad anti-inflammatory effect throughout the body.⁵ At high concentrations, CBD directly activates the 5-HT1A serotonin receptor, thereby conferring an antidepressant effect.⁶ Cannabidiol has been found to be an antagonist at the potentially new third cannabinoid receptor, GPR55, in the caudate nucleus and putamen, which if stimulated may contribute to osteoporosis.⁷

Since the 1940s, a considerable number of published articles have dealt with the chemistry, biochemistry, pharmacology, and clinical effects of CBD.⁸ The last decade has shown a notable increase in the scientific literature on CBD, owing to its identification for reducing nausea and vomiting, combating psychotic disorders, reducing inflammation, decreasing anxiety and depression, improving sleep, and increasing a sense of well-being.⁹⁻¹² Findings presented at the 2015 International Cannabinoid Research Society at its 25th Annual Symposium reported the use of CBD as beneficial for kidney fibrosis and inflammation, metabolic syndrome, overweight and obesity, anorexia-cachexia syndrome, and modification of osteoarthritic and other musculoskeletal conditions.¹³⁻¹⁶

Although studies have demonstrated the calming, anti-inflammatory, and relaxing effects of CBD, clinical data from actual cases is minimal. This case study offers evidence that CBD is effective as a safe alternative treatment to traditional psychiatric medications for reducing anxiety and insomnia.¹⁷

CASE PRESENTATION

A ten-year-old girl presented in January 2015 for a reevaluation of behaviors related to her diagnosis of posttraumatic stress disorder (PTSD) secondary to sexual

Scott Shannon, MD, ABIHM, is an Assistant Clinical Professor of Psychiatry at the University of Colorado School of Medicine in Fort Collins. E-mail: scottshannon@cowisp.net. Janet Opila-Lehman, ND, is a Naturopathic Physician at the Wholeness Center in Fort Collins, CO. E-mail: j.opila.lehman@gmail.com.

abuse. Her chief issues included anxiety, insomnia, outbursts at school, suicidal ideation, and self-destructive behaviors. Her grandmother, who has permanent custody of the patient and her younger brother, accompanied her.

Our patient had been seen for an initial evaluation in January 2012 and received a diagnosis of PTSD secondary to sexual abuse on the basis of her history, clinical observations, and behaviors (Table 1).

Her father had died 6 months earlier in a motor vehicle accident, and our patient's maternal grandparents became her permanent guardians. Before her father's death, our patient had no supervision from her father and very little supervision from her mother. An 11-year-old boy had molested her when she was 3 years old. Her medical history included her mother having methadone addiction, alcoholism, bipolar disorder, and depression. Her mother used

marijuana her entire pregnancy with the girl. The patient presented in January 2012 as displaying aggressive, disobedient, impulsive, and sexually inappropriate behaviors. She also demonstrated low self-esteem and anxiety and had poor sleep (restless, interrupted, and unable to sleep alone).

Workup during 2012 included laboratory studies, which ruled out a thyroid dysfunction and an iron or vitamin D deficiency. The patient was started on a

Table 1. Timeline

Date	Presentation	Medications	Supplements	Other
January 31, 2012	New evaluation: 7.5-year-old girl. History of sexual abuse and neglect. Issues: Insomnia, sexual behaviors. Diagnosis: PTSD secondary to sexual abuse.	None	Melatonin, 1 mg/night	February 14, 2012, laboratory values: TSH, 2.46 mIU/L (reference range, 0.47-4.68 mIU/L); ferritin: 21 ng/mL (reference range, 10-150 ng/mL). February 16, 2012, laboratory values: Vitamin D ₃ : 39 ng/mL (reference range, 20-50 ng/mL)
February 20, 2012	Sleeping 2-3 hours/night. Started counseling; Cooperative and good behavior at counseling session. Anxious, traumatized.	Clonidine, 0.05 mg (half tablet) at bedtime	Inositol, 3 g 3 times/d; EPA fish oil, 500 mg/d	Eye movement desensitization and reprocessing therapy recommended
February 22, 2012	Did not do well with clonidine because of hallucinations, so she discontinued that treatment. Behavior still very rough; sleep poor.	Started imipramine therapy, 25 mg at bedtime		March 7, 2012: ECG was normal
August 8, 2012 ^a	Good summer. In play therapy. Overall better sleep and energy with imipramine therapy. Patient's 6-year-old brother also now in therapy.	Imipramine, 25 mg at bedtime		
January 21, 2015	Returned for evaluation and treatment after 3 years. Suicidal ideation; cut self on leg; defiant and stubborn. Had psychotherapy 3 years straight twice a month. Sleeps with brother; can't sleep alone.	Off all medications for past 18 months	Melatonin, 5 mg; St John's wort, 450 mg twice/d; magnesium, 300 mg/d; diphenhydramine, 25 mg/night	
February 16, 2015	Hard to manage. Has outbursts at school.		Magnesium and St John's wort: stopped treatment; EPA fish oil, 750 mg/d; diphenhydramine, 25 mg/night	February 11, 2015: Normal cortisol and DHEA levels
March 16, 2015	Better overall. Started animal-assisted therapy.		EPA fish oil, 750 mg/d; diphenhydramine, 25 mg/night	Started a regimen of CBD oil, 25 mg (1 capsule)/d at 6 pm
April 14, 2015	Sleeping better with CBD treatment. Getting biofeedback. Has stomachaches. Mood is more at ease.		EPA fish oil, 750 mg/d; diphenhydramine, 25 mg/night	CBD oil, 25 mg (1 capsule)/d at 6 pm
May 26, 2015	"Ghosts" waking patient up at night.		EPA fish oil, 750 mg/d	CBD oil, 25 mg (1 capsule)/d at 6 pm
July 22, 2015	Sleeping better; able to sleep in own room 3-4 nights/wk.		EPA fish oil, 750 mg/d	CBD liquid, 12 mg (in 4 sublingual sprays)/night; 12 mg more (in 4 sublingual sprays) during the day as needed for anxiety, typically 3 or 4 times/wk
August 24, 2015	Sleeping well. Handling school well.		EPA fish oil, 750 mg/d	CBD oil, 25 mg (1 capsule)/night; CBD liquid, 6-12 mg (in 2-4 sublingual sprays) as needed for anxiety, typically 2 or 3 times/wk

^a There were additional visits in 2012 with no substantial changes.

CBD = cannabidiol; DHEA = dehydroepiandrosterone; ECG = electrocardiogram; EPA = eicosapentaenoic acid; PTSD = posttraumatic stress disorder; TSH = thyroid stimulating hormone.

regimen of 1 mg/night of melatonin, which helped her sleep duration. Three grams of inositol 3 times a day and 500 mg/d of eicosapentaenoic fish oil were also helpful in reducing her anxiety. A trial of clonidine was implemented, which resulted in hallucinations and thus was discontinued. The patient was switched to a regimen of 25 mg of imipramine at bedtime to decrease her anxiety, which appeared to be helpful. Counseling sessions were started. The patient continued psychotherapy for 3 years, but she was not seen again in our clinic until the return visit in January 2015, when she was not receiving any of her medications and supplements.

CBD oil can be an effective compound to reduce anxiety and insomnia secondary to PTSD.

At the patient's return in January 2015, she demonstrated the same prominent symptoms as at her initial presentation. At that time, the initial treatment included the following supplements and medications to assist with her sleep and anxiety: melatonin, 5 mg/night; magnesium, 300 mg/d; and diphenhydramine (Benadryl), 25 mg/night. Our patient demonstrated slight gains but was still having outbursts at school and was reportedly difficult to manage at home. In addition, her underlying anxiety continued.

Cannabidiol oil was explored as a potential additional treatment to help her insomnia and anxiety, but we deferred for two months while we waited for a response from other interventions. The grandmother preferred reducing the pharmacologic load given her granddaughter's failure to respond long term to psychiatric medications.

In March 2015, CBD oil was recommended as a potential additional treatment to help her insomnia and anxiety, and her grandmother provided full informed consent. Our patient was administered the Sleep Disturbance Scale for Children¹⁸ and the Screen for Anxiety Related Disorders (SCARED)¹⁹ before taking the CBD oil and each month afterward for the next 5 months. Test scores on the Sleep Disturbance Scale for Children and Screen for

Anxiety Related Disorders demonstrated an improvement (Table 2).

A trial of CBD supplements (25 mg) was then initiated at bedtime, and 6 mg to 12 mg of CBD sublingual spray was administered during the day as needed for anxiety. A gradual increase in sleep quality and quantity and a decrease in her anxiety were noted. After 5 months, the patient was sleeping in her own room most nights and handling the new school year with no difficulties. No side effects were observed from taking the CBD oil.

DISCUSSION

Studies repeatedly recognize the prevalence of an anxiety-provoked sleep disorder after a traumatic experience.²⁰ Our patient was definitely experiencing this phenomenon, which was aggravated by daily stressful activities.

The main finding from this case study is that CBD oil can be an effective compound to reduce anxiety and insomnia secondary to PTSD. A review of the literature suggests some benefits from the use of CBD because of its anxiolytic and sleep-inducing effects.⁹ Animal studies support use of this treatment and report that "CBD may block anxiety-induced [rapid eye movement] sleep alteration via its anxiolytic effect on the brain."²¹

The strength of this particular case is that our patient was receiving no pharmaceutical medications (other than non-prescription diphenhydramine) but only nutritional supplements and the CBD oil to control her symptoms. Her scores on the sleep scale and the anxiety scale consistently and steadily decreased during a period of 5 months (see Table 2). She

was ultimately able to sleep through the night most nights in her own room, was less anxious at school and home, and displayed appropriate behaviors. The patient's grandmother (her caregiver) reported: "My granddaughter's behaviors are definitely better being on the CBD. Her anxiety is not gone, but it is not as intense and she is much easier to be around. She now sleeps in her own room most of the time, which has never happened before."

Further study will need to be conducted to determine the permanency of our patient's positive behaviors and how long she will need to continue taking the CBD oil. We do not have a reasonable foundation to recommend dosing from the scientific literature. However, in our experience, this supplement given 12 mg to 25 mg once daily appears to provide relief of key symptoms with minimal side effects. Our patient did not voice any complaints or discomfort from the use of CBD. We routinely asked about headache, fatigue, and change in appetite or agitation in addition to conducting a routine psychiatric evaluation. Although CBD is considered generally safe,¹⁷ the long-term effects are yet to be studied.

The ultimate goal is to gradually taper her off the use of CBD oil and transition our patient into lifelong coping strategies such as yoga, meditation, and various other therapeutic activities. ♦

Marijuana and Medicine

Scientific data indicate the potential therapeutic value of cannabinoid drugs, primarily [tetrahydrocannabinol], for pain relief, control of nausea and vomiting, and appetite stimulation; smoked marijuana, however, is a crude [tetrahydrocannabinol] delivery system that also delivers harmful substances.

Access to cannabis

ABSTRACT

Background: The authorized and unauthorized use of cannabis for therapeutic purposes (CTP) has increased dramatically in recent years, and physicians have called for further research to better clarify the parameters of effective and appropriate use. We report findings from a large cross-sectional study of the use of CTP in Canada and compare use across medical conditions and across authorized and unauthorized users.

Methods: We examined cannabis use history, medical conditions and symptoms, patterns of current use of CTP, modes of access and perceived effectiveness among 628 self-selected Canadians consumers of CTP. Participants were recruited from medical cannabis dispensaries and from organizations that assist users of CTP.

Results: Patients reported using cannabis to treat multiple symptoms, with sleep, pain, and anxiety being the most common. Cannabis was perceived to provide effective symptoms relief across medical conditions. Patterns of use were also consistent across medical conditions. Notable differences were observed with regard to modes of access.

Conclusion: Across medical conditions respondents reported using cannabis to effectively address diverse symptoms. Results indicate a substantial disconnect between the therapeutic use of cannabis and research on the risks and benefits of such use; particularly with regard to the anxiolytic and sedative use of cannabis. Authorized and unauthorized users exhibited few meaningful differences with regard to medical conditions and patterns of use, but faced substantial differences regarding access.

© 2013 Elsevier B.V. All rights reserved.

Cannabis has a long history of medical use (Abel, 1980; Earleywine, 2005; Iverson, 2008), and after decades of marginalization the therapeutic properties of cannabis and cannabis derivatives are receiving increased attention (Earleywine, 2005; Holland, 2010; Lucas, 2008). Indeed, robust and growing evidence indicates that cannabis has medical benefits for diverse conditions and an acceptable risk profile (Joy, Watson, & Benson, 2003). In response to legal recognition of the constitutional rights of Canadians to access cannabis for therapeutic purposes (CTP), the federal government enacted the *Marihuana Medical Access Regulations* and

initiated a centralized program in 2001, and in 2003 Health Canada began to provide CTP to patients. This program authorizes two categories of individuals to possess cannabis for medical purposes; Category 1 includes symptoms associated with HIV/AIDS, arthritis, spinal cord injury or disease, cancer, epilepsy, or MS, whereas Category 2 includes other symptoms and conditions assessed by a physician and a specialist. Those authorized can purchase dried cannabis from Health Canada, can purchase seeds to grow cannabis, or designate a person to grow cannabis on their behalf. In addition, medical cannabis dispensaries that operate under an ambiguous legal status provide CTP and related services to over 50,000 patients across Canada (Lucas, 2008).

Despite widespread concern with the efficiency of the Health Canada program (Holland, 2010), registration has grown exponentially from under 500 registrants in 2002 to over 26,000 in 2012 (Health Canada, 2012a). National surveys indicate substantial access outside of the Health Canada program; recent estimates

E-mail addresses: zachary.walsh@ubc.ca (Z. Walsh), rojocal@yahoo.ca (R. Callaway), LynneB@cdnaids.ca (L. Belle-Isle), rielle@telus.net (R. Capler), bekindok@hotmail.com (R. Kay), plucas@uvic.ca (P. Lucas), susan.holtzman@ubc.ca (S. Holtzman).

suggest that 400,000 to 1,000,000 Canadians use CTP (Health Canada, 2011). Diverse reasons for use and multiple modes of access complicate the characterization of use of CTP, and health care professionals have expressed concern regarding the dearth of information on CTP; a recent Canadian Medical Association-sponsored survey reported that over 80% of physicians wanted more information on therapeutic indications, clinical guidelines, and risks and benefits of CTP (CMA, 2012).

Several studies have examined CTP use among Canadians. A regional survey reported that approximately 2% of adults used CTP in the past year, primarily to relieve nausea and pain (Braitstein et al., 2001), and a more recent national survey estimated that one million Canadians, or 4% of those aged 15 and older, used cannabis to treat self-defined medical conditions in the previous 12 months (Adlaf, Begin, & Sawka, 2005). Studies of persons living with HIV/AIDS report rates of 15–30% use of CTP, primarily for treatment of nausea, pain, and mood-related symptoms (Belle-Isle & Hathaway, 2007; Ware, Rueda, Singer, & Kilby, 2003). Studies of patients with MS and patients with chronic pain report similar results; approximately 15% of respondents report use of CTP with high levels of perceived effectiveness for diverse symptoms including nausea, pain, and mood (Belle-Isle & Hathaway, 2007; Ware et al., 2003; Clark, Ware, Yazer, Murray, & Lynch, 2004). Studies of CTP from the US, Europe, and Australia report findings that are consistent with those of Canadian studies; CTP is perceived to be an effective treatment for symptoms including pain, nausea, and negative mood (Grotenherman & Schnelle, 2003; Harris et al., 2000; Lucas, 2012; Reiman, 2007; Reinerman, Nunberg, Lanthier, & Heddleston, 2011; Swift, Gates, & Dillon, 2005; Ware, Adams, & Guy, 2005).

In sum, patient-centered research provides evidence for the acceptability and perceived effectiveness of CTP. However, substantial knowledge gaps remain and health care professionals have explicitly called for further research to better specify the parameters for appropriate use of CTP (CMA, 2012). Indeed, to date no studies have directly compared use of CTP across medical conditions or across modes of access (i.e., authorized vs. unauthorized). In the present study we report demographic characteristics, medical conditions and symptoms, reasons for use, perceived effects, and authorized and unauthorized modes of accessing CTP among Canadians. Comparing users of CTP across symptoms and across medical conditions with regard to patterns of use, and perceived effectiveness may help direct future controlled studies of the efficacy of CTP for specific conditions, and inform the development of tailored CTP regimens. In addition, comparing authorized and unauthorized CTP users may elucidate factors that underlie patient adoption of the Canadian CTP program, and help to guide the refinement of the complex process of CTP distribution and monitoring.

Method

Design

We obtained cross-sectional data in 2011–2012 from 628 self-selected current CTP users. Participants were recruited from two contexts; *national* participants completed the survey online from the location of their choice, and *local* participants completed the survey at a cannabis dispensary in the Interior region of British Columbia (BC). This recruitment strategy was designed to allow for comparison of the relatively less controlled online *national* condition with the confirmed CTP users queried in-person in the *local* condition. A total of 702 *national* participants completed the consent form, of whom 541 (77%) reported current CTP use. All 87 *local* participants who completed the consent form reported current CTP use. The *national* survey was promoted via organizations and media

^a $p < .01$.

that serve users of CTP patients (e.g., Canadian AIDS Society, Canadian Aboriginal AIDS Network, Cannabis Culture), and by national advertisements at MC dispensaries. To preserve confidentiality, no identifying data (i.e. IP addresses) were collected for *national* participants. The *local* group was comprised of dispensary members who were either authorized to possess cannabis through Health Canada or had documented confirmation of a medical condition for which CTP is indicated. No confirmation of medical condition was provided for *national* participants; however such confirmation is required to obtain Health Canada authorization and to obtain dispensary membership. Participants in the *local* group were compensated \$10 and were aided by research assistants; participants in the *national* group were not assisted or financially compensated.

The survey was designed to be completed in less than one hour, and consisted of a total of 414 adaptive questions administered online without forced response. The survey was organized hierarchically such that many items were contingent on prior responses; as a result, respondents were presented with diverse item sets and response rates for specific items, and total response times varied accordingly. The survey was developed based on previous research, and on consultations with a community research board comprised of CTP patients and experts, and includes questions drawn from a prior study of CTP use (Belle-Isle & Hathaway, 2007). It queried access, perceived effectiveness, patterns and history of cannabis use, medical diagnoses and symptoms, mood, and demographics (a copy of the survey is available upon request from the first author). The study was approved by the Behavioural Research Ethics Board of the Okanagan campus of the University of British Columbia. All categorical data were compared using χ^2 . In light of varying response rates across items, total number of responses is reported for each analysis. Due to the large number of comparisons all significance testing was conducted at the $p < .01$ level to minimize the likelihood of interpreting chance results while maintaining power (Nakagawa, 2004).

Results

Preliminary analyses

We compared the responses of *local* participants who reported residency in the province of BC and accessing CTP via

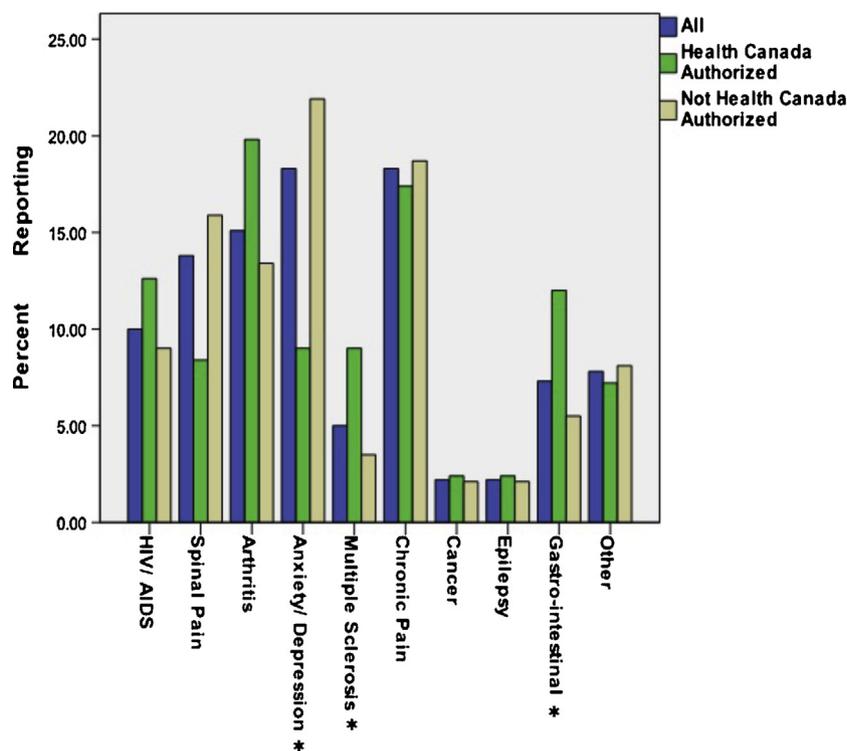

Fig. 1. Primary medical conditions treated with cannabis by authorization. *Note:* Sleep Disorders, Attention Deficit Disorder, Fibromyalgia, Hepatitis C, Parkinson’s Disease, Wilson’s Disease, Scleroderma, Tourette’s Syndrome, and unspecified Psychotic Disorder Conditions each comprised less than 2% of the sample and were aggregated into the category ‘Other’. The anxiety and mood disorders category included 35 participants who reported a primary *illness/condition* of anxiety, 34 who reported depression and 40 who reported both anxiety and depression. Comparisons of these groups indicated equivalent profiles with regard to demographic characteristics, health, and use of CTP, and were therefore aggregated for statistical analyses; $n = 502$ * = difference between proportion Health Canada Authorized and Unauthorized $p < .01$.

dispensary ($n = 63$) to *national* participants who reported BC residency and accessing CTP via dispensary ($n = 53$). Analysis indicated no differences with regard to quantity or frequency of cannabis use, and indicated substantial similarity with regard to primary medical condition; the only difference was a smaller proportion of *local* respondents reporting gastrointestinal (GI) condition as primary ($\chi^2 = 8.94 (1), p < .01$). This broad similarity between in-person confirmed users of CTP (i.e. *local*) and online respondents increased our confidence in the validity of online responses.

Demographics

Comparisons of the sample to values drawn from the Canadian 2006 Census of Population (Statistics Canada, 2006; Table 1) indicated that male, White, and Aboriginal participants were over-represented. The users of CTP were also younger, had a higher income, and were more likely to have completed high school. The regional distribution was consistent with participation in the Health Canada program (Health Canada, 2012b).

Medical conditions and symptoms

Participants were queried regarding a single primary *condition* treated with cannabis (Fig. 1). Participants also checked all applicable *symptoms* (Table 2) they treated with cannabis from a list. The mean number of symptoms patients endorsed treating was 6.74 ($n = 605$, $SD = 3.00$, Median = 6.00, Interquartile range = 4.00–8.00). Symptoms reportedly treated with CTP by fewer than 10% of the sample include high blood pressure (9%), tics (8%), regulating blood sugar (7%), seizures (6%), bladder dyscontrol (6%) and impotence (6%). Aggregate examination across *condition* indicated that pain, anxiety, and sleep problems were the most frequently endorsed

symptoms; 57% reported use to address all three symptoms, and 99% endorsed treating one or more of the three.

Symptoms treated with cannabis varied across *condition* (Table 2). Use to address pain symptoms was more prevalent among individuals whose primary conditions were pain-related (i.e., chronic spinal and non-spinal pain, arthritis). Chronic spinal pain participants were more likely to report treating muscle spasms. Participants with arthritis were more likely to report use for inflammation and ocular pressure, and less likely to report use to address anxiety and appetite. Participants who identified mood and anxiety disorders as their primary condition were more likely to use cannabis to address mental health-related symptoms (i.e., anxiety, depression, aggression, mania/psychosis), and were less likely to treat pain, inflammation, and muscle spasms. Participants who identified HIV/AIDS or GI as their primary conditions were more likely to treat symptoms of nausea and appetite, and HIV/AIDS was associated with less treatment of pain and aggression. Overall, cannabis was perceived to provide effective symptoms relief; 72% ($n = 439$) reported that CTP was *always* helpful and an additional 24% ($n = 147$) described it as *often* helpful. The proportion of participants who described CTP as *always* helpful was relatively consistent across conditions. The only difference across groups was relatively lower endorsement of *always* helpful (55%) by participants with HIV/AIDS ($\chi^2 = 10.04 (1), n = 593, p < .01$). Over half (57%, $n = 358$) of participants reported using other medications to address the symptoms they were treating with CTP. Of these, 79% ($n = 281$) described CTP as having fewer side effects than the concurrent treatment.

Use patterns

History of non-therapeutic cannabis use prior to therapeutic use was reported by 82% ($n = 441$) of participants.

^a p < .01.

Mean age was 17.30 years ($n=540$, $SD=7.08$, Median = 16, Interquartile range = 14.00–18.00) for first use and 28.35 years ($n=538$, $SD=11.25$, Median = 25, Interquartile range = 19.00–37.00) for first therapeutic use. Individuals with and without history of non-therapeutic use did not differ with regard to demographic characteristics, or conditions and symptoms. Most participants who reported prior use reported increased use with the initiation of therapeutic use; 33% reported a large increase and 32% a small increase, whereas 7% reported a large decrease and 10% a small decrease. Aggregate analyses indicated that 40% ($n=167$) of users fell into the modal quantity of use category of *more than 14 grams per week*, and that 42% ($n=226$) fell in the modal frequency of use group reporting *2–3 uses per day*. Among the group that used more than 14 grams per week, the median weekly amount used was 28 grams (Interquartile range = 21–45). Comparisons of the six medical conditions that each account for 5% or more of the sample (Table 3) indicated no difference with regard to modes of use and few differences in patterns of use; a larger proportion of individuals identifying HIV/AIDS as primary condition were among the groups with lowest quantity and frequency of use, and those who identified anxiety and/or depression as primary conditions were less likely to fall in the most frequent use group. Overall health quality was also associated with frequency of use such that participants who described their overall health as *fair* or

poor (34%, $n=161$) were overrepresented in the most frequent use group ($X^2=8.31$ (1), $n=473$, $p<.01$).

Access

Aggregate examination indicated that 32% ($n=167$) of respondents had Health Canada authorization to possess CTP. An additional 12% ($n=64$) had applications in process, and 3% ($n=13$) had applied and been rejected. The proportion of authorized individuals varied across condition (Fig. 1); individuals who identified anxiety and/or depression as primary condition were less likely to be authorized ($X^2=13.13$ (1), $n=502$, $p<.01$), whereas a greater proportion of MS ($X^2=11.08$ (1), $n=502$, $p<.01$) and GI ($X^2=8.68$ (1), $n=502$, $p<.01$) participants were authorized. Most participants reported using more than one mode of accessing CTP; the mean number of access modalities was 1.89 ($n=500$, $SD=.88$, Median = 2.00, Interquartile range = 1.00–2.00). Authorization was a determinant of access (Fig. 2); the mean number of access modalities for authorized individuals was 2.11 ($n=162$, $SD=.98$, Median = 2.00, Interquartile range = 1.00–3.00) compared to 1.78 ($n=337$, $SD=.81$, Median = 2.00, Interquartile range = 1.00–2.00) for unauthorized users ($F(1, 497)=16.26$, $p<.01$). Authorized users were more likely to access CTP via Health Canada ($X^2=11.88$ (1), $n=443$, $p<.01$), to grow for themselves ($X^2=31.42$ (1), $n=493$,

In contrast, unauthorized users were more likely to access CTP from a friend ($X^2 = 25.46$ (1), $n = 495$, $p < .01$) or from a stranger ($X^2 = 18.69$ (1), $n = 494$, $p < .01$).

Discussion

Canadians use cannabis to treat diverse conditions and symptoms in a manner that only partially overlaps with the federally authorized program. There is considerable consistency with regard to patterns of use and reported effectiveness; nearly all respondents used cannabis to treat pain, anxiety, or sleep disturbances, and over half used it to treat all three symptoms. We also observed consistency across participants with and without histories of non-therapeutic cannabis use, which suggests that, with regard to CTP, individuals who may enjoy non-therapeutic use of cannabis were not different with regard to therapeutic application of cannabis from those participants who may have been less likely to expect extra-therapeutic benefit. The substantial minority of respondents who were federally authorized to possess cannabis exhibited few differences from unauthorized users with regard to symptoms treated and patterns of use, but differed considerably with regard to mode of access.

Most respondents reported using CTP to treat conditions that are explicitly listed within the federal program; however, a large contingent also reported use for other conditions. Comparisons of symptoms treated across conditions indicated high levels of congruence (e.g., respondents with pain-related conditions were more likely to use cannabis to address pain symptoms), but also reflected substantial consistency across conditions. Specifically, use to treat sleep disturbances, and to a lesser extent anxiety and depression, was consistently high across conditions. However, despite widespread use for anxiolytic and sedative purposes, participants who reported anxiety or depression as primary reason for CTP use were less likely to have obtained federal authorization to access CTP. This may be due to the absence of these conditions among those explicitly listed by the federal program, but may also reflect accentuated stigma associated with the use of cannabis to address mental health issues. Indeed, stigma has been identified as a

substantial barrier to accessing care for mental health conditions such as depression and anxiety (Brown et al., 2010), and this may be compounded by the considerable stigma associated with use of CTP (Bottorff et al., 2013) to create a substantial barrier to accessing treatment. Research that further elucidates the appropriateness of using cannabis to treat anxiety and depression is required to guide effective treatment and help to reduce stigma.

Patterns of use were also consistent across medical conditions, with the only notable difference being slightly lower levels of use among respondents with HIV/AIDS, a difference which may be due to intermittent use to address nausea. Most participants reported initiating non-therapeutic use prior to use of CTP, and noted increased levels of use associated with the transition to therapeutic use. This reported increase is consistent with our observation that the median level of therapeutic use exceeds typical levels of non-therapeutic use (Reinarman, Cohen, & Kaal, 2004; Hazekamp et al., 2013; but see also Hazekamp & Heerdink, 2013), and suggests a potentially meaningful distinction between therapeutic and non-therapeutic use. In contrast, the relative consistency of use among CTP-users suggests that CTP regimens might transfer well across conditions, and enjoy good adherence. The most pronounced differences across respondents involved modes of access, such that unauthorized users were much less likely to access CTP from authorized, or semi-authorized (i.e. dispensaries) sources. This discrepancy contrasts with the pronounced similarity between authorized and unauthorized users on indicators of health and use of CTP, and suggests that the current system of authorization may not be discriminating among qualitatively different groups.

The primary limitations of this study are common to online medical surveys such as potential for multiple responses from a single respondent, a potentially unrepresentative sample, and lack of physician confirmation of medical conditions. In addition, response bias related to participant self-selection, and recruitment through organizations that support medical cannabis patients likely resulted in overrepresentation in our sample by individuals who respond favourably to CTP. In light of this potential bias, our characterization of the therapeutic use of cannabis should be interpreted with caution pending replication from research that employs a more systematic recruitment approach. However, these limitations are counterbalanced by several methodological

strengths including the inclusion of an in-person subsample, engagement of a community research board in the development and dissemination of the survey, and general adherence to established standards for reporting internet-based surveys (Eysenbach, 2004).

Conclusions

This was the largest and most comprehensive study to date of the therapeutic use of cannabis in Canada. We draw three primary conclusions from the data. First, reasons for use and perceived effectiveness were generally consistent across medical conditions; respondents overwhelmingly reported using cannabis to effectively address pain, sleep disturbance, and anxiety. Second, further research is required to address the substantial disconnect between the therapeutic use of cannabis and research on the risks and benefits of such use. This is particularly evident with regard to the anxiolytic and sedative use of cannabis; extrapolation from our sample to the national population of CTP users suggests levels of use for anxiolytic and sedative purposes that may be comparable to the number of Canadians who currently use benzodiazepine and other sedatives (Kassam & Patten, 2006). Such widespread use suggests a need for the systematic evaluation of the effectiveness and adverse effects of cannabis for the treatment of these conditions, as well as comparisons of cannabis with the widely-used pharmaceutical products that currently represent frontline treatments. Finally, our findings highlight the apparent discrepancy in access to cannabis across CTP users. Authorized and unauthorized users exhibit few meaningful differences with regard to medical conditions and patterns of use, but face substantial differences regarding access; many seriously ill Canadians risk increased stigma (Bottorf, Bissell, Balneaves, Oliffe, Capler & Buxton, 2013), legal sanction, and other negative outcomes associated with accessing cannabis from illegal markets. At the time of this writing the federal medical cannabis program is undergoing substantial structural changes. The present study provides a baseline for assessing the impact of these changes, the most important of which must surely involve providing a program that facilitates informed, safe, legal, and affordable access to a source of CTP for ill Canadians.

Acknowledgements

This research was supported by a grant from the UBC Institute for Healthy Living and Chronic Disease Prevention. The authors thank the people who took the time to respond to the survey. We would also like to thank Ben Atkinson, Kim Crosby and Megan Hiles for their contribution to data collection and management, and Brian Emerson for providing valuable feedback on the manuscript.

Conflict of interest statement

None of the authors have any conflicts of interest with regard to the contents of this manuscript. Access.

Patterns of cannabis use among patients with multiple sclerosis

A.J. Clark, MD, FRCPC; M.A. Ware, MBBS, MRCP(UK); E. Yazer, BSc; T.J. Murray, FRCPC; and M.E. Lynch, MD, FRCPC

Abstract—To estimate the patterns and prevalence of cannabis use among patients with multiple sclerosis (MS), 220 patients were surveyed in Halifax, Nova Scotia. Seventy-two subjects (36%) reported ever having used cannabis for any purpose; 29 respondents (14%) reported continuing use of cannabis for symptom treatment. Medical cannabis use was associated with male gender, tobacco use, and recreational cannabis use. The symptoms reported by medical cannabis users to be most effectively relieved were stress, sleep, mood, stiffness/spasm, and pain.

NEUROLOGY 2004;62:2098–2100

Published reports spanning 100 years suggest that people with spasticity may experience relief with cannabis.¹ The epidemiology of cannabis use among patients with multiple sclerosis (MS) is not well described. A recent postal survey (60% response rate) of 420 patients with MS from southern Alberta, Canada in 2000 estimated that 16% of patients had used cannabis for therapeutic purposes.² We report the results of a 2002 survey in which we evaluated the patterns and prevalence of cannabis use in Halifax, Nova Scotia.

Methods. A cross-sectional questionnaire-based survey was designed to collect information on demographics (age, gender, years with MS, and medications used) and medicinal and recreational cannabis use. Subjective cannabis effects were documented using 5-point Likert scales on a range of symptoms, including spasticity, pain, mobility, sleep, and mood. Side effects experienced were recorded. Information on doses used, means of administration, frequency, and duration of use was collected. In addition, strength of commitment to use cannabis in the future was recorded. The Queen Elizabeth II Health Sciences Centre Research Ethics Committee approved the study protocol and questionnaire.

A sample size of 144 was calculated to be sufficient to detect an estimated prevalence of 10% with a 2.5% standard error. To account for 20% refusals and those who incorrectly filled in forms, we aimed to administer 175 questionnaires; 220 forms were prepared and administered at the study site.

Data were double entered and validated using standard procedures by a central data management agency (GEREQ, Quebec, Canada). Missing values constituting <5% of the total were not included in summary statistics. Analyses were conducted using statistical software (Stata version 8.0, Houston, TX).

Data are presented as summary statistics (means and medians) as appropriate. Ordered categorical data (e.g., degree of relief and severity of side effects) were summarized as proportions (e.g., number of patients indicating moderate to complete relief com-

pared with total responses). The prevalence and patterns of cannabis use were estimated and analyzed by cross-tabulating the responses from medicinal cannabis users and others with respect to demographic characteristics. Continuous normally distributed data were compared using Student's *t*-test. Categorical data were compared using Pearson χ^2 tests. Ordered categorical data were analyzed using Mantel-Haenszel tests. Significance was set at the 95% level, and all tests were two sided.

Results. Two hundred five questionnaires were returned (93% response rate). The demographic characteristics of the subjects are shown in table 1. Subjects are shown categorized by their medicinal cannabis use status. Ever-use of cannabis for medical purposes was found to be significantly associated with male gender ($p = 0.03$), use of tobacco ($p < 0.001$), and recreational use of cannabis ($p = 0.009$).

Perceived effects and side effects. The 34 medical users rated the overall effectiveness of cannabis; more than half of these subjects reported cannabis as being very effective (2, not effective; 2, slightly; 10, somewhat; and 20, very effective). The perceived effectiveness of cannabis on individual symptoms is shown in table 2. Cannabis use was reported to reduce the number of doses of routine medication taken by 14 subjects, whereas 19 reported that cannabis had no effect on the number of doses of routine medication used.

Of the 34 medical cannabis users, 15 reported no overall side effects, 10 reported very mild side effects, 8 reported moderate side effects, and 1 reported strong side effects. No subject reported severe side effects. The most common side effect was "high," which was reported by 24 subjects, followed by drowsiness by 20, dry mouth by 14, paranoia by 3, anxiety by 3, and palpitations by 3.

Nine subjects gave reasons why they had stopped using cannabis: three stated that obtaining it was too risky; two said cannabis had no effect at all; one reported that side effects were intolerable; and one said that symptoms had improved. No subject stated that symptoms got worse with cannabis use.

Patterns of cannabis use. Of 34 medical cannabis users, 15 reported only rare use, whereas 7 reported weekly use, 4 reported daily use, and 8 reported use more than once per day. Seventeen subjects had used cannabis in the past 24 hours; 4 had used in the past week; 3 had used in the past month; 5 had used in the past year; and 5 had not used in more than a year.

Thirty-two subjects gave information on single-dose

size: the most common was an entire joint (14 subjects); three or four puffs at a dose was reported by 13 subjects; and one to two puffs was reported by 4 subjects. One subject stated that he smoked more than one joint per dose. Of the 12 who consumed cannabis orally, 11 stated that they used <1 g at each dose. The most common time of use was at night (29 subjects), followed by late afternoon (22), early afternoon (8), before noon (7), and morning (6).

Discussion. This survey demonstrates a prevalence of current medicinal cannabis use among patients seeking treatment at the MS clinic in Nova Scotia of 14%. This is consistent with data recently published from Alberta, Canada, which found a current use prevalence of 16%.² Medical use is reportedly effective for pain, stress, sleep, mood, and muscle spasm, consistent with reports from the United Kingdom and the United States,³ as well as Canada.² The use of cannabis for stress and anxiety is reported in other populations, such as patients with HIV/AIDS and chronic noncancer pain, and emphasizes the need to better address these symptoms in clinical practice.⁴

Clinical trials of cannabinoids in MS have not been consistent in demonstrating beneficial effects. One small randomized controlled trial in 13 patients with MS found that doses of tetrahydrocannabinol (THC) >7.5 mg reduced patient reports of spasticity compared with placebo.⁵ Reductions in tremor⁶ and

Table 2 Self-reported effects of cannabis on multiple sclerosis symptoms by 34 medicinal cannabis users

Symptom	n	None-mild relief	Moderate-complete relief
Stress	21	1	20
Sleep	18	1	17
Stiffness	17	1	16
Mood	16	0	16
Spasm	15	1	14
Pain	12	2	10
Weight loss	5	1	4

pendular nystagmus⁷ during cannabis smoking have also been observed.

In contrast, cannabis (1.54% THC) increased postural tracking errors among 10 patients with MS and 10 healthy control subjects, especially in the patients with MS.⁸ In a recent randomized controlled trial of 16 patients comparing an oral cannabis extract with oral THC and placebo, cannabinoid treatment did not reduce spasticity or improve subjective impressions.⁹

A large randomized controlled trial (n = 660) recently compared the effects of oral cannabis extracts with pure oral THC and placebo. The study found no difference with respect to the primary outcome measure (modified Ashworth score) but did note significant subjective improvements in pain, spasm, and sleep.¹⁰

In the meantime, patients with MS continue to use cannabis to manage their symptoms. What can we learn from these patients? First, that pain and spasticity are not the only reasons for use, and the effects of cannabis on mood, sleep, and stress are important areas of therapeutic need and should be addressed in clinical trials. Second, there is a wide variance in doses used. Our study found doses ranging from single puffs to >1 g at a time. This may be explained in part by different potencies of available cannabis, with lower-potency preparations requiring larger doses, or by variation between individuals in tolerability or symptom severity. Clinical trials of cannabis for MS will need to include early dose-finding phases and allow for considerable intersubject variability in dose adjustments. Third, cannabis appears to be well tolerated, although some subjects experienced intolerable side effects and deterioration

of symptoms. Access to cannabis emerged as an important obstacle in the use of this drug for medical purposes.

In conclusion, the current study found that patients with MS use cannabis for a range of symptoms. Health care providers should ask about, and be prepared to discuss, the use of this drug with their patients. Coupled with emerging evidence regarding the subjective effectiveness of cannabis on MS symptomatology, further exploration of the utility of cannabinoids in MS is warranted.

Medicinal Cannabis: History, Pharmacology, And Implications for the Acute Care Setting

Mary Barna Bridgeman, PharmD, BCPS, BCGP; and Daniel T. Abazia, PharmD, BCPS, CPE

INTRODUCTION

Medicinal cannabis, or medicinal marijuana, is a therapy that has garnered much national attention in recent years. Controversies surrounding legal, ethical, and societal implications associated with use; safe administration, packaging, and dispensing; adverse health consequences and deaths attributed to marijuana intoxication; and therapeutic indications based on limited clinical data represent some of the complexities associated with this treatment. Marijuana is currently recognized by the U.S. Drug Enforcement Agency's (DEA's) Comprehensive Drug Abuse Prevention and Control Act (Controlled Substances Act) of 1970 as a Schedule I controlled substance, defined as having a high potential for abuse, no currently accepted medicinal use in treatment in the United States, and a lack of accepted safety data for use of the treatment under medical supervision.¹

Cannabis is the most commonly cultivated, trafficked, and abused illicit drug worldwide; according to the World Health Organization (WHO), marijuana consumption has an annual prevalence rate of approximately 147 million individuals or nearly 2.5% of the global population.² In 2014, approximately 22.2 million Americans 12 years of age or older reported current cannabis use, with 8.4% of this population reporting use within the previous month.^{3,4} General cannabis use, both for recreational and medicinal purposes, has garnered increasing acceptance across the country as evidenced by legislative actions, ballot measures, and public opinion polls; an October 2016 Gallup poll on American's views on legalizing cannabis indicated that 60% of the population surveyed believed the substance should be legalized.⁵ Further, a recent Quinnipiac University poll concluded 54% of American voters surveyed would favor the legalization of cannabis without additional constraints, while 81% of respondents favored legalization of cannabis for medicinal purposes.⁶ Limited data suggest that health care providers also may consider this therapy in certain circumstances.⁷⁻⁹ In the United States, cannabis is approved for medicinal use in 28 states, the District of Columbia, Guam, and Puerto Rico as of January 2017.¹⁰

The use and acceptance of medicinal cannabis continues to evolve, as shown by the growing number of states now permitting use for specific medical indications. The Food and Drug Administration (FDA) has considered how it might support the scientific rigor of medicinal cannabis claims, and the review of public data regarding safety and abuse potential

is ongoing.^{11,12} The purpose of this article is to review the historical significance of the use of medicinal cannabis and to discuss its pharmacology, pharmacokinetics, and select evidence on medicinal uses, as well as to describe the implications of evolving medicinal cannabis regulations and their effects on the acute care hospital setting.

HISTORICAL SIGNIFICANCE

Cannabis is a plant-based, or botanical, product with origins tracing back to the ancient world. Evidence suggesting its use more than 5,000 years ago in what is now Romania has been described extensively.¹³ There is only one direct source of evidence (Δ^6 -tetrahydrocannabinol [Δ^6 -THC] in ashes) that cannabis was first used medicinally around 400 AD.¹⁴ In the U.S., cannabis was widely utilized as a patent medicine during the 19th and early 20th centuries, described in the *United States Pharmacopoeia* for the first time in 1850. Federal restriction of cannabis use and cannabis sale first occurred in 1937 with the passage of the Marihuana Tax Act.^{15,16} Subsequent to the act of 1937, cannabis was dropped from the *United States Pharmacopoeia* in 1942, with legal penalties for possession increasing in 1951 and 1956 with the enactment of the Boggs and Narcotic Control Acts, respectively, and prohibition under federal law occurring with the Controlled Substances Act of 1970.^{1,17,18} Beyond criminalization, these legislative actions contributed to creating limitations on research by restricting procurement of cannabis for academic purposes.

In 1996, California became the first state to permit legal access to and use of botanical cannabis for medicinal purposes under physician supervision with the enactment of the Compassionate Use Act. As previously stated, as of January 1, 2017, 28 states as well as Washington, D.C., Guam, and Puerto Rico will have enacted legislation governing medicinal cannabis sale and distribution; 21 states and the District of Columbia will have decriminalized marijuana and eliminated prohibition for possession of small amounts, while eight states, including Alaska, California, Colorado, Maine, Massachusetts, Nevada, Oregon, and Washington, as well as the District of Columbia, will have legalized use of marijuana for adult recreation.^{10,19}

THE MEDICINAL CANNABIS DEBATE

As a Schedule I controlled substance with no accepted medicinal use, high abuse potential, concerns for dependence, and lack of accepted safety for use under medical supervision—along with a national stigma surrounding the potential harms and implication of cannabis use as a gateway drug to other substances—transitioning from a vilified substance to one with therapeutic merits has been controversial. The *United States Pharmacopoeia* and the FDA have considered the complexities

Medicinal Cannabis: History, Pharmacology, and Implications for the Acute Care Setting

of regulating this plant-based therapy, including the numerous compounds and complex interactions between substances in this product, and how it might fit into the current regulatory framework of drugs in United States.^{11,12,17}

The emergence of interest in botanical medicinal cannabis is thought by many to be a collateral effect of the opioid abuse epidemic; public perception surrounding the use of medicinal cannabis suggests that this plant-based therapy is viewed as not much different than a botanical drug product or supplement used for health or relief of symptoms if disease persists. Like some herbal preparations or supplements, however, medicinal cannabis may similarly pose health risks associated with its use, including psychoactive, intoxicating, and impairing effects, which have not been completely elucidated through clinical trials. Proponents argue that there is evidence to support botanical medicinal cannabis in the treatment of a variety of conditions, particularly when symptoms are refractory to other therapies; that beneficial cannabinoids exist, as evidenced by single-entity agents derived from cannabis containing the compounds THC and cannabidiol (CBD); that cannabis is relatively safe, with few deaths reported from use; that therapy is self-titratable by the patient; and that therapy is relatively inexpensive compared with pharmaceutical agents.^{20–22} Opponents of medicinal cannabis use argue, in part, that well-designed randomized trials to confirm benefits and harms are lacking; that it has not been subject to the rigors of the FDA approval process; that standardization in potency or quantity of pharmacologically active constituents is absent; that adverse health effects relate not only to smoking cannabis but to unmasking mental health disorders, impairing coordination, and affecting judgment; that standardization does not exist for product packaging and controls to prevent inadvertent use by minors or pets; that there is a potential for dependence, addiction, and abuse; and that costs pose a potential burden.^{23–25}

Regardless of personal views and perceptions, to deny or disregard the implications of use of this substance on patient health and the infrastructure of the health care system is irresponsible; clinicians must be aware of these implications and informed about how this therapy may influence practice in a variety of health care settings, including acute care.

PHARMACOLOGY

Endocannabinoids (eCBs) and their receptors are found throughout the human body: nervous system, internal organs, connective tissues, glands, and immune cells. The eCB system has a homeostatic role, having been characterized as “eat, sleep, relax, forget, and protect.”²⁶ It is known that eCBs have a role in the pathology of many disorders while also serving a protective function in certain medical conditions.²⁷ It has been proposed that migraine, fibromyalgia, irritable bowel syndrome, and related conditions represent clinical eCB deficiency syndromes (CEDs). Deficiencies in eCB signaling could be also involved in the pathogenesis of depression. In human studies, eCB system deficiencies have been implicated in schizophrenia, multiple sclerosis (MS), Huntington’s disease, Parkinson’s disease, anorexia, chronic motion sickness, and failure to thrive in infants.²⁸

The eCB system represents a microcosm of psycho-neuroimmunology or “mind–body” medicine. The eCB system consists of receptors, endogenous ligands, and ligand metabolic

enzymes. A variety of physiological processes occur when cannabinoid receptors are stimulated. Cannabinoid receptor type 1 (CB₁) is the most abundant G-protein–coupled receptor. It is expressed in the central nervous system, with particularly dense expression in (ranked in order): the substantia nigra, globus pallidus, hippocampus, cerebral cortex, putamen, caudate, cerebellum, and amygdala. CB₁ is also expressed in non-neuronal cells, such as adipocytes and hepatocytes, connective and musculoskeletal tissues, and the gonads. CB₂ is principally associated with cells governing immune function, although it may also be expressed in the central nervous system.

The most well-known eCB ligands are N-arachidonylethanolamide (anandamide or AEA) and sn-2-arachidonoylglycerol (2-AG). AEA and 2-AG are released upon demand from cell membrane phospholipid precursors. This “classic” eCB system has expanded with the discovery of secondary receptors, ligands, and ligand metabolic enzymes. For example, AEA, 2-AG, N-arachidonoyl glycine (NAGly), and the phytocannabinoids Δ⁹-THC and CBD may also serve, to different extents, as ligands at GPR55, GPR18, GPR119, and several transient receptor potential ion channels (e.g., TRPV1, TRPV2, TRPA1, TRPM8) that have actions similar to capsaicin.²⁸ The effects of AEA and 2-AG can be enhanced by “entourage compounds” that inhibit their hydrolysis via substrate competition, and thereby prolong their action through synergy and augmentation. Entourage compounds include N-palmitylethanolamide (PEA), N-oleoylethanolamide (SEA), and cis-9-octadecenoamide (OEA or oleamide) and may represent a novel route for molecular regulation of endogenous cannabinoid activity.²⁹

Additional noncannabinoid targets are also linked to cannabis. G-protein–coupled receptors provide noncompetitive inhibition at mu and delta opioid receptors as well as norepinephrine, dopamine, and serotonin. Ligand-gated ion channels create allosteric antagonism at serotonin and nicotinic receptors, and enhance activation of glycine receptors. Inhibition of calcium, potassium, and sodium channels by noncompetitive antagonism occurs at nonspecific ion channels and activation of PPARα and PPARγ at the peroxisome proliferator-activated receptors is influenced by AEA.³⁰

THC is known to be the major psychoactive component of cannabis mediated by activation of the CB₁ receptors in the central nervous system; however, this very mechanism limits its use due to untoward adverse effects. It is now accepted that other phytocannabinoids with weak or no psychoactivity have promise as therapeutic agents in humans. The cannabinoid that has sparked the most interest as a nonpsychoactive component is CBD.³¹ Unlike THC, CBD elicits its pharmacological effects without exerting any significant intrinsic activity on CB₁ and CB₂ receptors. Several activities give CBD a high potential for therapeutic use, including antiepileptic, anxiolytic, anti-psychotic, anti-inflammatory, and neuroprotective effects. CBD in combination with THC has received regulatory approvals in several European countries and is under study in registered trials with the FDA. And, some states have passed legislation to allow for the use of majority CBD preparations of cannabis for certain pathological conditions, despite lack of standardization of CBD content and optimal route of administration for effect.³² Specific applications of CBD have recently emerged in pain (chronic and neuropathic), diabetes, cancer, and neuro-

Medicinal Cannabis: History, Pharmacology, and Implications for the Acute Care Setting

degenerative diseases, such as Huntington's disease. Animal studies indicate that a high dose of CBD inhibits the effects of lower doses of THC. Moreover, clinical studies suggest that oral or oromucosal CBD may prolong and/or intensify the effects of THC. Finally, preliminary clinical trials suggest that high-dose oral CBD (150–600 mg per day) may exert a therapeutic effect for epilepsy, insomnia, and social anxiety disorder. Nonetheless, such doses of CBD have also been shown to cause sedation.³³

PHARMACOKINETICS AND ADMINISTRATION

The three most common methods of administration are inhalation via smoking, inhalation via vaporization, and ingestion of edible products. The method of administration can impact the onset, intensity, and duration of psychoactive effects; effects on organ systems; and the addictive potential and negative consequences associated with use.³⁴

Cannabinoid pharmacokinetic research has been challenging; low analyte concentrations, rapid and extensive metabolism, and physicochemical characteristics hinder the separation of compounds of interest from biological matrices and from each other. The net effect is lower drug recovery due to adsorption of compounds of interest to multiple surfaces.³⁵ The primary psychoactive constituent of marijuana— Δ^9 -THC—is rapidly transferred from lungs to blood during smoking. In a randomized controlled trial conducted by Huestis and colleagues, THC was detected in plasma immediately after the first inhalation of marijuana smoke, attesting to the efficient absorption of THC from the lungs. THC levels rose rapidly and peaked prior to the end of smoking.³⁶ Although smoking is the most common cannabis administration route, the use of vaporization is increasing rapidly. Vaporization provides effects similar to smoking while reducing exposure to the byproducts of combustion and possible carcinogens and decreasing adverse respiratory syndromes. THC is highly lipophilic, distributing rapidly to highly perfused tissues and later to fat.³⁷ A trial of 11 healthy subjects administered Δ^9 -THC intravenously, by smoking, and by mouth demonstrated that plasma profiles of THC after smoking and intravenous injection were similar, whereas plasma levels after oral doses were low and irregular, indicating slow and erratic absorption. The time courses of plasma concentrations and clinical “high” were of the same order for intravenous injection and smoking, with prompt onset and steady decline over a four-hour period. After oral THC, the onset of clinical effects was slower and lasted longer, but effects occurred at much lower plasma concentrations than they did after the other two methods of administration.³⁸

Cannabinoids are usually inhaled or taken orally; the rectal route, sublingual administration, transdermal delivery, eye drops, and aerosols have been used in only a few studies and are of little relevance in practice today. The pharmacokinetics of THC vary as a function of its route of administration. Inhalation of THC causes a maximum plasma concentration within minutes and psychotropic effects within seconds to a few minutes. These effects reach their maximum after 15 to 30 minutes and taper off within two to three hours. Following oral ingestion, psychotropic effects manifest within 30 to 90 minutes, reach their maximum effect after two to three hours, and last for about four to 12 hours, depending on the dose.³⁹

Within the shifting legal landscape of medical cannabis, different methods of cannabis administration have important public health implications. A survey using data from Qualtrics and Facebook showed that individuals in states with medical cannabis laws had a significantly higher likelihood of ever having used the substance with a history of vaporizing marijuana (odds ratio [OR], 2.04; 99% confidence interval [CI], 1.62–2.58) and a history of oral administration of edible marijuana (OR, 1.78; 99% CI, 1.39–2.26) than those in states without such laws. Longer duration of medical cannabis status and higher dispensary density were also significantly associated with use of vaporized and edible forms of marijuana. Medical cannabis laws are related to state-level patterns of utilization of alternative methods of cannabis administration.³⁴

DRUG INTERACTIONS

Metabolic and pharmacodynamic interactions may exist between medical cannabis and other pharmaceuticals. Quantification of the *in vitro* metabolism of exogenous cannabinoids, including THC, CBD, and cannabinol (CBN), indicates hepatic cytochrome 450 (CYP450) isoenzymes 2C9 and 3A4 play a significant role in the primary metabolism of THC and CBN, whereas 2C19 and 3A4 and may be responsible for metabolism of CBD.⁴⁰ Limited clinical trials quantifying the effect of the exogenous cannabinoids on the metabolism of other medications exist; however, drug interaction data may be gleaned from the prescribing information from cannabinoid-derived pharmaceutical products such as Sativex (GW Pharmaceuticals, United Kingdom) and dronabinol (Marinol, AbbVie [United States]).^{41,42} Concomitant administration of ketoconazole with oromucosal cannabis extract containing THC and CBD resulted in an increase in the maximum serum concentration and area under the curve for both THC and CBD by 1.2-fold to 1.8-fold and twofold, respectively; coadministration of rifampin is associated with a reduction in THC and CBD levels.^{40,41} In clinical trials, dronabinol use was not associated with clinically significant drug interactions, although additive pharmacodynamic effects are possible when it is coadministered with other agents having similar physiological effects (e.g., sedatives, alcohol, and antihistamines may increase sedation; tricyclic antidepressants, stimulants, and sympathomimetics may increase tachycardia).⁴¹ Additionally, smoking cannabis may increase theophylline metabolism, as is also seen after smoking tobacco.^{40,42}

ADVERSE EFFECTS

Much of what is known about the adverse effects of medicinal cannabis comes from studies of recreational users of marijuana.⁴³ Short-term use of cannabis has led to impaired short-term memory; impaired motor coordination; altered judgment; and paranoia or psychosis at high doses.⁴⁴ Long-term or heavy use of cannabis, especially in individuals who begin using as adolescents, has led to addiction; altered brain development; cognitive impairment; poor educational outcomes (e.g., dropping out of school); and diminished life satisfaction.⁴⁵ Long-term or heavy use of cannabis is also associated with chronic bronchitis and an increased risk of chronic psychosis-related health disorders, including schizophrenia and variants of depression, in persons with a predisposition to

Medicinal Cannabis: History, Pharmacology, and Implications for the Acute Care Setting

such disorders.^{46–48} Vascular conditions, including myocardial infarction, stroke, and transient ischemic attack, have also been associated with cannabis use.^{49–51} The use of cannabis for management of symptoms in neurodegenerative diseases, such as Parkinson's, Alzheimer's, and MS, has provided data related to impaired cognition in these individuals.^{52,53}

A systematic review of published trials on the use of medical cannabinoids over a 40-year period was conducted to quantify adverse effects of this therapy.⁵⁴ A total of 31 studies evaluating the use of medicinal cannabis, including 23 randomized controlled trials and eight observational studies, was included. In the randomized trials, the median duration of cannabinoid exposure was two weeks, with a range between eight hours and 12 months. Of patients assigned to active treatment in these trials, a total of 4,779 adverse effects were reported; 96.6% (4,615) of these were not deemed by authors to be serious. The most common serious adverse effects included relapsing MS (9.1%; 15 events), vomiting (9.8%; 16 events), and urinary tract infections (9.1%; 15 events). No significant differences in the rates of serious adverse events between individuals receiving medical cannabis and controls were identified (relative risk, 1.04; 95% CI, 0.78–1.39). The most commonly reported non-serious adverse event was dizziness, with an occurrence rate of 15.5% (714 events) among people exposed to cannabinoids.⁵⁴

Other negative adverse effects reported with acute cannabis use include hyperemesis syndrome, impaired coordination and performance, anxiety, suicidal ideations or tendencies, and psychotic symptoms, whereas chronic effects may include mood disturbances, exacerbation of psychotic disorders, cannabis use disorders, withdrawal syndrome, and neurocognitive impairments, as well as cardiovascular and respiratory conditions.⁵² Long-term studies evaluating adverse effects of chronic medicinal cannabis use are needed to conclusively evaluate the risks when used for an extended period of time.

MEDICINAL USES

Cannabis and cannabinoid agents are widely used to alleviate symptoms or treat disease, but their efficacy for specific indications is not well established. For chronic pain, the analgesic effect remains unclear. A systematic review of randomized controlled trials was conducted examining cannabinoids in the treatment of chronic noncancer pain, including smoked cannabis, oromucosal extracts of cannabis-based medicine, nabilone, dronabinol, and a novel THC analogue.⁵⁵ Pain conditions included neuropathic pain, fibromyalgia, rheumatoid arthritis, and mixed chronic pain. Fifteen of the 18 included trials demonstrated a significant analgesic effect of cannabinoids compared with placebo. Cannabinoid use was generally well tolerated; adverse effects most commonly reported were mild to moderate in severity. Overall, evidence suggests that cannabinoids are safe and moderately effective in neuropathic pain with preliminary evidence of efficacy in fibromyalgia and rheumatoid arthritis.⁵⁵

While there is not enough evidence to suggest routine use of medicinal cannabis for alleviating chemotherapy-related nausea and vomiting by national or international cancer societies, therapeutic agents based on THC (e.g., dronabinol) have been approved for use as an antiemetic in the United States for a number of years. Only recently has the efficacy and safety of

cannabis-based medicines in managing nausea and vomiting due to chemotherapy been evaluated. In a review of 23 randomized, controlled trials, patients who received cannabis-based products experienced less nausea and vomiting than subjects who received placebo.⁵⁶ The proportion of people experiencing nausea and vomiting who received cannabis-based products was similar to those receiving conventional antiemetics. Subjects using cannabis-based products experienced side effects such as “feeling high,” dizziness, sedation, and dysphoria and dropped out of the studies at a higher rate due to adverse effects compared with participants receiving either placebo or conventional antiemetics. In crossover trials in which patients received cannabis-based products and conventional antiemetics, patients preferred the cannabis-based medicines. Cannabis-based medications may be useful for treating chemotherapy-induced nausea and vomiting that responds poorly to conventional antiemetics. However, the trials produced low to moderate quality evidence and reflected chemotherapy agents and antiemetics that were available in the 1980s and 1990s.

With regard to the management of neurological disorders, including epilepsy and MS, a Cochrane review of four clinical trials that included 48 epileptic patients using CBD as an adjunct treatment to other antiepileptic medications concluded that there were no serious adverse effects associated with CBD use but that no reliable conclusions on the efficacy and safety of the therapy can be drawn from this limited evidence.⁵⁷ The American Academy of Neurology (AAN) has issued a Summary of Systematic Reviews for Clinicians that indicates oral cannabis extract is effective for reducing patient-reported spasticity scores and central pain or painful spasms when used for MS.⁵⁸ THC is probably effective for reducing patient-reported spasticity scores but is likely ineffective for reducing objective measures of spasticity at 15 weeks, the AAN found; there is limited evidence to support the use of cannabis extracts for treatment of Huntington's disease, levodopa-induced dyskinesias in patients with Parkinson's disease, or reducing tic severity in Tourette's.⁵⁸

In older patients, medical cannabinoids have shown no efficacy on dyskinesia, breathlessness, and chemotherapy-induced nausea and vomiting. Some evidence has shown that THC might be useful in treatment of anorexia and behavioral symptoms in patients with dementia. The most common adverse events reported during cannabinoid treatment in older adults were sedation-like symptoms.⁵⁹

Despite limited clinical evidence, a number of medical conditions and associated symptoms have been approved by state legislatures as qualifying conditions for medicinal cannabis use. Table 1 contains a summary of medicinal cannabis indications by state, including select disease states and qualifying debilitating medical conditions or symptoms.^{10,60,61} The most common conditions accepted by states that allow medicinal cannabis relate to relief of the symptoms of cancer, glaucoma, human immunodeficiency virus/acquired immunodeficiency syndrome, and MS. A total of 28 states, the District of Columbia, Guam, and Puerto Rico now allow comprehensive public medical marijuana and cannabis programs.¹⁰ The National Conference of State Legislatures uses the following criteria to determine if a program is comprehensive:

1. Protection from criminal penalties for using marijuana for a medical purpose;

Table adapted with permission from the Marijuana Policy Project;⁶⁰ table is not all-encompassing and other medical conditions for use may exist. The reader should refer to individual state laws regarding medicinal cannabis for specific details of approved conditions for use. In addition, states may permit the addition of approved indications; list is subject to change.

Medicinal Cannabis: History, Pharmacology, and Implications for the Acute Care Setting

2. Access to marijuana through home cultivation, dispensaries, or some other system that is likely to be implemented;
3. Allows a variety of strains, including more than those labeled as “low THC;” and
4. Allows either smoking or vaporization of some kind of marijuana products, plant material, or extract.

Some of the most common policy questions regarding medical cannabis now include how to regulate its recommendation and indications for use; dispensing, including quality and standardization of cultivars or strains, labeling, packaging, and role of the pharmacist or health care professional in education or administration; and registration of approved patients and providers.

REGULATORY IMPLICATIONS OF MEDICINAL CANNABIS

The regulation of cannabis therapy is complex and unique; possession, cultivation, and distribution of this substance, regardless of purpose, remain illegal at the federal level, while states that permit medicinal cannabis use have established individual laws and restrictions on the sale of cannabis for medical purposes. In a 2013 U.S. Department of Justice memorandum to all U.S. attorneys, Deputy Attorney General James M. Cole noted that despite the enactment of state laws authorizing marijuana production and sale having a regulatory structure that is counter to the usual joint efforts of federal authorities working together with local jurisdictions, prosecution of individuals cultivating and distributing marijuana to seriously ill individuals for medicinal purpose has not been identified as a federal priority.⁶²

There are, however, other regulatory implications to consider based on the federal restriction of cannabis. Physicians cannot legally “prescribe” medicinal cannabis therapy, given its Schedule I classification, but rather in accordance with state laws may certify or recommend patients for treatment. Medical cannabis expenses are not reimbursable through government medical assistance programs or private health insurers. As previously described, the Schedule I listing of cannabis according to federal law and DEA regulations has led to difficulties in access for research purposes; nonpractitioner researchers can register with the DEA more easily to study substances in Schedules II–V compared with Schedule I substances.⁶³ Beyond issues related to procurement of the substance for research purposes, other limitations in cannabis research also exist. For example, the Center for Medicinal Cannabis Research at the University of California–San Diego had access to funding, marijuana at different THC levels, and approval for a number of clinical research trials, and yet failed to recruit an adequate number of patients to conduct five major trials, which were subsequently canceled.⁶⁴ Unforeseen factors, including the prohibition of driving during the clinical trials, deterred patients from trial enrollment. The limited availability of clinical research to support or refute therapeutic claims and indications for use of cannabis for medicinal purposes has frequently left both state legislative authorities and clinicians to rely on anecdotal evidence, which has not been subjected to the same rigors of peer review and scrutiny as well-conducted, randomized trials, to validate the safety and efficacy of medicinal cannabis therapy. Furthermore, although individual single-entity pharmaceutical medications, such as dronabinol, have been isolated, evaluated, and approved for use

by the FDA, a plant cannot be patented and mass produced by a corporate entity.⁶⁵ Despite this limitation, some corporations, including GW Pharmaceuticals, are mass producing cannabis plants and extracting complex mixtures or single cannabinoids for clinical trials.⁶⁵ The complex pharmacology related to the numerous substances and interactions among chemicals in the cannabis plant coupled with environmental variables in cultivation further complicate regulation, standardization, purity, and potency as a botanical drug product.

RELEVANCE TO HOSPITAL PRACTITIONERS

Although the public has largely accepted medicinal cannabis therapy as having a benefit when used under a provider’s supervision, the implications of the use of this substance when patients transition into the acute care setting are additionally complex and multifaceted. The Schedule I designation of cannabis causes hospitals and other care settings that receive federal funding, either through Medicare reimbursement or other federal grants or programs, to pause to consider the potential for loss of these funds should the federal government intercede and take action if patients are permitted to use this therapy on campus. Similarly, licensed practitioners registered to certify patients for state medicinal cannabis programs may have comparable concerns regarding jeopardizing their federal DEA registrations and ability to prescribe other controlled substances as well as jeopardizing Medicare reimbursements. In 2009, U.S. Attorney General Eric Holder recommended that enforcement of federal marijuana laws not be a priority in states that have enacted medicinal cannabis programs and are enforcing the rules and regulations of such a program; despite this, concerns persist.

The argument for or against the use of medicinal cannabis in the acute care setting encompasses both legal and ethical considerations, with the argument against use perhaps seeming obvious on its surface. States adopting medical cannabis laws may advise patients to utilize the therapy only in their own residence and not to transport the substances unless absolutely necessary.⁶⁶ Further, many acute care institutions have policies prohibiting smoking on facility grounds, thus restricting the smoking of cannabis, regardless of purpose or indication. Of note, several Canadian hospitals, including Montreal’s Jewish General Hospital and Quebec’s Centre Hospitalier Universitaire de Sherbrooke, have permitted inpatient cannabis use via vaporization; the pharmacy departments of the respective institutions control and dispense cannabis much like opioids for pain. Canada has adopted national regulations to control and standardize dried cannabis for medical use.^{67,68} There are complicated logistics for self-administration of medicinal cannabis by the patient or caregiver; in particular, many hospitals have policies on self-administration of medicines that permit patients to use their own medications only after identification and labeling by pharmacy personnel. The argument can be made that an herb- or plant-based entity cannot be identified by pharmacy personnel as is commonly done for traditional medicines, although medicinal cannabis dispensed through state programs must be labeled in accordance with state laws. Dispensing and storage concerns, including an evaluation of where and how this product should be stored (e.g., within the pharmacy department and treated as a controlled substance, by security personnel, or with the patient); who should admin-

Medicinal Cannabis: History, Pharmacology, and Implications for the Acute Care Setting

ister it, and implications or violations of federal law by those administering treatment; what pharmaceutical preparations should be permitted (e.g., smoked, vaporized, edible); and how it should be charted in the medical record represent other logistical concerns. Inpatient use of medicinal cannabis also carries implications for nursing and medical staff members. The therapy cannot be prescribed, and states may require physicians authorizing patient use to be registered with local programs. In a transition into the acute care setting from the community setting, a different clinician who is not registered could be responsible for the patient's care; that clinician would be restricted in ordering continuation of therapy.

Despite the complexities in the logistics of continuing medicinal cannabis in the acute care setting, proponents of palliative care and continuity of care argue that prohibiting medicinal cannabis use disrupts treatment of chronic and debilitating medical conditions. Patients have been denied this therapy during acute care hospitalizations for reasons stated above.⁶⁹ Permission to use medicinal cannabis in the acute care setting may be dependent on state legislation and restrictions imposed by such laws. Legislation in Minnesota, as one example, has been amended to permit hospitals as facilities that can dispense and control cannabis use; similar legislative actions protecting nurses from criminal, civil, or disciplinary action when administering medical cannabis to qualified patients have been enacted in Connecticut and Maine.^{70–73} Proposed legislation to remove restrictions on the certification of patients to receive medicinal cannabis by doctors at the Department of Veterans Affairs was struck down in June; prohibitions continue on the use of this therapy even in facilities located in states permitting medicinal cannabis use.⁷⁴

CONCLUSION

Despite lingering controversy, use of botanical cannabis for medicinal purposes represents the revival of a plant with historical significance reemerging in present day health care. Legislation governing use of medicinal cannabis continues to evolve rapidly, necessitating that pharmacists and other clinicians keep abreast of new or changing state regulations and institutional implications. Ultimately, as the medicinal cannabis landscape continues to evolve, hospitals, acute care facilities, clinics, hospices, and long-term care centers need to consider the implications, address logistical concerns, and explore the feasibility of permitting patient access to this treatment. Whether national policy—particularly with a new presidential administration—will offer some clarity or further complicate regulation of this treatment remains to be seen.

Parkinson's disease (PD), a neurodegenerative disorder, is the second most common neurological illness in United States. Neurologically, it is characterized by the selective degeneration of a unique population of cells, the nigrostriatal dopamine neurons. The current treatment is symptomatic and mainly involves replacement of dopamine deficiency. This therapy improves only motor symptoms of Parkinson's disease and is associated with a number of adverse effects including dyskinesia. Therefore, there is unmet need for more comprehensive approach in the management of PD. Cannabis and related compounds have created significant research interest as a promising therapy in neurodegenerative and movement disorders. In this review we examine the potential benefits of medical marijuana and related compounds in the treatment of both motor and nonmotor symptoms as well as in slowing the progression of the disease. The potential for cannabis to enhance the quality of life of Parkinson's patients is explored.

1. Introduction

Marijuana, the crude product (dried flowers, stems, seeds, and leaves) derived from the cannabis sativa plant, consists of more than 85 phytocannabinoids [1, 2]. The term phytocannabinoids is used to differentiate these plant-derived cannabinoids from the synthetic cannabinoids and the structurally different endogenous cannabinoids (endocannabinoids). Among the phytocannabinoids, Cannabidiol (CBD) and Δ^9 -Tetrahydrocannabinol (Δ^9 -THC, THC) are the major constituents of marijuana [3]. Δ^9 -THC is a psychoactive agent with analgesic and muscle relaxant property [3, 4]. While CBD is a nonpsychoactive compound and has been shown to have hypnotic, anxiolytic, antipsychotic, antioxidant, and neuroprotective effects [5], THC is a partial agonist at the cannabinoid receptor 1 (CB1) and receptor 2 (CB2). Unlike Δ^9 -THC, CBD has antagonistic/inverse agonistic property at CB1 receptor and appears to modulate Δ^9 -THC-associated side effects including anxiety, tachycardia, and hunger [3]. CBD also appears to potentiate the effect of endocannabinoids by inhibiting their inactivation, thereby alleviating psychotic symptom [6].

Despite the placement of marijuana in the schedule 1 category under the US Federal Controlled Substance Act [7] and the US Federal Government's continued opposition on its legalization, 24 states and Washington DC have enacted laws allowing marijuana to treat certain medical conditions [8]. The range and types of disease conditions for which medical marijuana have been approved vary from state to state. The most common disease conditions approved by the states include cancer, HIV/AIDS, glaucoma, chronic and/or severe pain, seizure/epilepsy, cachexia, and multiple sclerosis. Moreover, two cannabinoids (dronabinol and nabilone) have been approved by the FDA for clinical use. The synthetically produced Δ^9 -THC, dronabinol (Marinol®), is a schedule III drug, which is indicated in the treatment of chemotherapy-induced nausea and emesis as well as anorexia associated with weight loss in AIDS patients. A synthetic cannabinoid, nabilone (Cesamet®), is a schedule II drug that is indicated for the treatment of nausea and vomiting associated with cancer chemotherapy. Another cannabinoid, Cannabidiol (Epidiolex®), is in a clinical trial for the treatment of drug-resistant epilepsy in children [9]. A phytocannabinoid preparation, nabiximols (Sativex®), has been approved for the

treatment of spasticity due to multiple sclerosis in a number of countries outside the United States. Nabiximols is an extract of *Cannabis sativa* L that consists of mainly THC and CBD [10, 11].

Although recent studies have provided strong evidence for the therapeutic benefit of medical marijuana [12–16], increasing access to cannabis and/or cannabinoids can result in side effects such as addiction, respiratory illness, and decline in cognitive processing. Cannabis use has been indicated as a potential cause, aggravator, or masker of major psychiatric symptoms, including psychotic, depressive, and anxiety disorders, particularly in young people [17–19]. Other negative effects include working memory deficits, reduced attention and processing speed, anhedonia, abnormal social behavior, and susceptibility to mood and anxiety disorders [20, 21]. While adult users seem comparatively resistant to cannabis-induced behavioral and brain morphologic changes, the individuals who start using cannabis during their early teens can have more severe and more long-lasting effects [22].

The target of medical marijuana and its constituents is the endocannabinoid system, which is involved in the modulation of a number of physiological functions. The endocannabinoid system includes the endocannabinoids, the cannabinoid receptors, and the enzymes involved in the biosynthesis and inactivation of the endocannabinoids [23]. The cannabinoid receptors are mainly expressed in the central nervous system and the immune system, but they have also been identified in a number of other parts of the body including the cardiovascular system, the peripheral nervous system, the reproductive system, and the gastrointestinal tract. Due to its wide distribution and effects on a range of biological process, the cannabinoid system has become an attractive target for the development of drugs that can potentially be used for the treatment of a number of pathological conditions including mood disorders and movement disorders such as PD [24]. Components of the endocannabinoid system are abundant in the striatum and other parts of the basal ganglia and play a crucial role in modulating dopamine activity and motor functions [25–27].

Parkinson's disease (PD) is the second most common neurodegenerative disorder following Alzheimer's disease and the 14th leading cause of death in all age groups in the United States [28]. The prevalence of PD increases with age and is shown to be higher in males than females in some age groups [29]. The number of people with PD is projected at approximately 9 million by 2030 in the 15 most populous countries in the world [30, 31]. Neurologically PD is characterized by the destruction of dopaminergic cells in the pars compacta region of the substantia nigra in the midbrain, resulting in dopamine deficiency in the nerve terminals of the striatum in the forebrain [32]. These changes cause impairments not just to the motor system but also to the cognitive and neuropsychological systems [33]. The nigrostriatal pathway is one of the dopamine pathways in the brain that regulates movement. The exact cause for the loss of neuronal cells is unknown, and the trigger of dopaminergic degeneration seems to be multifactorial including environmental factors and genetic susceptibilities

[34–36]. Clinically, PD is characterized by resting tremor, muscle rigidity, bradykinesia, and postural instability [32, 34, 37, 38] and it is also associated with a number of nonmotor symptoms including depression, anxiety, constipation, orthostatic hypotension, fatigue, and sleep disorders, as well as, in advanced disease, dementia [39–44]. Although dopamine deficiency accounts for the major motor symptoms of the disease, loss of noradrenergic and serotonergic nerve terminals in the limbic system may account for several of the nonmotor features seen in Parkinson's disease [45, 46].

Current therapy involves treatment of motor symptoms of PD through replacement of dopamine deficiency [47]. This includes (1) enhancement of the synthesis of brain dopamine by administration of levodopa, a dopamine precursor, (2) direct stimulation of dopamine receptors, (3) decreasing dopamine catabolism, and (4) stimulation of dopamine release and inhibition of dopamine reuptake from presynaptic sites. Another therapy involves restoring the normal balance of cholinergic and dopaminergic actions on the basal ganglia using anticholinergic drugs [47–49].

However these drugs treat only motor symptoms of Parkinson's disease and are associated with a number of adverse effects. Long-term use of levodopa, the mainstay therapy for PD, is associated with motor fluctuations [50] and levodopa-induced dyskinesia [51–53]. The monoamine oxidase B (MAO-B) inhibitors (selegiline and rasagiline) as well as inhibitors of catechol-o-methyltransferase, COMT (tolcapone and entacapone), are used mostly to reduce the motor fluctuations associated with levodopa therapy due to their levodopa-sparing effect [54–59]. Several dopamine agonists including pramipexole, ropinirole, rotigotine, and apomorphine are used as monotherapy in early stage of Parkinson disease or as adjunctive therapy with levodopa in patients with advanced PD in order to reduce motor fluctuations [56, 60–64]. In addition to their limited efficacy on motor symptoms and their adverse effects, drugs that are currently used for the treatment of PD do not have an effect on disease progression. Therefore, there is an urgent need for the development of safer drugs that treat both the motor and nonmotor symptoms of PD as well as drugs that slow the progression of the disease.

Medical marijuana has been demonstrated to improve motor symptoms including tremor, rigidity, and bradykinesia as well as nonmotor symptoms such as pain and sleep disorders of PD in observational studies [65]. Survey of PD patients in Colorado, USA, also indicated the beneficial effects of marijuana in alleviating nonmotor symptoms of PD [66]. Cannabidiol (CBD), one of the major constituents of marijuana, has been shown to be effective in the treatment of psychosis and sleep disorders in PD patients [67–69]. Another phytocannabinoid, Δ^9 -tetrahydrocannabinol (Δ^9 -THCV, THCV), was studied in animal disease model of PD and found to have neuroprotective and symptom-relieving effects [70]. Therefore, marijuana may provide an alternative or add-on therapy for Parkinson's disease. In addition, Parkinson's disease has been listed as one of the disease conditions for which medical marijuana is allowed in Connecticut, Illinois, Massachusetts, New Hampshire, New

Mexico, and New York. However, it may also be covered under chronic illnesses in several other states.

In this review we seek to investigate any scientific evidence that indicates the potential use of marijuana and/or its components for the treatment of Parkinson's disease. The review aims to (i) examine briefly current treatment and the unmet need of PD therapy, (ii) assess the role of the cannabinoid system in the modulation of movement and neuroprotection, (iii) look at the mechanism of action of marijuana constituents in the modulation of movement and PD-associated disorders, (iv) assess other beneficial effects of marijuana that contribute to the amelioration of PD, and (v) gather scientific evidence on the clinical benefit of marijuana and/or its constituents in PD patients.

2. Marijuana and Its Influence on the Endocannabinoid System

Cannabis has been used to treat disease since ancient times. Marijuana is derived from the *Cannabis sativa L.* plant. Marijuana contains the active chemicals known as cannabinoids. At least 85 cannabinoids have been identified as unique compounds in *Cannabis* [1]. The therapeutic potential of many of these ligands still remains largely unexplored prompting a need for further research. The chemicals responsible for the medicinal effects of marijuana are D9-Tetrahydrocannabinol (THC) and Cannabidiol (CBD) [71, 72]. THC is the major psychoactive ingredient, acting primarily upon the central nervous system where it affects brain function. CBD is the major nonpsychoactive ingredient in cannabis and produces neuroprotective and anti-inflammatory effects [73]. Both compounds, TCH and CBD, have anticonvulsant properties [74]. Cannabinoids have also potential to alleviate motor disorders by reducing motor impairments and neuron degeneration [75]. In addition, cannabinoids have been shown to be effective in preclinical studies involving excitotoxicity, oxidative stress, neuroinflammation, and motor complications associated with PD [76].

Some cannabinoids (endocannabinoids or ECBs) are found in the body. Initially, ECBs were discovered in the brain and subsequently in the periphery in humans and animals. Endocannabinoids are produced by cultured neurons [77], microglia, and astrocytes [78]. ECBs interact with the endocannabinoid system and aid in regulation of memory, pleasure, concentration, thinking, movement and coordination, sensory and time perception, appetite, and pain [24, 79, 80]. The ECBs activate two guanine nucleotide-binding protein-(G-protein-) coupled cell membrane receptors, consequently named the cannabinoid type 1 (CB1) and type 2 (CB2) receptors [81]. CB1 receptors are located primarily in the central and peripheral neurons and CB2 receptors are predominantly found in immune cells [82]. CB1 receptors are important mediators in signaling pathways and have been identified on both glutamatergic and gamma-aminobutyric (GABA) neurons [83]. It is believed that one important role of the neuronal CB1 component is to modulate neurotransmitter release in a manner that maintains homeostasis by preventing the development of excessive neuronal activity in the central

nervous system [82]. Animal models illustrate that activation of the CB1 receptor by their endogenous ligands can result in prominent neuroprotective effects and may prevent epileptic seizures [84]. Other studies suggest that activation of CB1 receptors offers neuroprotection against dopaminergic lesion and the development of L-DOPA-induced dyskinesias [85]. CB2 receptors are closely related to CB1 and are mainly expressed on T cells of the immune system, on macrophages and B cells, and in hematopoietic cells [86]. They are also expressed on peripheral nerve terminals where these receptors play a role in antinociception and the relief of pain [87]. In the brain, CB2 receptors are mainly expressed by microglial cells, where their role remains unclear [88].

The major identified ECBs are arachidonoyl ethanolamide (anandamide, AEA), 2-arachidonoyl glycerol (2-AG), O-arachidonoyl ethanolamine (virodhamine), and 2-arachidonoyl glyceryl ether (noladin ether) [89]. Both AEA and 2-AG are specific ligands of CB1 and CB2 receptors. Besides having activity on CB1 and CB2 receptors, AEA also has full agonistic activity at TRPV1 receptor [90]. AEA is localized in the brain and periphery [91]. In the brain AEA shows high distribution in the hippocampus, thalamus, striatum, and brainstem and to a lesser extent in the cerebral cortex and cerebellum [92]. Lower concentrations of AEA are found in human serum, plasma, and cerebrospinal fluid [93]. Similarly, 2-AG is observed in both the brain and periphery, although its concentration is almost 150 times higher in brain compared to that of AEA [92, 94, 95]. 2-AG has greater potency, stability, and agonistic activity at CB1 and CB2 receptors compared to that of AEA [96, 97]. Two prominent areas involved in the control of movement, such as the globus pallidus and the substantia nigra, contain not only the highest densities of CB1 receptors [88], but also the highest levels of ECBs, especially AEA [98, 99]. Tissue levels of AEA are regulated by fatty acid amide hydrolase (FAAH) [100]. It has also been shown that the basal ganglia contain the precursor of AEA [98, 99], supporting the theory of in situ synthesis for this compound. Studies have demonstrated that AEA synthesis is regulated by dopaminergic D2 receptors in the striatum, suggesting that the endocannabinoid system acts as an inhibitory feedback mechanism countering the dopamine-induced facilitation of motor activity [101].

Marijuana compound THC is CB₁ and CB₂ receptor partial agonist [82]. Due to the structural similarity of natural cannabinoid THC to the endogenous cannabinoid AEA, many therapeutic advantages of THC have been identified, such as lowering ocular pressure, inhibiting smooth muscle contractions, and increasing appetite [102]. When smoked, THC is rapidly absorbed from the lungs into the bloodstream and has an effect on the cannabinoid receptors. The central nervous system and specific areas of the brain contain the highest concentration of cannabinoid receptors. Therefore, cannabis or THC administration can create an overexcitation of the system that results in altered perceptions, pleasure, and mood [103].

Unlike THC, CBD has little affinity for CB1 and CB2 receptors but acts as an indirect antagonist of cannabinoid agonists. While this should cause CBD to reduce the effects of THC, it may potentiate THC's effects by increasing CB1

receptor density or through another CB1-related mechanism [73]. CBD is also an inverse agonist of CB2 receptors. CBD can counteract some of the functional consequences of CB1 activation in the brain, possibly by indirect enhancement of adenosine A1 receptors activity through equilibrative nucleoside transporter (ENT) inhibition [73]. CBD helps to augment some of THC's beneficial effects, as it reduces the psychoactivity of THC, enhances its tolerability, and widens THC's therapeutic window [104].

Other cannabinoids can also contribute to the cannabis medicinal effects. Studies in experimental models and humans have suggested anti-inflammatory, neuroprotective, anxiolytic, and antipsychotic properties of chemicals extracted from marijuana [6, 15, 82, 105, 106].

3. Cannabinoids and Parkinson's Disease

3.1. Changes in the Cannabinoid System in Parkinson's Disease. Recent data from several studies indicate the important role of the endocannabinoid system in Parkinson's disease. The components of the endocannabinoid system are highly expressed in the neural circuit of basal ganglia, which is part of a complex neuronal system. This neuronal system coordinates activities from different cortical regions that directly or indirectly participate in the control of movement [107, 108]. In the basal ganglia, the endocannabinoid system bidirectionally interacts with dopaminergic, glutamatergic, and GABAergic signaling systems [109]. Endocannabinoids play a dominant role in controlling transmission at synapses between cortical and striatal neurons, in mediating the induction of a particular form of synaptic plasticity, and in modulating basal ganglia activity and motor functions [110]. The progressive loss of dopaminergic neurons that occurs in PD leads to lower striatal levels of dopamine. These low levels of dopamine result in the alteration of the equilibrium between the direct and the indirect basal ganglia pathways and ECB signaling [111].

The cannabinoid signaling system mentioned above experiences a biphasic pattern of changes during the progression of PD [112]. Early and presymptomatic PD stages, characterized by neuronal malfunction with little evidence of neuronal death, are associated with desensitization/down-regulation of CB1 receptors and aggravation of various cytotoxic insults such as excitotoxicity, oxidative stress, and glial activation [113]. However, intermediate and advanced stages of PD, characterized by a deep nigral degeneration and manifestation of major Parkinsonian symptoms, are associated with upregulatory responses of CB1 receptors and the endocannabinoid ligands [113]. This could explain the potential of CB1 receptor ligands in alleviating common PD symptoms.

In the brain, CB1 receptors are expressed by GABAergic neurons innervating the external and internal segments of the globus pallidus and the substantia nigra [114–116]. CB1 receptors are also present in the corticostriatal glutamatergic terminals and in the excitatory projections from the subthalamic nucleus to the internal segment of the globus pallidus and the substantia nigra [114–116]. Within the striatum, CB1 receptors

are expressed in parvalbumin immune-reactive interneurons, cholinergic interneurons, and nitric oxide synthase-positive neurons [117, 118]. Animal models of Parkinson's disease show an increase in the density of CB1 receptors, levels of endogenous ligands, and CB1 receptor binding in the basal ganglia [119–122]. Endogenous cannabinoids activate CB1 receptors on presynaptic axons and reduce neurotransmitter and glutamate release, working as retrograde synaptic messengers released from postsynaptic neurons [123]. Similarly, activation of CB1 receptors inhibits both glutamate release from substantia nigra afferents and GABA release from striatal afferents. At the same time, activation of presynaptic CB1 receptors in the external segments of the globus pallidus can increase local GABA levels by reducing GABA reuptake from striatal afferents to the nucleus and decrease GABA release from striatal afferents of the substantia nigra [114, 116, 118]. Based on these evidences, it is thought that the function of the basal ganglia neuronal system is controlled by ECB. The presence of endocannabinoid systems in different neural structures and their interaction with dopaminergic, glutamatergic, and GABAergic neurotransmitter signaling systems make the components of endocannabinoid system ideal targets for a novel nondopaminergic treatment of PD.

Endocannabinoid signaling is also bidirectionally linked to dopaminergic signaling within the basal ganglia [118]. The CB1, D1, and D2 dopamine receptors are localized in the striatum [114, 115]. In animal models, CB1 and D2 dopamine receptors share a common pool of G proteins, suggesting the link of their signal transduction mechanisms [124, 125]. In addition, D2 receptor stimulation resulted in release of ECBs in the striatum [101]. However, stimulation of CB1 receptors completely inhibited D1-dopamine receptor mediated activation of adenylyl cyclase and decreased GABA release from striatal afferents of dopaminergic neurons of the substantia nigra resulting in an increased firing of these cells [114–116].

Another receptor involved in control of movement is transient receptor potential vanilloid type 1 (TRPV1), which is expressed in sensory neurons and basal ganglia circuitry of dopaminergic neurons [126, 127]. TRPV1 receptors are molecular integrators of nociceptive stimuli activated by endovanilloids [128]. TRPV1 also interacts with ECB. In particular, anandamide is one of the major endogenous activators of TRPV1 [129–131]. Studies have revealed that motor behavior can be suppressed by the activation of vanilloid receptors [98, 99], suggesting that TRPV1 receptors might play a role in the control of motor function.

3.2. Preclinical Data on the Endocannabinoid System as a Target for Parkinson's Disease Therapy. The association of cannabinoids with regulation of motor functions is well established [132–135]. The effect of the cannabinoids on motor activity depends on the impact of the endocannabinoid system on the dopaminergic, glutamatergic, and GABAergic signaling systems throughout the basal ganglia [112, 136]. The high density of cannabinoid, dopamine, and vanilloid-like receptors coupled with ECBs within the basal ganglia and cerebellum suggests a potential therapeutic role for the

cannabinoids in the control of voluntary movement and in movement disorders such as Parkinson's disease [98, 99, 121, 137]. Additional indications of an important role of the endocannabinoid system in the control of movement involve an inhibitory action of cannabinoids through fine tuning of various classical neurotransmitters activity [138], prominent changes in transmission of ECBs in the basal ganglia [139], and alteration of the CB1 binding as well as CB1 availability in the substantia nigra [85, 112, 119, 120, 140, 141]. These data support the idea that cannabinoid-based compounds act on vital pathways of endocannabinoid transmission and therefore might be of therapeutic interest due to their potential to diminish motor symptoms in extrapyramidal disorders such as Parkinson's disease [27, 76, 142].

Research with cannabinoid agonists and antagonists demonstrates that the cannabinoids can modulate motor activity and produce alterations in corresponding molecular correlates [129, 143–145]. It has been widely reported that synthetic, plant-derived, or endogenous cannabinoid agonists exert a powerful motor inhibition in laboratory species [129, 144, 146–149]. This hypokinetic effect was shown to be mediated by the activation of CB1 receptors in neurons of the basal ganglia circuitry [88, 137, 141, 150–152]. Stimulation of the CB1 receptor by a synthetic cannabinoid HU-210 decreased spontaneous glutamatergic activity and reduced the rotations induced by levodopa/carbidopa by 34% in PD rats [153, 154]. Administration of CB1 receptor agonists THC and two synthetic cannabinoids WIN 55,212-2 and CP 55,940 increased extracellular dopamine concentrations in rats [152, 155, 156]. WIN 55,212-2 and CP 55,940 also weakened contralateral rotations induced by a selective D₁/D₅ receptor partial agonist SKF38393 without developing catalepsy in PD rats [148]. In a gender study THC produced an increase in tyrosine hydroxylase activity in parkin-null male mice (a model of early stages of PD) and caused a motor inhibition that was significantly greater compared to wild-type animals [122]. Treatment with THC inhibited motor activity and produced catalepsy in rats [109, 144, 146, 147] and caused antinociception and ring immobility in mice [157]. In other studies THC diminished the motor inhibition caused by 6-hydroxydopamine [70] and potentiated the hypokinetic effect of reserpine in rats more than 20-fold [135]. However, in a primate model of Parkinson's disease THC did not affect locomotor activity but increased bradykinesia [125].

Administration of WIN 55,212-2 increased stimulation of GTPγ_s binding in the caudate nucleus, putamen, globus pallidus, and substantia nigra of marmosets, indicating an effective activation of CB1 signaling mechanisms [119, 120]. WIN 55,212-2 produced a dose-dependent reduction of the spontaneous motor activity and catalepsy in mutant Syrian hamsters, increased antidystonic efficacy of benzodiazepines [158], and significantly reduced the antikinetic effects of quinpirole in the reserpine-treated rats [159]. Treatment with WIN 55,212-2 also reduced levodopa-induced dyskinesias, attenuated axial, limb, and severe orolingual abnormal involuntary movements in 6-hydroxydopamine- (6-OHDA-) lesioned rats [160–163]. An endogenous cannabinoid agonist oleylethanolamide (OAE) produced reduction in dyskinetic contralateral rotations correlated with reduction of molecular

associates of L-DOPA-induced dyskinesia: reduced FosB striatal overexpression and phosphoacetylation of histone 3 [164]. Another synthetic agonist levonantradol decreased general and locomotor activity and increased bradykinesia in a primate model of Parkinson's disease [125]. Nabilone, a synthetic cannabinoid agonist, coadministered with levodopa significantly decreased total dyskinesia compared with levodopa alone treatment and increased the duration of antiparkinsonian action of levodopa by 76% in PD marmosets [165, 166].

Cannabinoid agonist anandamide (AEA) and its synthetic analog methanandamide increased the extracellular dopamine levels in the nucleus accumbens shell of rats by the activation of the mesolimbic dopaminergic system [167]. This dopamine increase was inhibited by the cannabinoid CB1 receptor antagonist rimonabant [167]. However, recent discoveries indicate that AEA is also able to activate vanilloid VR(1) receptors and that the activation of these receptors might also be responsible for changes in nigrostriatal dopaminergic activity and anandamide-induced hypokinesia [168–170]. AEA produced a tonic facilitation of glutamate release in the substantia nigra via stimulation of VRI receptors, indicating the involvement of this receptor in motor and cognitive functions of the dopaminergic system [171]. Preclinical data have shown that AEA decreased the activity of nigrostriatal dopaminergic neurons and produced hypokinesia that was completely reversed by an antagonist of vanilloid-like receptors, capsazepine [129]. Additional studies have demonstrated that AEA inhibited ambulation and stereotypic behavior, increased inactivity, and occluded the effects of an agonist of vanilloid VR₁ receptors, livanil, on locomotion in mice, suggesting a common mechanism of action for the two compounds [170]. Treatment with anandamide lowered motor activity with the maximal inhibition by approximately 85% and produced hypothermia and analgesia in mice, increased the inactivity time, and markedly decreased the ambulation and the frequency of spontaneous non-ambulatory activities in rats [146, 147, 172, 173]. Moreover, AEA produced a decrease in spontaneous motor activity in laboratory animals similar to the reported actions of THC [129, 145, 153, 170]. The hypokinetic actions of AEA were boosted by coadministration with a selective inhibitor of endocannabinoid uptake N-(3-furylmethyl) eicosa-5,8,11,14-tetraenamide, UCM707 [174].

Tissue concentrations of endocannabinoids are important for producing motor effects. Levels and activities of AEA and 2-AG can be manipulated by inhibition of FAAH enzyme, the action of which is reduced in experimental models of PD [153, 175]. Animal studies have shown that the FAAH enzyme inhibitor [3-(3-carbamoylphenyl) phenyl] N-cyclohexylcarbamate (URB597) magnified and prolonged a rapid, brief dopamine increase that was produced by AEA [167]. Additional studies have confirmed that FAAH inhibition remarkably increases AEA tissue levels but reduces 2-AG levels [176, 177]. To determine whether FAAH inhibition has beneficial impact on PD symptoms the effect of the FAAH inhibitor, URB597, was studied in MPTP-lesioned marmosets. Treatment with URB597 increased plasma levels

of AEA, did not modify the antiparkinsonian actions of L-DOPA, and reduced the magnitude of hyperactivity to levels equivalent to those seen in normal animals [178]. In PD mice URB597 prevented induced motor impairment [179]. Moreover, other FAAH inhibitors, JNJ1661010 and TCF2, also have anticataleptic properties [179]. These results reveal that FAAH inhibition may represent a new strategy for treatment of PD.

Overall, these results indicate that endogenous or exogenous cannabinoid agonists activate the dopaminergic system and play a very important role in modulation of motor behavior [180]. In addition to the effects on movement activity, cannabinoid agonists have demonstrated neuroprotective properties, suggesting that the cannabinoids have a promising pharmacological profile for not only improving Parkinsonian symptoms but also delaying PD progression [70, 85, 181–183].

The CB1 receptor antagonists can also influence movement syndromes of Parkinson's disease suggesting that modulation of the CB1 signaling system might be valuable in treatment of motor disorders. In a study with PD rats rimobabant (SR141716A), a selective antagonist of CB1 receptors has shown the potential to act as an antihypokinetic agent by enhancing glutamate release from excitatory afferents to the striatum [184]. Moreover, SR141716A prevented the effects of THC on dopamine release [156, 167] and also increased the locomotor activity in mice and rats preexposed to THC [170, 185]. SR141716A produced a 71% increase in motor activity in MPTP-lesioned marmosets with LID [136]. Coadministration of SR141716A with levodopa resulted in significantly less dyskinesia than administration of levodopa alone [136, 160]. SR141716A also reversed effect of the cannabinoid agonist WIN 55,212-2 and increased the locomotor activity in 6-OHDA-lesioned animals [159, 163]. Coadministration of SR141716A with a selective D₂/D₃ receptor agonist quinpirole reduced levels of AEA and 2AG by sevenfold in the globus pallidus, boosted the locomotive effects of quinpirole, and produced restoration of locomotion in animal models of Parkinson's disease [98, 99, 101, 136, 186]. In parkin-null mice SR141716A produced a decrease in tyrosine hydroxylase activity in the caudate-putamen and as result formed a hyperkinetic response [122]. However, SR141716A did not alleviate the motor deficits in a primate model of Parkinson's disease [125].

Another CB1 receptor antagonist AM251 and SR141716A produced antiparkinsonian effects in rats with very severe nigral degeneration (>95% cell loss) [187]. Local administration of these antagonists into denervated striatum, globus pallidus, and subthalamic nucleus reduced motor asymmetry in Parkinsonian rats [187, 188], which was inhibited by CB1 receptor agonist AM404 [187]. Another CB1 antagonist CE-178253 produced a 30% increase in motor behavior responses to L-DOPA in MPTP-treated rhesus monkeys but did not modify levodopa-induced dyskinesias [189]. THCV caused changes in glutamatergic transmission and attenuated the motor inhibition in PD rats [70]. Overall, these findings suggest that cannabinoid CB1 antagonists might be therapeutically effective in the control of Parkinson's disease and levodopa-induced dyskinesia [114, 190].

The activation of CB2 receptors might also contribute to some extent to the potential of cannabinoids in PD [191]. THCV, which is not only a CB1 antagonist but also a CB2 partial agonist, reduced the loss of tyrosine hydroxylase-positive neurons in the substantia nigra with preservation of these neurons in CB2 receptor-deficient mice [70]. CBD has also reduced the loss of tyrosine hydroxylase-positive neurons in the substantia nigra of PD rats. Both compounds, THCV and CBD, have acted via neuroprotective and antioxidant mechanisms [70, 182, 191]. CBD has also demonstrated significant effects in preclinical models of neurodegenerative disorders in combination with other cannabinoids [15, 70, 192]. CB2 receptor agonists display a promising pharmacological profile for delaying disease progression.

The cannabinoid pharmacologic manipulation represents a promising therapy to alleviate movement disorders and levodopa-induced dyskinesias. Thus, CB1 antagonists appear to have antiparkinsonian effects, while cannabinoid receptor agonists may be useful in the treatment of motor complications in Parkinson's disease.

3.3. Effect of Cannabinoids on Patients with Movement Disorders. Cannabis and related compounds have created significant research interest as a promising therapy in neurodegenerative and movement disorders. The successful use of tincture of *Cannabis indica* in treating PD was first described in Europe by Gowers [193]. Despite the lack of controlled studies, there is evidence that cannabinoids are of therapeutic value in the treatment of tics in Tourette syndrome, some forms of tremor and dystonia, chorea in Huntington's disease, the reduction of levodopa-induced dyskinesia in Parkinson's disease, and Parkinsonian syndromes [194–201].

A study with smoked cannabis queried 339 PD patients indicated that marijuana produced significant improvement of general PD symptoms in 46% of the patients; 31% of them reported improvement in resting tremor, 38% reported relief from rigidity, 45% defined reduced bradykinesia, and 14% of the patients reported alleviated dyskinesias [202]. High urine concentration (>50 ng/ml) of the THC primary active metabolite, 11-HO-THC, was associated with relief from PD symptoms [202]. The dose and frequency of the cannabis administrations were important in relieving PD symptoms. Smoked cannabis also produced a statistically significant improvement in tremor, rigidity, and bradykinesia as well as improvement in sleep and pain scores in 22 PD patients [65]. In another study, smoked cannabis was responsible for a significant improvement in the mean total motor Unified Parkinson's Disease Rating Scale (UPDRS) score, tremor, rigidity, and bradykinesia in 17 patients with PD [203]. One dose of smoked marijuana provided symptoms relief for up to 3 hours [203]. Moreover, both studies reported significant improvement of nonmotor symptoms of PD, such as pain and sleep [65, 203]. However, smoked marijuana did not reduce Parkinsonian symptoms in 5 patients with idiopathic Parkinson's disease and severe tremor [204]. A clinical trial in 19 PD and 6 patients with levodopa-induced dyskinesia demonstrated that oral cannabis extract was ineffective for alleviating parkinsonism or dyskinesia [205].

Few studies have evaluated the effects of CBD on PD symptoms. In a pilot study CBD lowered total UPDRS scores and significantly reduced psychotic symptoms in 6 PD patients with psychosis [67]. In another study CBD administration produced no improvement in measures of motor and general symptoms in 21 PD patients [68, 69]. However, the group treated with CBD had significantly different mean total scores in the Parkinson's Disease Questionnaire, 39 compared to the placebo group [68, 69]. Oral CBD improved dyskinesia by up to 30% without a significant worsening of the parkinsonism in PD patients [206]. CBD withdrawal caused severe generalized dystonia [206].

Clinical studies have been conducted to evaluate the effect of a synthetic cannabinoid nabilone. Oral nabilone significantly reduced dyskinesia without aggravating parkinsonism in seven PD patients with severe L-DOPA-induced dyskinesia [207]. In another study, nabilone produced a 22% reduction in levodopa-induced dyskinesia in PD patients [208]. Nabilone showed efficacy not only against LID but also against bradykinesia in PD patients [209]. Some other cannabinoid related compounds such as CE178253, OEA, and HU-210 have also been reported to be efficacious against L-DOPA-induced dyskinesia and bradykinesia in PD [199, 209]. However, SR 141716 did not improve Parkinsonian motor disability in PD patients [210]. The American Academy of Neurology (AAN) review deemed marijuana "probably ineffective" for treating L-DOPA-induced dyskinesia [211]. These conflicting results indicate the need for more research in this area.

Several clinical studies have been performed to evaluate the effect of marijuana on dystonia. Inhaled cannabis has provided a marked reduction in dystonia and complete pain relief in patients with right hemiplegic painful dystonia. Moreover, the patients have been able to completely discontinue opioid use [212]. Smoked cannabis also improved idiopathic dystonia and generalized dystonia due to Wilson's disease [213, 214]. In a preliminary study, administration of CBD resulted in a 50% improvement in spasm severity and frequency in a patient with blepharospasm- oromandibular dystonia [215] and amelioration of the dystonic movements within 2-3 hours in patients with dystonic movement disorders [201]. CBD also improved dystonia by 20–50% in dystonic patients and stopped tremor and hypokinesia in 2 patients with Parkinson's disease [200]. Another cannabis compound, THC, produced a reduction of abnormal movement patterns in a 14-year-old girl with marked dystonia [216] and decreased intensity of myoclonic movements in a 13-year-old boy with athetosis and myoclonic movements [216]. In contrast to these findings, one study found no significant reduction in dystonia following treatment with nabilone [165, 166].

Studies have looked at the potential benefits of medical marijuana and cannabinoids for the treatment of Huntington's disease (HD). Nabilone versus placebo showed a treatment difference of 0.86 for total motor score; 1.68 for chorea; 3.57 for Unified Huntington's Disease Rating Scale (UHDRS) cognition; 4.01 for UHDRS behavior; and 6.43 for the neuropsychiatric inventory in HD patients [217]. However, in previous study nabilone was found to increase

choreatic movements in patients with HD [197, 198]. AAN guideline examining the efficacy of marijuana for treating chorea in HD stated nabilone can be used for modest decreases in HD chorea [218]. Available data regarding the effect of CBD on HD symptoms are inconsistent. CBD produced improvement (20–40%) in the choreic movements in HD patients [219]. However, a latter study did not confirm the earlier finding [220]. A comparison of the effects of CBD and placebo on chorea severity in neuroleptic-free HD patients indicated no significant or clinically important differences [220].

Few studies have indicated that marijuana and THC can reduce tics and associated behavioral disorders in patients with Tourette's syndrome (TS) [221]. Cannabis inhalations produced a significant amelioration of TS symptoms [222]. Following marijuana administration 82% of TS patients ($N = 64$) reported a reduction, or complete remission of motor and vocal tics, and an amelioration of premonitory urges and obsessive-compulsive symptoms (OCB) [199]. Smoked marijuana also eliminated TS symptoms in one case study [223]. Administration of THC to a boy with TS improved tics and enhanced short-interval intracortical inhibition and the prolongation of the cortical silent period [224]. TCH significantly reduced tics and improve driving ability in a Tourette's patient [225]. Treatment with THC lowered the mean $C1$ specific over nonspecific binding ratio (V_3'') from 0.30 to 0.25 in six TS patients, although the difference was not significant. However V_3'' clearly declined in a patient with a marked clinical response [226]. To date, there have been only two controlled trials that investigated the effect of THC on TS [194], both of which reported a significant improvement of tics and OCB after THC administration [195, 196].

Considering the relevance of these data, the need for alternative treatments for PD motor and nonmotor symptoms, medical marijuana, or related compounds may provide a new approach to the treatment of Parkinson's disease.

4. Beneficial Effects of Cannabinoids in the Amelioration of Nonmotor Symptoms and Progression of Parkinson's Disease

4.1. Neuroprotective Actions of Cannabinoids. Cannabinoids have been shown to have neuroprotective effect due to their antioxidative, anti-inflammatory actions and their ability to suppress excitotoxicity. Plant-derived cannabinoids such as THC and CBD can provide neuroprotection against the in vivo and in vitro toxicity of 6-hydroxydopamine and this was thought to be due to their antioxidative property or modulation of glial cell function or a combination of both [182]. Studies found that CBD was able to recover 6-hydroxydopamine-induced dopamine depletion and also induced upregulation of Cu, Zn-superoxide dismutase, which is a key enzyme in endogenous defense against oxidative stress [70, 191, 227]. The reported data suggest that CBD also diminishes the increase in nicotinamide adenine dinucleotide phosphate (NADPH) oxidase expression and decreases the markers of oxidative stress, inflammation, and cell death in the kidneys [228]. Another study has also emphasized a role for

superoxide anion produced by microglial NADPH oxidase in augmenting the demise of dopaminergic neurons in the PD brain [229]. The mechanism by which CBD acts to reduce NADPH oxidase expression and inhibit oxidative injury within the PD brain has yet to be confirmed but it seems to act through mechanisms independent of CB1 or CB2 receptors [76]. However, data obtained from recent studies have hinted towards a direct relationship between the CB1 receptor and mitochondrial functions in the brain [230]. The phenolic ring moieties in cannabinoids display antioxidant activity guarding against glutamate-induced neurotoxicity in a cellular model [231]. CBD produced reduction of hydroperoxide-induced oxidative damage and was more protective against glutamate neurotoxicity compared to ascorbate and α -tocopherol, indicating that CBD is a potent antioxidant [232]. Taken together, these discoveries support the hypothesis that treatment with cannabinoids having antioxidant effects may modulate mitochondrial reactive oxygen species production [233] in the PD brain.

Inflammation has been shown to be a crucial pathological factor responsible for the demise of dopaminergic neurons in PD [234–236]. Glial cells appear to play a key role in neuroinflammation, since higher levels of activated microglia are reported in the substantia nigra of patients with PD compared to brains of control subjects [237, 238]. Cannabinoids demonstrate anti-inflammatory activities by suppressing toxic cytokine release and microglia activation [181–183]. Increased CB2 receptor expression in nigral cells and stimulation of these receptors protect dopaminergic neurons from microglia-induced inflammation and regulate neuronal survival [70]. The cannabinoids are known to be able to activate the CB2 receptor, which mediate the anti-inflammatory effects of the compounds and preserve cells from excessive apoptosis. Recent evidence substantiates that some cannabinoids may attenuate the neuroinflammation associated with PD [191, 239–241]. Several studies showed that CBD has anti-inflammatory properties [242–246] and can produce beneficial effect in acute inflammation and chronic neuropathic states [5, 247, 248]. THC demonstrates anti-inflammatory effect via activation of the CB1 receptor [249–251]. In addition, cannabinoids provide anti-inflammation effect by reducing the vasoconstriction and restoring blood supply to the injured area [252]. All these data support that cannabinoids are potentially effective compounds for the treatment of neuroinflammatory conditions, including neurodegenerative diseases like PD.

Marijuana may prevent brain damage by protecting against neuronal injury. There are a few mechanisms by which cannabinoids provide neuroprotection. One of the mechanisms involves an induction/upregulation of cannabinoid CB2 receptors, mainly in reactive microglia, and regulates the influence of these glial cells on homeostasis of surrounding neurons [253]. In combination with the increased antitoxic effects observed in cell cultures containing glia, this suggests that immunomodulation produced by CB2 receptor activation may play a primary role in the neuroprotective properties of cannabinoids [182]. Another mechanism of neuroprotection is activation of CB1 receptors. Loss of dopaminergic neurons and greater degree of motor impairment in

CB1 knockout mice have been reported [85]. Cannabinoids activating the CB1 receptor are antiexcitotoxic due to suppression of glutamatergic activity with a subsequent decrease in calcium ion influx and eventual nitric oxide production [254–256]. Sativex-like combination of phytocannabinoids has been demonstrated to produce neuroprotective effect via interaction with both CB1 and CB2 receptors [134, 257]. In addition, THC reduced the loss of tyrosine hydroxylase-positive neurons in the substantia nigra [70] and exhibited neuroprotective effect by activation of the PPAR γ receptors [258]. Overall, these data suggest that cannabinoids are neuroprotective in acute and chronic neurodegeneration and can delay or even stop progressive degeneration of brain dopaminergic system, a process that cannot be prevented currently.

4.2. Analgesic Effect of Cannabinoids. Pain is a relevant and often underestimated nonmotor symptom of PD [259, 260]. Pain affects more than 50% of people with this disorder and can cause extreme physical, psychological, and social disorders and worsen Parkinsonian disability [261, 262]. Different treatment options are used to treat PD pain [262–265]. However, these medications have significant side effects and do not provide universal efficacy [264, 265]. Cannabis is well known as a pain-relieving plant. The cannabinoid receptors in the central and peripheral nervous systems have been shown to modulate pain perception [266, 267].

Several clinical studies have been performed to investigate the effect of marijuana or cannabinoids on pain. Smoked cannabis significantly reduced neuropathic pain intensity as well as significantly improved mood disturbance, physical disability, and quality of life in HIV-patients [268]. Cannabis was effective at ameliorating neuropathic pain in patients with central and peripheral neuropathic pain [269]. Inhaled cannabis significantly reduced pain intensity (34%) compared to placebo in a clinical trial of painful distal symmetric polyneuropathy (DSPN) [270]. Whole plant extracts of *Cannabis sativa* produced statistically significant improvements on the mean pain severity score [271]. Cannabis-based medicine significantly decreased chronic pain intensity as well as sleep disturbance in multiple sclerosis patients [272, 273]. Oromucosal nabiximols (1:1 combination of the THC and CBD) produced a reduction in pain intensity scores in patients with neuropathic pain [274].

These findings are consistent with other discoveries supporting the efficacy of cannabis in relieving pain. The analgesic effect of cannabinoids has been reviewed [75, 211, 275–281]. The review of the literature suggests that marijuana and/or cannabinoids may be efficacious for pain relieving in various disease states including PD.

4.3. Antidepressant Effect of Cannabinoids. Depression is one of the common nonmotor symptoms of PD and the estimated rate varies widely, with an average prevalence of up to 50%. [282–284]. Despite its association with poor health outcomes and quality of life, depression in PD patients is underdiagnosed and undertreated [285–287]. Studies have indicated that the endocannabinoid system is involved in

the regulation of mood and emotional behavior, and the loss or blockade of the endocannabinoid signaling system results in depressive symptoms [288]. For example, the CB1 receptor antagonist rimonabant has been shown to induce symptoms of anxiety and depression [289–291]. In addition, polymorphism of the gene that encodes the CB1 receptor has been associated with depression in PD [292]. In animal models, low level of THC produced antidepressant activity and increased serotonergic activity via activation of the CB1 receptor [293]. Animal studies have also shown that inhibition of hydrolysis of the endocannabinoid anandamide exerts antidepressant effect [294] and resulted in an increased serotonergic and noradrenergic neuronal activity in the midbrain. Currently available antidepressant drugs act via increasing serotonin and/or noradrenaline levels. These, and many other studies, indicate that the cannabinoid system is a potential target for the development of novel antidepressant drugs. Epidemiological studies have demonstrated that people who used cannabis daily or weekly exhibit less depressed mood and more positive effect than nonusers of cannabis [295]. Other studies have shown an association between heavy cannabis use and depressive symptoms. However, it is not clear whether the increased depressive symptoms are due to cannabis use or other factors that increased the risk of both depression and heavy use of cannabis [296]. Therefore, moderate use of cannabis in PD patients may help alleviate depressive symptoms and improve quality of life.

4.4. Effect of Cannabinoids on Sleep Disorders. Sleep disorders are common in PD patients and negatively affect the quality of life. The reported prevalence ranges from 25% to 98% and this wide variation could be due to differences in study design and diagnostic tools used [297]. The causes of the sleep disturbances in PD are multifactorial and include neurodegeneration and the medications used to treat motor symptoms of PD [298]. Various sleep disorders including rapid eye movement sleep behavior disorder, insomnia, sleep fragmentation, excessive daytime sleepiness, restless legs syndrome, and obstructive sleep apnea have been described in PD patients [299, 300]. Cannabidiol, the major nonpsychotic component of marijuana, has been reported to improve rapid eye movement sleep behavior disorder in PD patients [68, 69]. Marijuana has also been shown to improve nonmotor symptoms of PD including sleep [65]. In clinical trials involving 2000 patients with various pain conditions, nabiximols has been demonstrated to improve subjective sleep parameters [301]. Thus, marijuana could be used to enhance the quality of life of PD patients by alleviating sleep disorders and pain.

5. Summary

Cannabis and related compounds have recently been studied as promising therapeutic agents in treatment of neurodegenerative and movement disorders including Parkinson's disease. In this review we have examined the potential benefits of medical marijuana and cannabinoids in the treatment of both motor and nonmotor symptoms as well as

in slowing the progression of the disease. We have looked into any scientific evidence that indicates the potential use of marijuana and/or related compounds for the treatment of PD. Current treatments of PD provide only relief of motor symptoms and are associated with adverse effects such as dyskinesia. In addition, these therapies do not slow the progression of the disease. Therefore, there is an urgent need for safer drugs that can treat both motor and nonmotor symptoms of PD as well as drugs that slow the progression of the disease.

In spite of the placement of marijuana in schedule 1 category under the US Federal Controlled Substance Act, 24 states and Washington DC have enacted laws allowing the use of marijuana to treat a range of medical conditions. Parkinson's disease has been listed as one of the disease conditions for which medical marijuana is allowed in a number of states. Research studies have provided evidence for the potential effectiveness of medical marijuana and its components in the treatment of PD as cannabinoids act on the same neurological pathway that is disrupted in Parkinson's disease. Involvement of the endocannabinoid system in the regulation of motor behavior, the localization of the cannabinoid receptors in areas that control movement, and the effect of cannabinoids on motor activity indicate that cannabinoids can be potentially used in the treatment of movement disorders. Cannabinoid agonists and antagonists have been shown to modulate the endocannabinoid system and modify motor activity. Cannabinoid receptor antagonists appear to produce antiparkinsonian effects while cannabinoid receptor agonists exert a powerful motor inhibition and may be useful in the treatment of motor complications. In addition, we have assessed the role of the cannabinoid system and marijuana constituents in neuroprotection as well as considered other beneficial effects of marijuana. Marijuana has been shown to improve nonmotor symptoms of PD such as depression, pain, sleep, and anxiety. Moreover, components of cannabis have been demonstrated to have neuroprotective effect due to their anti-inflammatory, antioxidative, and antiexcitotoxic properties. Due to combination of the above mentioned beneficial effects, cannabis may provide a viable alternative or addition to the current treatment of Parkinson's disease. However, there are concerns regarding the use of medical marijuana including lack of standardization and regulation, imprecise dosing, possible adverse effects, and medication interactions. Further studies are needed to provide more data on efficacy, safety, pharmacokinetics, and interactions of cannabinoids.

Competing Interests

The authors declare that there is no conflict of interests regarding the publication of this paper.

Medical Cannabis in Arizona: Patient Characteristics, Perceptions, and Impressions of Medical Cannabis Legalization

William D. Troutt, N.M.D. & Matthew D. DiDonato, Ph.D.

Abstract—Many advances have been made toward understanding the benefits of medical cannabis. However, less is known about medical cannabis patients themselves. Prior research has uncovered many important patient characteristics, but most of that work has been conducted with participants in California, who may not represent medical cannabis patients throughout the United States. Furthermore, it is unknown if medical cannabis legalization, which typically imposes strict regulations on cannabis cultivation and sale, impacts patients' experiences acquiring and using cannabis. The goal of this study was to address these limitations by (1) examining the characteristics, perceptions, and behaviors of medical cannabis patients in Arizona; and (2) questioning participants with a history of cannabis use regarding their experiences with cannabis before and after legalization. Patients in Arizona share many characteristics with those in California, but also key differences, such as average age and degree of cannabis consumption. Participants also had positive perceptions of the effect of medical cannabis legalization, reporting that feelings of safety and awareness were higher after legalization compared to before. The results are discussed in relation to evidence from patients in other states and in terms of their potential policy implications.

Keywords—Arizona, medical cannabis, medical cannabis legalization, patient characteristics, perceptions

Support for the use of cannabis for medical purposes is growing throughout the United States. To date, 23 states and the District of Columbia have enacted laws legalizing medical cannabis, and 16 states have similar legislation under consideration. Recent polls also show that the majority of Americans believe that cannabis should be legalized for medical purposes (Anderson Robbins Research & Shaw & Company Research 2013; Associated Press-CNBC 2010), and the popularity of this sentiment has

increased over time (Anderson Robbins Research & Shaw & Company Research 2013).

Support may be on the rise, in part, due to research that shows the potential therapeutic effects of medical cannabis. Animal studies, for example, show that cannabis-derived extracts mitigate cancer cell proliferation and tumor growth (Aviello et al. 2012) and have antidepressant-like effects (Jiang et al. 2005). Studies also show that cannabis may be beneficial for humans. Bar-Sela and colleagues (2013) found that nausea, vomiting, weight loss, sleep disorders, and pain were reduced in cancer patients after 6–8 weeks of cannabis use. Studies also show that cannabis significantly reduces chronic pain (see Lynch and Campbell 2011),

inflammatory bowel disease (Allegretti et al. 2013), post-traumatic stress disorder (Greer, Grob, and Halberstadt 2014), and seizure disorders (Lorenz 2004).

Although many advances have been made in understanding the benefits of medical cannabis, less is known about US medical cannabis patients themselves. Demographically, most patients are White, male, and approximately 35 to 45 years of age (Bonn-Miller et al. 2014; Grella, Rodriguez, and Kim 2014; Ryan-Ibarra, Induni, and Ewing 2015; Aggarwal et al. 2013; Ilgen et al. 2013; Nunberg et al. 2011; Reinerman et al. 2011; Aggarwal et al. 2009; Reiman 2009; O'Connell and Bou-Matar 2007; Harris et al. 2000). Most patients report medicating with cannabis daily (Bonn-Miller et al. 2014; Ilgen et al. 2013; Reinerman et al. 2011; O'Connell and Bou-Matar 2007), consuming six to nine grams of cannabis per week (Bonn-Miller et al. 2014; Reinerman et al. 2011; O'Connell and Bou-Matar 2007), and prefer inhalation as the method of consumption (O'Connell and Bou-Matar 2007).

Studies also show that the majority of patients use medical cannabis to relieve pain. However, patients also report using cannabis to treat a variety of other conditions, including anxiety, sleep apnea, hypertension, incontinence, and depression (Aggarwal et al. 2013; Nunberg et al. 2011; Reinerman et al. 2011). Generally, patients report that medical cannabis is effective for helping them manage their condition(s) (Bonn-Miller et al. 2014; Ryan-Ibarra, Induni, and Ewing 2015; Aggarwal et al. 2013; Harris et al. 2000). For example, Aggarwal and colleagues (2013) found that, on a scale from 1 to 10, where 10 indicated absolute symptom control, patients reported that cannabis provided symptom control in the range of 7 to 10 across a variety of conditions. Patients also often reduce their use of other medications (i.e., prescription and over-the-counter drugs) when using medical cannabis (Nunberg et al. 2011; Aggarwal et al. 2009; Reiman 2009, 2007).

Though these studies are informative, one limitation is that most were conducted with samples of patients living in California. California patients may not represent those living in other areas of the country because the regulations that govern patients in California are different from those in other states. For example, residents of California may legally obtain medical cannabis to treat a number of ailments, including any chronic or persistent condition that considerably limits major life activities or that, if not alleviated, may compromise the patient's safety or health (California Senate Bill 420 2003). Because the list of conditions for which the legal medical use of cannabis is granted in other states is often less inclusive, patients from these states may differ from those in California.

Considering that medical cannabis has been legalized in many states, there is an opportunity to paint a more comprehensive picture of American medical cannabis patients by conducting similar studies in other geographic locations.

Scientists have begun to conduct such research through the examination of patients living in Washington State (Aggarwal et al. 2013, 2009) and Michigan (Ilgen et al. 2013). Our first goal was to continue this line of research by studying medical cannabis patients in Arizona. To aid comparisons with previous research, we assessed patient characteristics, behaviors, and perceptions that have been examined in prior studies. These included patterns of use (e.g., frequency of consumption, amount of consumption, preferred method of consumption), degree of relief experienced when using medical cannabis, and use of other medications.

In addition to the limited research on medical cannabis patients outside of California, to our knowledge there has been no systematic examination of patients' perceptions of the outcomes of medical cannabis legalization. One objective of legalizing cannabis for medical use is to safeguard its acquisition and production, which often involves strict regulation of its cultivation and sale. For instance, the rules and regulations of the Arizona Medical Marijuana Program require that those authorized to operate medical cannabis dispensaries and cultivation facilities enact strict security policies and procedures (Arizona Department of Health Services Medical Marijuana Rules 2012). In addition, many dispensaries and facilities employ third-party laboratories to test cannabis products for possible contaminants. However, it is unknown if such regulations translate to changes in patient safety or product quality.

Because individuals who use cannabis medicinally are those most affected by these regulations, surveying patients regarding their experiences purchasing and using medical cannabis may uncover the changes legalization has had on patient safety and product quality. In particular, patients with a history of using cannabis medicinally prior to legalization can provide their perspective on the changes that legalization has generated. The second goal of the present study was to determine the effectiveness of measures invoked to regulate and secure the cultivation and sale of medical cannabis by examining the perceptions of patients that used cannabis medicinally prior to legalization. Patients were asked to compare their perceptions of safety, product knowledge, and the effectiveness of cannabis for treating their condition(s) before and after legalization. Because of the regulations imposed with the legalization of medical cannabis, we hypothesized that patients would feel greater safety, have better knowledge, and that cannabis effectiveness would be greater after legalization.

METHOD

Participants and Procedures

Participants were 367 patients recruited from four medical cannabis dispensaries located throughout Arizona. The majority of the patients were male (63.8%), and

ranged from 18 to 83 years of age ($M = 45.78$ years; $SD = 13.76$ years). Most of the patients were White (86.4%), whereas the rest were Hispanic (6.3%), Black (2.5%), Native American (1.9%), Asian (0.8%), or Other (2.1%). These figures are similar to those reported by the Arizona Department of Health Services (2014) for this patient population.

To protect patient confidentiality, the authors did not directly contact patients, but approached dispensary owners to request assistance in recruiting participants. Dispensary owners informed their patients of the study, and interested patients were directed to a website that provided information about the research, including a description of the study, an explanation of patients' rights as participants, and information regarding the collection and storage of participant responses (i.e., responses were anonymous and would be stored on a password-protected server and/or computer only accessible to the researchers). If the patient agreed to participate, he or she checked a box indicating his or her agreement and the survey questions appeared.

Measures

Patient conditions. Participants were asked to select from an extensive list of conditions for which they use medical cannabis to control or treat. For each condition selected, participants completed subsequent questions and rated them on five-point Likert-type scales regarding the degree of relief experienced overall (1 = No relief at all; 5 = Almost complete relief), the degree of relief compared to other medications (1 = Much less relief; 5 = Much more relief), and the use of other medications since using medical cannabis (1 = I use other medications much less frequently; 5 = I use other medications much more frequently). Higher scores indicated greater relief or more frequent use of other medications.

Patterns and methods of cannabis use. Patients reported on the frequency ("On average, how frequently do you medicate with medical cannabis?": "Less than once per month" to "Several times per day") and amount ("On average, how much medical cannabis do you consume in a month?": "Less than one gram" to "More than one ounce") of consumption. Patients also completed a single-item measure regarding their preferred method of consumption (smoking, edibles, tinctures, vaporizing, raw consumption, or oils).

Perceptions of prior medical cannabis users. Participants were asked if they had used cannabis to treat their condition(s) before its legalization in Arizona. Those who replied "yes" were asked to complete four additional items. These items included the perceived safety of acquiring cannabis ("Compared to when you did not have a medical marijuana card, acquiring cannabis as a medical marijuana card holder feels": 1 = Much more dangerous; 5 = Much safer), knowledge of strain

characteristics ("Compared to when you did not have a medical marijuana card, your knowledge of what strain you are acquiring and its characteristics is": 1 = Much worse; 5 = Much better), confidence in a safe product ("Compared to when you did not have a medical marijuana card, your confidence that you are receiving a safe, uncontaminated product is": 1 = Much lower; 5 = Much higher), and product effectiveness for treating their condition(s) ("Compared to when you did not have a medical marijuana card, the effectiveness of the cannabis you receive to treat your condition is": 1 = Much worse; 5 = Much better).

RESULTS

The conditions for which patients reported using medical cannabis are displayed in Table 1. Consistent with previous research, the majority of patients reported suffering from chronic pain. Other commonly reported conditions included anxiety, depression, headaches, insomnia, muscle spasms, nausea, and stress.

Figure 1 shows the distributions of patients for frequency of cannabis use (Figure 1A), amount of cannabis consumed per month (Figure 1B), and preferred method of cannabis consumption (Figure 1C). The large majority of patients (83.7%) reported using medical cannabis several times per week or more, with most using medical cannabis daily (61%). Most patients consumed one-half of an ounce of cannabis or less per month (78.1%), and the most popular method of consumption was inhalation (i.e., smoking or vaporizing; 67.2%).

Perceived Effectiveness of Medical Cannabis

Patients' perceptions of the effectiveness of medical cannabis for treating their condition(s) are presented in Table 1. The values reflect the percent of patients who reported experiencing, overall, *a lot of relief* or *almost complete relief* from their symptoms and conditions when using medical cannabis (second column), *a little more relief* or *much more relief* from medical cannabis compared to other medications (third column), and using other medications *a little less frequently* or *much less frequently* when medicating with cannabis (fourth column).

For many of the conditions, patients reported that cannabis was effective for helping them manage their ailments. For example, at least 70% of patients reported experiencing *a lot of relief* or *almost complete relief* for 24 of the 42 conditions. Similarly, for 27 of the 42 conditions, at least 70% of patients reported experiencing *a little more relief* or *much more relief* from medical cannabis compared to other medications. Finally, at least 70% of patients reported using other medications *a little less frequently* or *much less frequently* for 24 of the 42 conditions.

TABLE 1
Percent of Patients Who Experience Relief and Less Frequently Use other Medications Due to Medical Cannabis Use, by Condition

Condition	Number of patients (%)	General relief ^a	Relief compared to other medications ^b	Less frequent use of other medications ^c
Alcohol Dependency	23 (6.3%)	91.30%	100%	100%
Anxiety	181 (49.3%)	82.90%	79.30%	85.90%

^aThe percent of patients with this condition who reported that they experienced a lot or almost complete overall relief.
^bThe percent of patients with this condition who reported that they experienced a lot or almost complete overall relief.
^cThe percent of patients with this condition who reported that they use other medications a little or much less frequently.

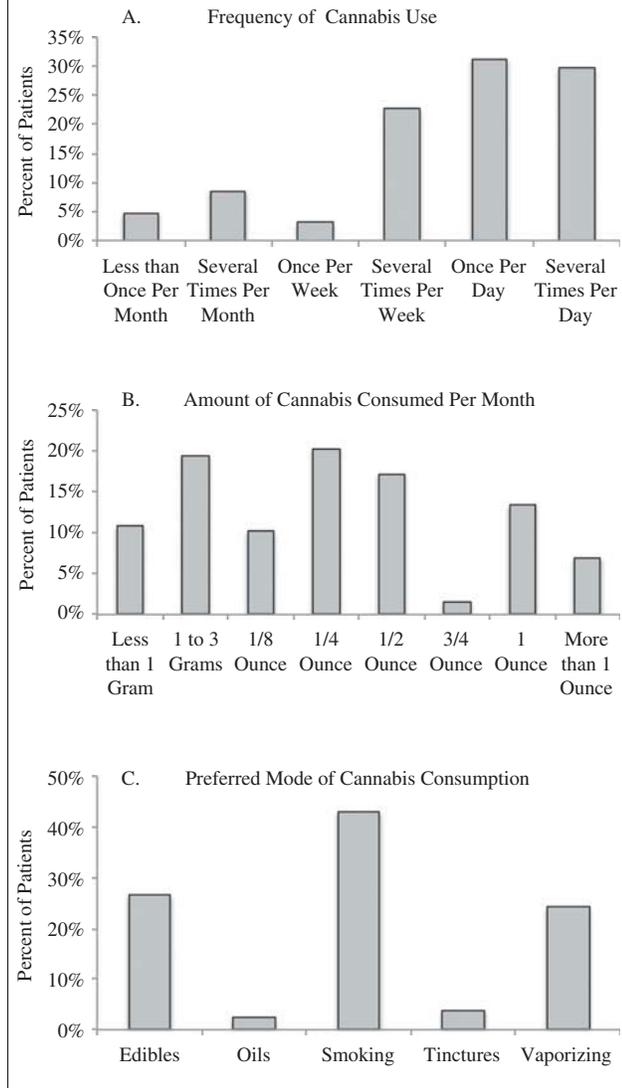

Perceived Effects of Medical Cannabis Legalization

Nearly two-thirds of participants ($n = 239$) reported using cannabis medicinally prior to legalization. These patients were asked to compare their current experiences

acquiring, their knowledge of, and their experiences using medical cannabis to their experiences and knowledge before legalization. Distributions of the patient's responses are shown in [Figure 2](#). Compared to their experiences

FIGURE 1

Distributions of patient responses, by percentage, for cannabis-related behaviors and perceptions: (A) the frequency of patient’s cannabis use; (B) the amount of cannabis consumed by patients per month; (C) patient’s preferred mode of cannabis consumption.

before legalization, 89.1% of patients reported that acquiring cannabis after legalization felt *somewhat safer* or *much safer*, 80.3% reported that their knowledge of the cannabis strains they acquired was *somewhat better* or *much better*, 85.4% reported that they had *somewhat more confidence* or *much more confidence* that they were purchasing a safe and uncontaminated product, and 79.5% reported that the medical cannabis was *somewhat more effective* or *much more effective* for treating their condition(s).

DISCUSSION

The goals of this study were to (1) examine the characteristics, perceptions, and behaviors of medical cannabis patients in Arizona; and (2) question participants with a history of cannabis use regarding their perceptions of safety acquiring cannabis, the quality of the cannabis they have obtained, their knowledge of the cannabis, and its perceived effectiveness, before and after legalization.

Patient Characteristics, Perceptions, and Behaviors

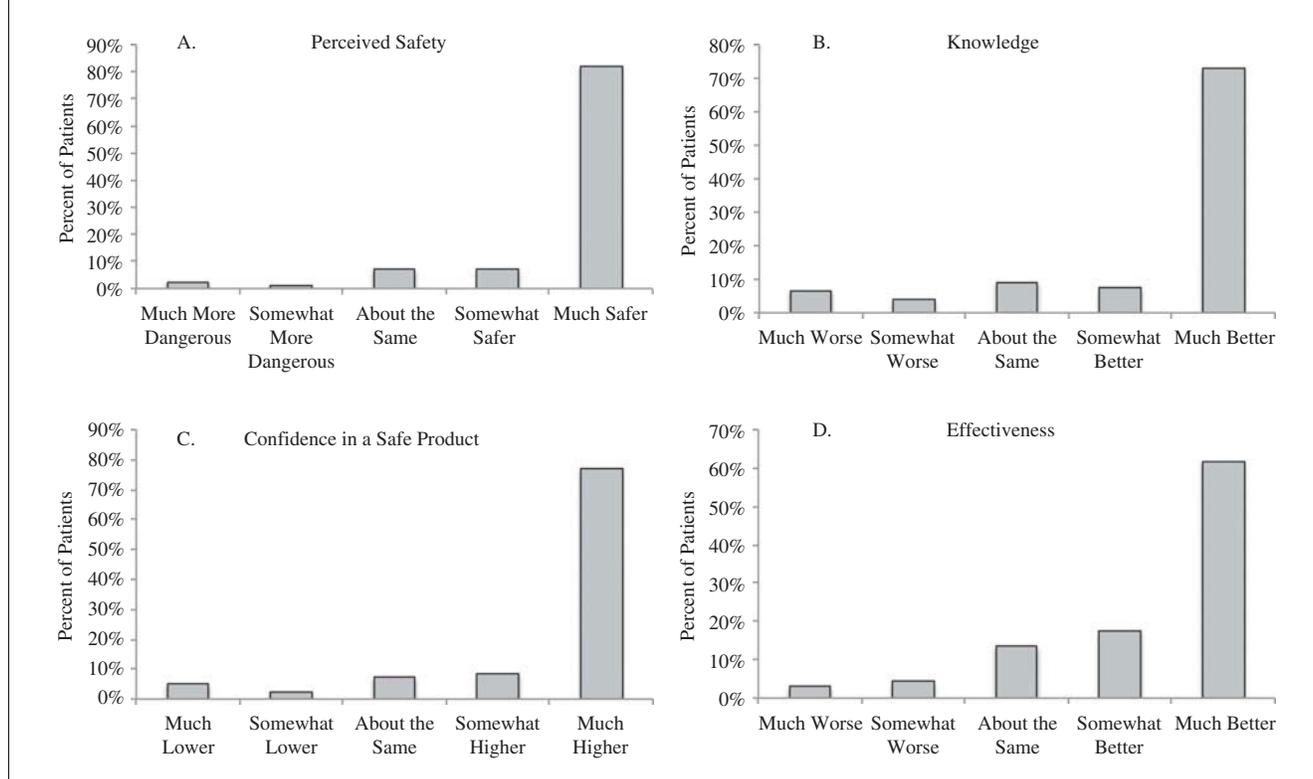

Consistent with research in other states (Bonn-Miller et al. 2014; Aggarwal et al. 2013; Ilgen et al. 2013; Nunberg et al. 2011; Reinerman et al. 2011; Aggarwal et al. 2009; Reiman 2009; O’Connell and Bou-Matar 2007; Harris et al. 2000), participants in the present study were mostly White men. Average patient age, approximately 46 years, differed from that in other states. For example, average ages reported in studies of patients from California range from 28 to 41 years (Bonn-Miller et al. 2014; Grella, Rodriguez, and Kim 2014; Reiman 2009, 2007; Harris et al. 2000). Average patient age is somewhat higher in Colorado (42 years of age; Colorado Department of Public Health and Environment 2014) and Washington State (41 to 47 years of age; Aggarwal et al. 2013, 2009). In Michigan (46 years of age; Murphy 2013) and Montana (47 years of age; Montana Department of Public Health and Human Services 2014), average patient age more closely approximates that of Arizona.

State-level variation in the average age of medical cannabis patients may in part be explained by the conditions that qualify a person to use medical cannabis in each state. For example, the qualifying conditions in Arizona, Colorado, Montana, Michigan, and Washington State are less inclusive than those in California, and are generally limited to more debilitating diseases. Individuals who suffer from more serious conditions may also be older, which may account for higher average patient ages in states other than California. The variability in these statistics underscores the risk of generalizing findings from patients living in California to those residing in other states and highlights the importance of studying patients throughout the United States. State-level differences in regulations also present an opportunity to explore how such regulations shape patient characteristics. A potential avenue for future work may be to study and compare patients in all states that have legalized the medical use of cannabis, ideally using a national sample to aid state-level comparisons.

Participants in the present study reported that, on average, they consumed cannabis on a daily basis and that inhalation was the preferred method of consumption, patterns of use that reflect those found in prior work (Bonn-Miller et al. 2014; Ilgen et al. 2013; Reinerman et al. 2011; O’Connell and Bou-Matar 2007). However, previous research shows that patients consume between

Downloaded by [Ecole Hautes Etudes Commer-Montreal] at 15:35 01 September 2015

FIGURE 2
Distributions of patient responses, by percentage, of their current experiences acquiring and knowledge of medical cannabis compared to their experiences before legalization: (A) the perceived safety of acquiring cannabis; (B) knowledge of medical cannabis characteristics; (C) perceived confidence in a safe product; and (D) perceived effectiveness of cannabis for treating their condition(s).

six and nine grams of cannabis per week or, equivalently, 0.85 to 1.25 ounces per month (Bonn-Miller et al. 2014; Reinerman et al. 2011; O’Connell and Bou-Matar 2007). This is in contrast to the findings of the present study, which show that 78% of patients consumed 0.5 ounces of cannabis per month or less.

State-level differences in average patient age, in particular, may affect variation in consumption. Patients in Arizona are, on average, older than those in California, and older patients may consume less cannabis than younger patients. Evidence from the present study supports this hypothesis, as there is a small, but significant, negative correlation between age and the amount of cannabis consumed per month ($r = -.11, p < .05$). Relatedly, Grella and colleagues (2014) found that younger patients visited dispensaries more frequently than older patients. Although there are likely other factors that contribute to consumption disparities, these findings also highlight the importance of studying medical cannabis patients across the US.

Patients reported using medical cannabis to treat a variety of conditions. The most commonly reported conditions included chronic pain, muscle spasms, nausea, anxiety, arthritis, depression, headaches, insomnia, and stress. Patients also reported that cannabis was effective for treating the symptoms of many of these conditions, findings that are consistent with previous research (Bonn-Miller et al. 2014; Ryan-Ibarra, Induni, and Ewing 2015; Aggarwal et al. 2013; Harris et al. 2000). This effectiveness included feelings of general relief and relief compared to other medications. The conditions for which the highest proportions of patients reported relief included alcohol dependency, anxiety, bowel distress, depression, insomnia, muscle spasms, and stress. Furthermore, patients reported using other medications less frequently when using cannabis. This is consistent with findings from other studies of patient perceptions (Reiman 2007, 2009; Nunberg et al. 2011; Reinerman et al. 2011), as well as a study of opiate overdose mortality, which showed that states with legalized medical cannabis had significantly lower opiate overdose mortality compared

Downloaded by [Ecole Hautes Etudes Commer-Montreal] at 15:35 01 September 2015

to those without legalized medical cannabis (Bachhuber et al. 2014).

Medical cannabis may benefit Arizona patients suffering from a variety of conditions. This conclusion has potential policy implications, as patients report deriving benefit not only for conditions that fall under the list of conditions that qualify a person to use medical cannabis (e.g., cancer, chronic pain, muscle spasms), but also for conditions that are not listed (e.g., anxiety, depression, insomnia). Officials in Arizona previously considered research on post-traumatic stress disorder (PTSD; Greer, Grob, and Halberstadt 2014) in their decision to include PTSD among Arizona's qualifying conditions. Thus, officials may consider the findings from the present study, in conjunction with other research, to determine the suitability of expanding the list of qualifying conditions in Arizona.

Legalization and Patient Experiences

The present study was, to our knowledge, the first to examine the effect of legalization on patient's experiences with medical cannabis. Regarding safety, the majority of patients reported feeling safer acquiring medical cannabis after legalization, and their confidence that they were acquiring a safe, uncontaminated product was higher. Patients also reported that their knowledge of the strains they acquired was better and that the cannabis they acquired after legalization was more effective for treating their condition(s) than the cannabis they acquired before legalization.

These findings show that the Arizona medical cannabis program has had some success, as regulations have provided a safe environment for patients to acquire a safe and high-quality product. However, the potential negative effects of medical cannabis legalization were not assessed in the present study. For example, participants in other studies have reported difficulties affording legal medical cannabis (Aggarwal et al. 2009), a factor which may preclude some individuals from taking advantage of the program, leaving them seeking other, potentially illegal means of cannabis acquisition. Other factors, such as limits on the amount of cannabis that can be purchased or legal

issues related to medical cannabis use, may also have negative consequences for some segments of the patient population.

The results of this study should be considered in light of some limitations. First, participant recruitment was conducted through medical cannabis dispensaries. Although this is a common method of recruitment (e.g., Bonn-Miller et al. 2014; Grella, Rodriguez, and Kim 2014; Aggarwal et al. 2013; Reiman 2009, 2007; Harris et al. 2000), such samples may have a positive bias for medical cannabis, as individuals who medicate with cannabis but for whom it was not effective are unlikely to be available to participate. However, at least one study using a large, representative sample of current and former medical cannabis users reported similar findings (Ryan-Ibarra, Induni, and Ewing 2015), lending validity to the results of the present study and those of previous research. Second, relatively few patients reported using medical cannabis for some of the conditions. Although this is not surprising, given the low incidence of some conditions, conclusions should be tempered for these conditions with respect to the effectiveness of medical cannabis for providing relief and/or for use as a substitute for other medications. Finally, patients' experiences acquiring and their knowledge of medical cannabis before and after legalization were assessed retrospectively, using a single measurement time-point.

Despite these limitations, this study has significance for understanding the characteristics, behaviors, and perceptions of Arizona medical cannabis patients. Additionally, it highlights the importance of studying patients throughout the US and understanding the potential effects of state-level regulatory differences on patient populations. The findings regarding the effectiveness of cannabis for treating various conditions have potential policy implications for the state of Arizona, as patients reported that cannabis was effective for treating conditions that currently do not qualify individuals for medical cannabis use. Furthermore, the results showed that the majority of patients report positive experiences as a result of legalization, although more work is needed to fully understand the consequences of Arizona's medical cannabis program.

RESEARCH

Open Access

It can't hurt to ask; a patient-centered quality of service assessment of health Canada's medical cannabis policy and program

Philippe Lucas

Abstract

Background: In 2001 Health Canada responded to a series of Ontario court decisions by creating the Marihuana Medical Access Division (MMAD) and the Marihuana Medical Access Regulations (MMAR). Although Health Canada has conducted a small number of stakeholder consultations, the federal government has never polled federally authorized cannabis patients. This study is an attempt to learn more about patient needs, challenges and experiences with the MMAD.

Methods: Launched in the spring of 2007, *Quality of Service Assessment of Health Canada's Medical Cannabis Policy and Program* pairs a 50 question online survey addressing the personal experiences of patients in the federal cannabis program with 25 semi-guided interviews. Data gathering for this study took place from April 2007 to Jan. 2008, eventually garnering survey responses from 100 federally-authorized users, which at the time represented about 5% of the patients enrolled in Health Canada's program. This paper presents the results of the survey portion of the study.

Results: 8% of respondents report getting their cannabis from Health Canada, while 66% grow it for themselves. >50% report that they frequent compassion clubs or dispensaries, which remain illegal and unregulated in Canada. 81% of patients would chose certified organic methods of cultivation; >90% state that not all strains are equally effective at relieving symptoms, and 97% would prefer to obtain cannabis from a source where multiple strains are available. Of the 48 patients polled that had tried the Health Canada cannabis supply, >75% rank it as either "1" or "2" on a scale of 1-10 (with "1" being "very poor", and 10 being "excellent").

Discussion: 72% of respondents report they are either "somewhat" or "totally unsatisfied" with Canada's medical cannabis program. These survey results and relevant court decisions suggest that the MMAR are not meeting the needs of most of the nation's medical cannabis patient community. It is hoped this research will help inform policy changes that will better address the needs of Canada's critically and chronically ill medical cannabis patient population, including the integration of community-based dispensaries into this novel healthcare delivery model.

Keywords: medical cannabis, Marihuana Medical Access Regulations, Health Canada, cannabis dispensary

Background

According to the United Nations Office for Drug Control and Crime Prevention (2001) [1] cannabis is the most popular illicit substance in the world. Despite the high rate of recreational use and over 5000 years of medical use, there has never been a substantiated case

of death resulting from cannabis overdose [2]. However, the therapeutic use of cannabis remains highly controversial, and only a few Western nations have introduced policies or programs to allow legal access to medical cannabis.

The Canadian government currently allows for limited access to medical cannabis through the Marihuana Medical Access Regulations (MMAR), which are administered by Health Canada's Marihuana Medical Access Division (MMAD). These court-ordered regulations are

Center for Addictions Research of BC, University of Victoria, Technology Enterprise Facility, Room 273, 2300 McKenzie Ave, Victoria, BC, V8P 5C2, Canada

the source of much criticism by end-users and advocates, and have been found by courts to be unconstitutional in a number of decisions for unnecessarily limiting access to legal protection and a safe supply of cannabis [3-6].

Initially established in response to patient needs and ineffective or non-existent federal medical cannabis policies, community-based medical cannabis dispensaries have become the main suppliers of medical cannabis in both Canada and in many of the 14 U.S. states that have legalized the medical use of cannabis [3,7]. In Canada, community-based dispensaries, otherwise known as "compassion clubs" currently supply over 30,000 critically or chronically ill Canadians with medical cannabis [8]. Although Canadian dispensaries continue to operate without legal sanction or protection, recent research suggests that this patient-centered healthcare delivery model builds social capital and provide patients with a safe supply of cannabis within a supportive environment that's conducive to healing [3,7,5].

A Brief History of Cannabis as a Medicine

The medical use of cannabis can be traced back at least 5000 years. The oldest reports originate in China and Egypt. It appears in a medical context in the Vedas, India's oldest religious text, and there are reports of its use as a medicine from fragments of Assyrian texts dating back to 700 B.C. The famous Chinese doctor Hua T'uo (approx. 100 A.D.) reportedly made use of a wine and cannabis mixture as an anesthetic for surgical operations [9].

There are numerous reports of the medicinal properties of cannabis from early in the nineteenth century, the most famous of which is an 1839 report titled "on the Preparations of the Indian Hemp, or Gunjah" by the Irish doctor William B. O'Shaughnessy in which he describes diverse applications for cannabis, including rheumatism, rabies, cholera, tetanus, cramps and delirium tremens [10]. A few years later Ernst Freiherr von Bibra published the renown "Narcotics and the Human Being", devoting thirty pages to the therapeutic use of cannabis preparations and hashish [11].

By the late 19th Century, cannabis-based preparations were manufactured and marketed by Burroughs-Wellcome & Co. in England; and Bristol-Meyers Squibb, Parke-Davis, and Eli Lilly in North America. The development of vaccines to prevent the spread of common infectious diseases, the increased use of opiates (with the introduction of the hypodermic syringe), and the discovery of aspirin at the end of the nineteenth and early twentieth century resulted in cannabis-based medicines losing their prevalence in the market place and Western pharmacopoeia [2].

In Canada, the non-medical use of cannabis was outlawed as part of the Opium and Narcotics Drugs Act of 1923, largely based on a series of misleading articles written by Emily Murphy for *MacLean's Magazine* in the early 1920's which claimed cannabis turned people into raving, blood-thirsty lunatics [12]. The US Pharmacopoeia listed Cannabis until 1941 and stated that cannabis can be used for treating fatigue, coughing, rheumatism, asthma, delirium tremens, migraine headaches, and the cramps and depressions associated with menstruation [13,2].

Although modern research into therapeutic applications for cannabis has been seriously stymied by its prohibition in most of the Western world, extensive anecdotal reports and a growing body of laboratory and clinical research suggest that it may have many medicinal uses, including hunger stimulation for wasting syndrome; anti-emetic and anti-nausea properties in AIDS or cancer chemotherapy; anti-spasmodic properties for MS, epilepsy and other neurological dysfunctions; reducing intra-ocular eye pressure in glaucoma; and analgesic properties in a large number of chronic pain conditions [14-16]. Recent research has found that cannabis can reduce the use of pharmaceutical drugs and even be an effective treatment for addiction [17-20].

Medical Cannabis Access in Canada

Although the Canadian Addiction Survey suggests that about 1 million Canadians use cannabis for medical purposes [5], as of January 2010 the MMAD had only authorized 4884 people in Canada to use cannabis legally [21]. Additionally, the federal supply of cannabis produced by a company called Prairie Plant Systems since 2000 remains highly problematic due to a lack of strain selection, controversial production methods, and patient concerns over the quality and safety [3-5].

Problems of safe access were noted by the Canadian Senate Special Committee on Illegal Drugs in their final report on cannabis from 2002, stating that:

while a process that authorizes the possession and production of marijuana has been established in Canada, this has not ensured that cannabis is suitably available to those in need... we have come to the conclusion that the MMAR have become a barrier to access. Rather than providing a compassionate framework, the regulations unduly restrict the availability of cannabis to those who may receive health benefits from its use [22].

According to this report, one of the main reasons for the small number of applicants to the program is reluctance by physicians to act as gatekeepers to medicinal

cannabis. Citing a perceived lack of information on dosage, side effects, and alternate routes of administration to smoking, both the Canadian Medical Association and the Canadian Medical Protection Agency (which insures nearly 95% of Canada's physicians) have warned against the therapeutic use of cannabis, and have recommended that doctors not participate in the federal program. For example, a CMA press release dated July 9th, 2003, declares:

The CMA has consistently raised concerns about the lack of evidence-based decisions to support the Medical Marijuana Access Regulations," said Dr. Dana Hanson, President of the CMA. "Our unease over use of medical marijuana has been ignored in this new policy. Physicians should not be the gatekeeper for a substance for which we do not have adequate scientific proof of safety or efficacy [23].

Such warnings have been a particular deterrent for medical specialists, whose support was initially necessary for all applicants to the program that were neither terminally ill nor likely to die in the next 12 months, such as those suffering from MS, HIV/AIDS and hepatitis C (terminal patients only required the support of a single physician). In addition, specialists were simply not available in many smaller rural communities. When compounded by the bureaucratic hurdle of filling out a 29-page application that sometimes took in excess of 12 months for Health Canada to process, the challenges to participation in this program ranged from onerous to impossible for many potential applicants.

Health Canada officially amended the MMAD application process in 2005 to remove the requirement of a supportive specialist under most circumstances. However, the new "simplified" application form was now 33 pages long, and potential applicants continue to face resistance from the medical community. The burden of this difficult application process is apparent in comparing the MMAD with the state-run Oregon Medical Marijuana Program (OMMP), one of twelve state-administered medical cannabis programs in the U.S. Although both programs originated in 1999 and have similar medical requirements for registration, Oregon's simple two page application process has led to the registration of 23,873 participants as of October 2009 (as compared to just over 4000 in Canada during the same period) - despite having a population one-tenth that of Canada [24].

Community-Based Dispensaries

Community-based medical cannabis dispensaries, also called "compassion clubs", supply cannabis for therapeutic use upon a valid recommendation or confirmation of

diagnosis from a licensed healthcare practitioner, and reflect a patient-centered response to the suffering of critically and chronically ill Canadians who might benefit from the medical use of cannabis [3-5,7].

During the late 1980's, as rates of HIV and AIDS began to rise in San Francisco, a few underground dispensaries began offering a safe source of cannabis to those needing it for medical purposes were established by compassionate people living with HIV/AIDS and drug policy reform activists. With the successful passage in 1996 of a state ballot initiative called "Proposition 215", California became the first U.S. state to allow for the legal medical use and distribution of cannabis. Within a few weeks dozens of these "compassion clubs" opened, and although they often had varied policies and practices, their common goal was facilitating access to a safe supply of cannabis for medical users [25]. Since then, over 1000 community-based medical cannabis dispensaries have opened up in California [26], and it is estimated that they currently supply over 250,000 state authorized patients [27]. Similar organizations have emerged all over the world, and in Canada and the U.S. these dispensaries remain the main source of cannabis-based medicines for therapeutic use [3].

In Canada, a loose network of community-based dispensaries provide over 30,000 critically and chronically ill Canadians access to a safe supply of cannabis within an environment conducive to healing [8]. Although Canadian dispensaries continue to operate without legal sanction or protection, communities, law enforcement, and criminal courts across Canada have shown support and tolerance for compassion clubs that self-regulate to ensure their services are strictly for medical purposes [3-5]

Quality of Service Assessment of Health Canada's Medical Cannabis Policy and Program

Although Health Canada hosted a stakeholder consultation in 2003 to address some of the early constitutional and bureaucratic deficiencies of the MMAR, the opinion of patients registered with the MMAD has never been officially polled by the federal government in any systematic manner. This survey is an attempt to address the dearth of information about actual patient experiences with medical cannabis and Health Canada's program.

The study was funded by the McMaster Arts Research Council, and ethics approval was granted by the McMaster Research Ethics Board. Data gathering took place from April 2007 to Jan. 2008, eventually garnering survey responses from 100 federally-authorized users, which at the time represented about 5% of the patients enrolled in Health Canada's program. The 50 item self-administered survey combines multiple choice and

open-ended questions, and includes items informed by validated questionnaires like the Short-Form Patient Satisfaction Questionnaire (PSQ-18) and a 2005 questionnaire designed by Belle-Isle and the Canadian AIDS Society to identify barriers to medical cannabis experienced by Canadians affected by HIV/AIDS [5,6]. In addition to basic socio-demographic data, survey questions generated by the researcher to address the history of involvement and experiences with the federal program, cannabis use patterns, and specific symptoms and conditions that cannabis has relieved.

For privacy reasons Health Canada does not make a list of federally authorized medical cannabis patients available to the public, so recruiting for this study was conducted through online and hard mail outreach to medical cannabis patient internet discussion groups and community-based dispensaries. In order to ensure that survey participants were federally authorized patients, respondents were asked to type in a specific word only found on the authorized user ID card supplied by Health Canada as a password to access the online questionnaire. Although the identity of survey respondents will be kept completely anonymous, participants were also asked to supply the registration number from their Health Canada medical cannabis ID card to allow for future verification/authentication if necessary.

Demographic Data

Study participants were > 78% male and 20.4% female, and > 87% were 35 or older. Over 93% report that they are Caucasian, with 3 participants identifying as First Nations, 2 as Metis, and 1 as “black” (n = 97). In terms of income 36.8% make less than \$20,000, and > 61% make less than \$30,000, so this is a group that is well below the medium income in Canada, which may be the result of physical disabilities stemming from serious and/or chronic medical conditions. Although a medical expense income tax claim can be filed for the cost of cannabis purchased from the government, or produced by individuals or their designated grower, there is currently no reimbursement of the actual costs of medical cannabis. In light of these findings, it is unsurprising that 46.3% of respondents state that they can “never” afford enough cannabis to relieve their symptoms. Despite the low-income levels, 77.8 had graduated from high school, and 22.3% had a university degree (Table 1). According to Statistics Canada, this is slightly higher than the Canadian average; the 2006 Census found that just over 76% of Canadians had graduated from high school, and that 18% had a university degree equivalent to a Bachelor’s or higher [28].

Although there is no way to verify that this limited sample is representative of participants in the MMAD, a recent study by Reinerman et al assessing population

Table 1 Demographics of Federally Authorized, Medical Cannabis Patients

Female	20.4%
Male	78.6%
Caucasian	93%
Metis	2%
Black	1%
Other	4%
18-24	2%
25-34	10.2%
35-44	23.5%
45-54	39.8%
55-64	23.4%
65-74	1%
Elementary School	5.1%
Secondary School	21.2%
Technical and Non-University Education	33.3%
University (Undergrad, BA)	18.2%
University (MA, PhD, post-doc)	5.1%
Less than \$10 000	8.2%
\$10 000-19 999	28.6%
\$20 000-29 000	24.5%
\$30 000-39 000	11.2%
\$40 000-49 000	5.1%
\$50 000-59 000	12.2%
\$60 000 and over	10.2%

characteristics of 1746 California-based medical cannabis patients offers some useful comparisons. Reinerman et al found that 72.9% of their sample was male, with the researchers theorizing that the underrepresentation of women may be related to the gender-distribution of certain kinds of sports or workplace injuries, as well as the “...double stigma women face in seeking MM (medical marijuana) - for using an illicit drug and for violating gender-specific norms against illegal behavior in general” [19].

Additionally, Reinerman et al found this population to be of slightly higher education levels than the general population, with 93.1% reporting at least high school graduation, and 23.8% having a post-secondary degree, which is also similar to this Canadian survey.

Patient Use Patterns and Preferences

While the overwhelming majority of participants reported using cannabis recreationally prior to their medical use, > 20% were cannabis-naïve prior to using it medically (n = 89). The average years of medical use is just over 10 years, which may be reflective of the older patient profile and additionally suggests that many patients have been using cannabis for far longer than Health Canada’s federal program has been in existence. When asked to check off all the major symptoms for

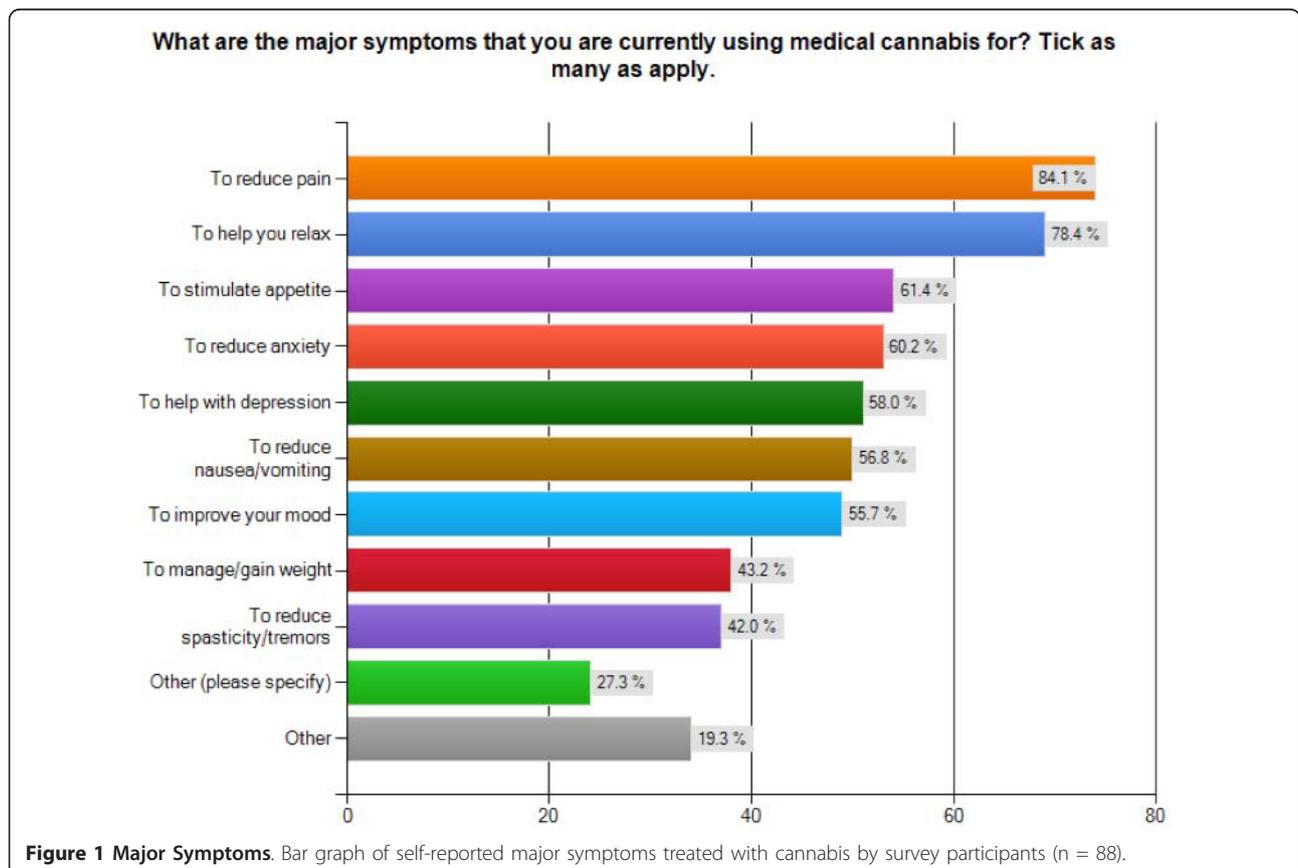

which they used medical cannabis, most cited multiple symptoms: 84.1% cited pain relief, 78.4% cited relaxation, 61.4% cited appetite stimulation, 60.2% cited anxiety reduction, 58% cited depression, 56.8% cited nausea reduction/vomiting, 55.7% cited mood improvement, 43.2% cited desire to manage/gain weight, 42% cited reduction in spasticity/tremors, and 23.9% cited side-effects of other medications. Of interest is the high number of individuals using cannabis for relaxation, anxiety reduction, depression and mood improvement, suggesting that patients with physical health conditions may also be self-medicating for mental health issues and/or general improvements in their quality of life (Figure 1).

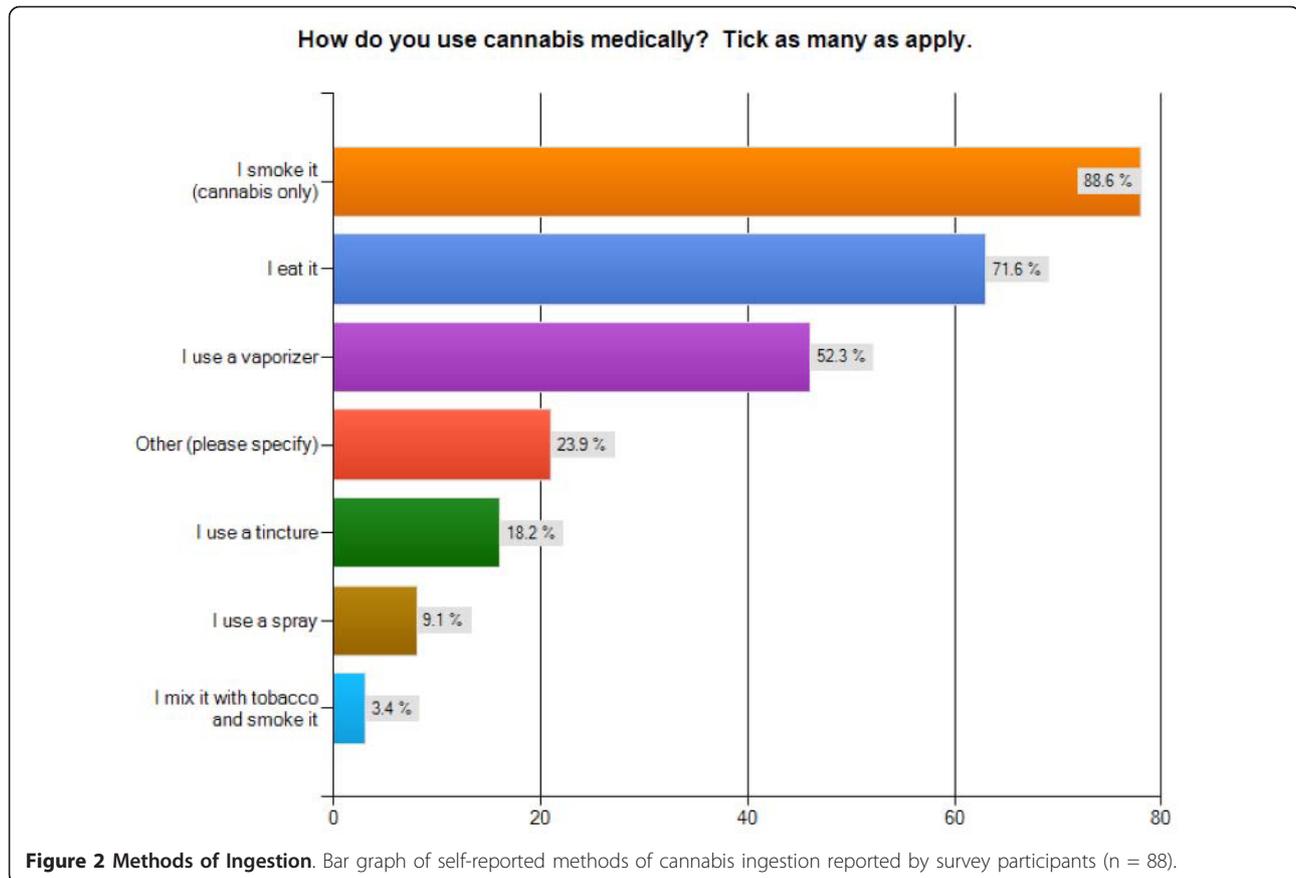

In terms of personal use patterns, over 94% stated that they use it every day, which is considerably higher than the 67% reported by Reinarman et al from their California patient survey [19]. Over 88% smoke cannabis, and 71.6% report that they eat it. Over 52% have used vaporizers, 18.2% use tinctures and, unlike Europe, less than 4% mix it with tobacco. While the rate of smoking is similar to the Reinarman et al sample, which found that 86.1% smoke cannabis [19], the comparatively higher use oral ingestion/edibles (71.6% v. 24.4%) and vaporizers (52% v. 21.8%) in the Canadian sample may suggest

a greater level of concern and mitigation for potential health impacts associated with smoking within the Canadian patient population [29] (Figure 2). This health awareness may also explain why 80.7% of respondents prefer to use cannabis grown using certified organic cultivation methods, whereas 19.3% either don't care (14.5%) or prefer non-organic cultivation (4.8%).

In terms of patient preferences and treatment efficacy, 90.9% report that not all strains are equally effective at relieving their symptoms. As a result, 97.6% would prefer to obtain cannabis from a source that offers a "large selection of different strains" rather than 1 or 2 strains, and over 90% would prefer to have access to raw cannabis as well as other methods of ingestion like baked goods, tinctures, and hashish, compared with 9.8% who would prefer a cannabis-only outlet. This creates a stark contrast between access through Health Canada and through community-based dispensaries. While Health Canada offers a single strain of raw cannabis and no alternatives to smoking, dispensaries make multiple strains and methods of ingestion other than smoking available to patients, including edibles, oils, tinctures, salves, and even oromucosal sprays [3].

When asked about other cannabinoid-based pharmaceutical medicines like Marinol (dronabinol), Cesamet

(nabilone) and Sativex, 34.9% had tried Cesamet, 33.7% had tried Marinol, and 14% had tried Sativex. 43% had not tried any of the above, and 81.5% stated that didn't use any of these pharmaceuticals on a regular basis.

Patient Access to Medical Cannabis

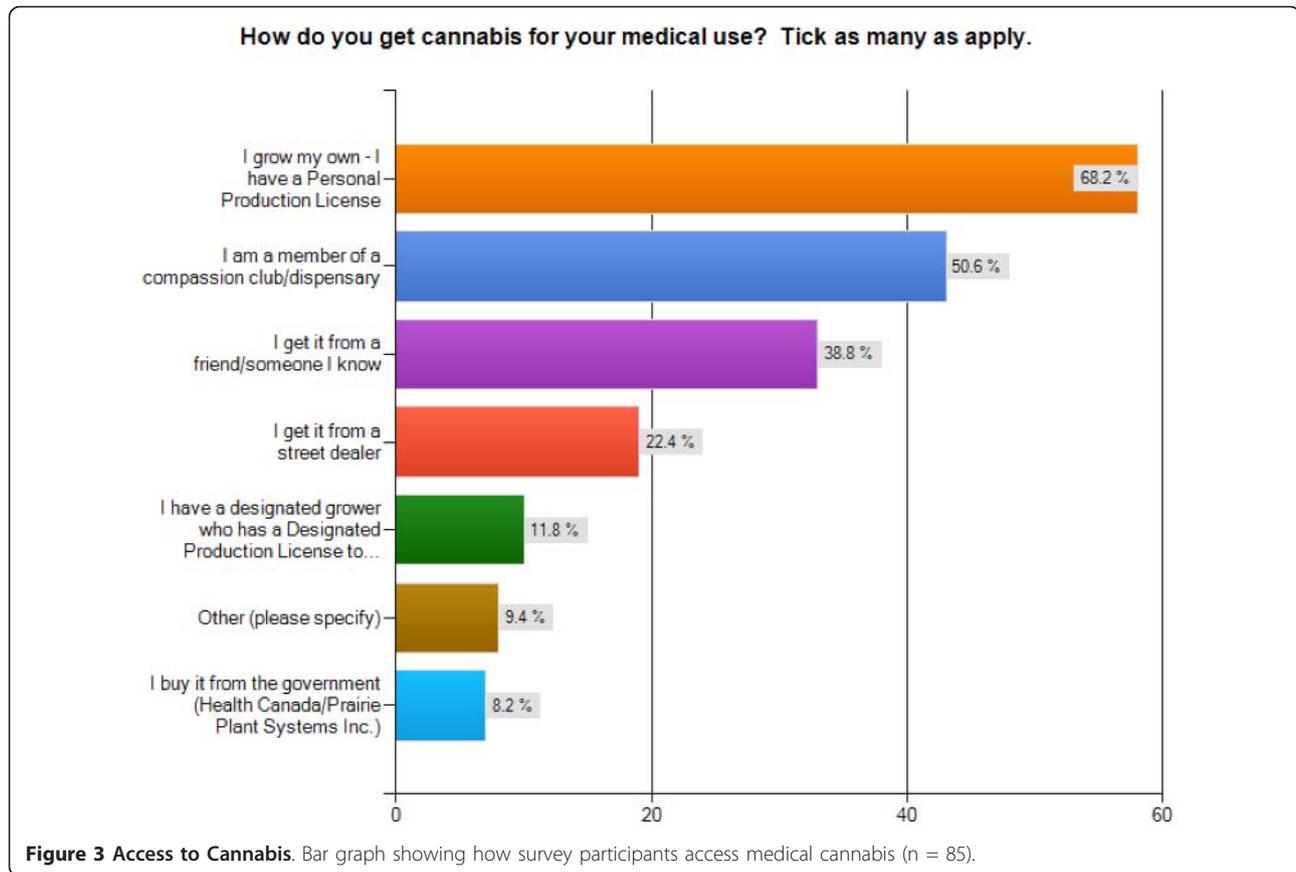

When asked how they obtain cannabis, only 8.2% of respondents report getting their cannabis from Health Canada (although nearly half state that they have tried the federal supply), while 80% grow it for themselves or have it grown for them by a Designated Producer. Over 50% report that they frequent compassion clubs or dispensaries, 38.8% report getting it from a friend, and > 22% get their medicine from street dealers (Figure 3).

When asked how they would rank the quality of the cannabis from their regular source, 87.8% rank it as 7 or above in a scale of 1-10, with 1 being "Very Poor", and 10 being "Excellent". By comparison, of the 41 patients who have tried the federal cannabis supply, over 75% rank it as either 1 or 2 on a scale of 1-10. While 3 respondents ranked it as either a 6, 7, or 8, no one ranked it any higher (Figure 4).

Since Health Canada's cannabis supply went through some modest improvements in regards to the size of the grind, humidity level, and amount of THC in August

2004, respondents were asked when they tried this cannabis. Of the 39 who answered this question, 37 (or > 94%) used the federal supply between 2005-2007, and 2 used it before that. As such, it can be deduced that the general dissatisfaction with the quality of the federal cannabis supply is based on patient experiences with the most recent "improved" version of this product.

When asked what their single preferred source for medical cannabis would be, 65.1% stated that they would like to grow their own, 24.1% cited dispensaries, 6% would like to get their medicine from a pharmacy, 4.8% would like to get it from a friend, while neither street dealers nor Health Canada were cited by a single patient as their preferred source. This is highly relevant since Health Canada's proposed regulatory changes include removing the right for individuals to produce their own cannabis, despite this being the preferred option cited by most study participants and the option chosen by the majority of patients in the federal program [30]. As of January 2010 (the latest statistics available on the Health Canada website) 3576 out of 4884 - or over 73% - of federally authorized patients chose to produce their own medicine or to have a Designated Producer do so for them [21]. If Health Canada intends to make this program more patient-centered, removing

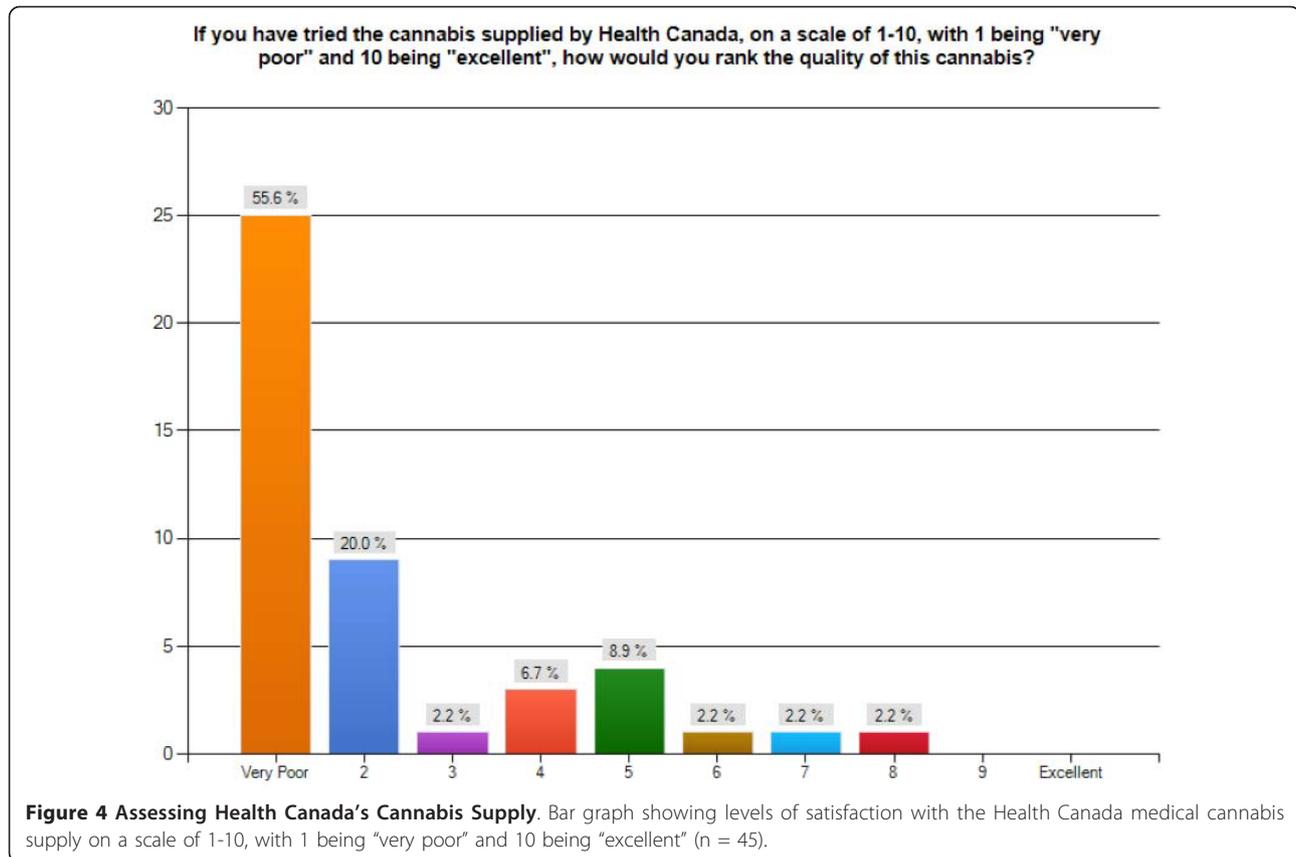

the right for patients to produce their own supply does not appear to reflect current patient needs, and as such this proposed significant amendment to the program should be highly controversial, and will likely lead to further court challenges by patients wishing to control the cost and quality of their supply of medicine.

Patient Experiences With Health Canada Marijuana Medical Access Division

Of study participants, nearly half (49.3%) became federally authorized patients in 2004 or later, while 50.7% joined the program prior to 2004. When asked if they had difficulty finding a physician to support their application, exactly 50% said “yes”, and 50% answered “no”, reflecting the diversity and unpredictability of medical support available throughout Canada. In terms of processing applications, 35.3% had theirs completed by Health Canada within 2-4 months, and 29.4% state that it took 60 days or less. However, 35.2% of participants suggest that it took over 4 months, with 17.6% citing that they waited over 12 months for their application to be processed. This suggests that for those suffering from serious or terminal conditions, processing times would be a significant concern and may not be quick enough

to allow some patients to legally use cannabis in end-of-life situations.

The following set of 6 questions put three statements with positive connotations and 3 statements with negative connotations to survey respondents, and are based on standardized and validated Short-Form Patient Satisfaction Questionnaire (PSQ-18) traditionally used to evaluate health service delivery at hospitals, clinical and insurance companies. In addressing the statement “I find the application for a federal authorization simple and uncomplicated”, only 21.8% “agreed” or “strongly agreed”, while 71.2% “disagreed” or “strongly disagreed” (42.5%), suggesting that for most patients the federal application process is onerous and challenging. When asked to comment on the statement “Employees at Health Canada’s MMAD act too businesslike and impersonal towards me”, 54% “agreed” or “strongly agreed”, while 28.7% “disagreed” or “strongly disagreed”. In regards to the statement “I am dissatisfied with the service I receive from Health Canada in regards to my use of medical cannabis”, 68.9% “agree” or “strongly agree”, while only 18.3% “disagree” or “strongly disagree”. However, when asked if “Employees at Health Canada’s MMAD treat me in a friendly and courteous manner”, respondents were split, with 35.6% “agreeing” or “strongly

agreeing", 27.6% "uncertain", and 36.8% "disagreeing" or "strongly disagreeing". When the statement "I have full confidence in the ability of the Health Canada employees that administer this program" was put to patients, 76.8% "disagreed" or "strongly disagreed", with only 5.9% "agreeing" or "strongly agreeing" with the statement, and 17.4% stating that they were "uncertain". Finally, when asked "I am able to get help from Health Canada in regards to my medical use of cannabis whenever I need it", 8.2% "agreed" or "strongly agreed", while 70.6% "disagreed" or "strongly disagreed", with 21.2% uncertain.

The final question of the survey asked participants to rate their overall satisfaction with Health Canada's medical cannabis program, and 15.1% of patients state that they are "completely" or "somewhat satisfied", 12.8% uncertain, and 72.1% either "somewhat" (20.9%) or "totally unsatisfied" (51.2%) (Figure 5). This suggests a very poor patient perception of the service quality at Health Canada Marihuana Medical Access Division, with many potential improvements in application processing times, cannabis selection and quality and overall responsiveness to patient queries and concerns.

In a federally-funded report titled "Our Rights, Our Choice," which examined the human rights, ethical and legal challenges faced by people living with HIV/AIDS

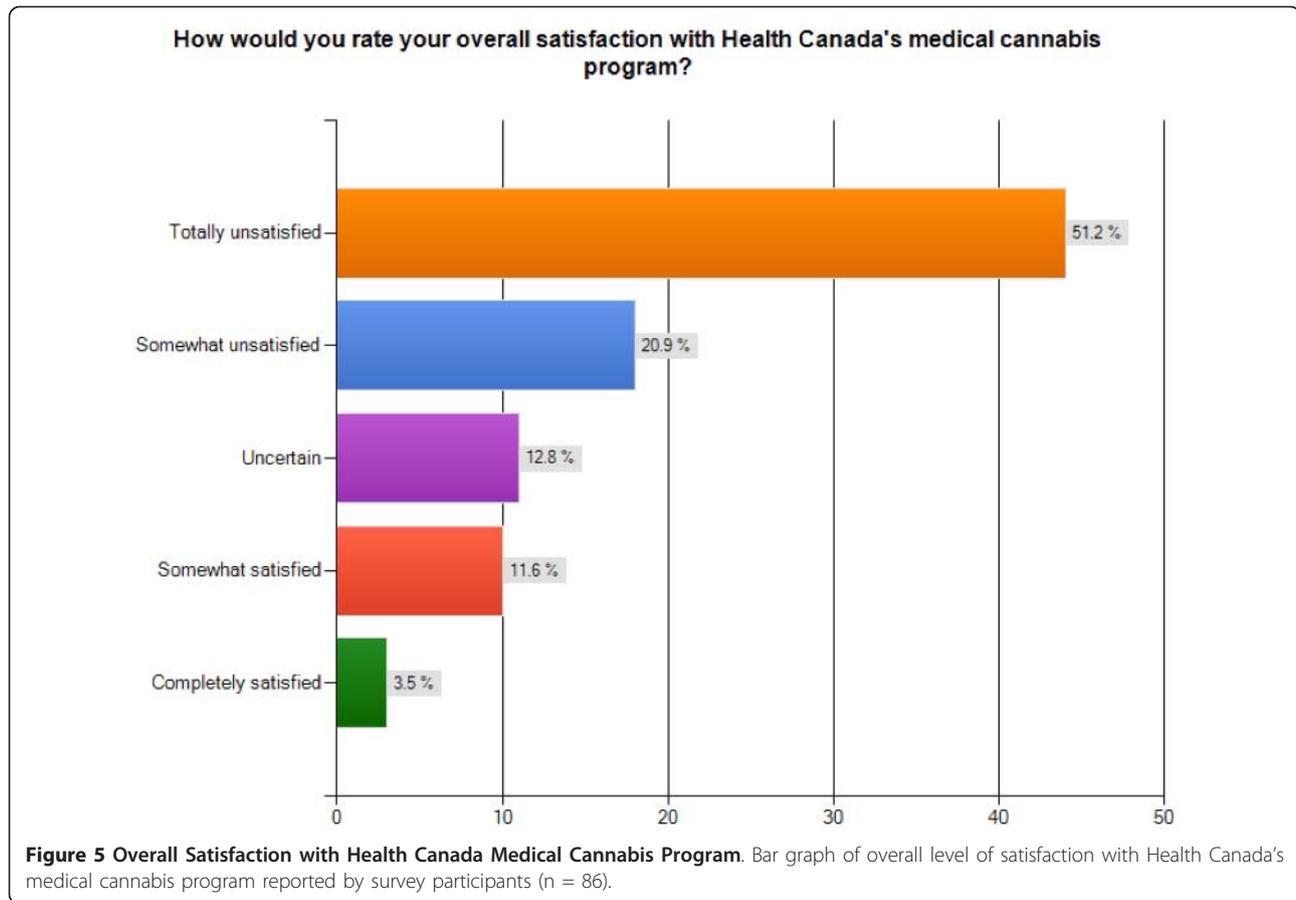

who choose to use medical cannabis, the Canadian AIDS Society found that although between 14 to 37% of people living with HIV/AIDS used cannabis to address their condition, many had faced hurdles accessing the federal program. The CAS report states that:

access to the federal program remains hindered by barriers such as a lack of awareness of the program's existence, mistrust in the government, misinformation about the program and difficulty in finding a physician to support their application. Thousands of seriously ill Canadians must therefore choose between breaking the law to use the therapy of their choice, or going without, which in many cases compromises their well-being and quality of life [6].

The results of this federally authorized medical cannabis patient survey support the findings of the CAS study and other research into the MMAR/MMAD [3-5].

Discussion

Creating policies and procedures for safe patient access to medical cannabis has proven to be a challenge in Canada and around the world. In the U.S., the 14 states that allow for the legal use of cannabis continue to

struggle to protect patients, address access issues, and mitigate community concerns, all of which is made all the more complicated by ongoing resistance and active legal threats by the federal government [7]. In Canada, patients face multiple challenges to safe access: 1) resistance from the medical community to act as gatekeepers to the program; 2) an onerous application process; 3) a very limited and much-criticized cannabis supply; 4) limited income and a lack of national cost-coverage; and 5) ongoing social prejudice against the use of medical cannabis [3-6]. Results from this survey suggest that reducing bureaucratic obstacles while increasing patient options for access would result in greater levels of patient participation and overall satisfaction with the federal program.

While there is a remarkable diversity in the demographics and medical conditions of cannabis patients, some common themes emerge from this research. It is clear that patients' would like to have a choice of many different strains and forms of ingestion in order to more safely and effectively address their many different symptoms and conditions. Since cost continues to be a significant obstacle for patients with low or fixed income, provincial or federal cost-reduction or coverage policies

should be implemented [5,6]. The high bureaucratic burden on both patients and physicians is reducing participation in the program, so allowing healthcare providers to treat cannabis like any other medicine would likely improve uptake and might also alleviate some of the social stigma associated with the therapeutic use of cannabis. Since this study and Health Canada's own statistics [21] show that the majority of participants in the Canadian federal program chose to produce their own medicine, policies and procedures should be put in place that maintain the option of personal production while also ensuring that both patients and communities are protected from the dangers of poorly-cultivated cannabis. This could range from basic information from Health Canada on safe production practices to electrical inspections at the municipal level. Additionally, with over half of respondents currently accessing cannabis through dispensaries and growing evidence that these organizations build social capital and provide an environment that is conducive to health and healing [3-7], the federal government should work with dispensaries to develop regulations that would incorporate this community-based model of access into Canada's medical cannabis program.

Finally, many of the challenges faced by the MMAD could have been addressed or avoided through a more robust and active strategy for patient engagement and involvement. Although there are many stakeholders directly or indirectly affected by the federal medical cannabis program - municipalities, police, physicians, etc. - the key stakeholders are the Canada's critically or chronically ill who could or do benefit from the use of cannabis. Unfortunately, the short history of the MMAR/MMAD shows that the needs and concerns of patients has all too often been ignored or overshadowed by other interests and concerns [3-6]. The future success of this cutting-edge program will depend largely on the willingness of the federal government to create a truly patient-centered approach to medical cannabis access, including active and ongoing engagement with end-users, support for research into the potential harms and benefits of medical cannabis, and increased options for patients, potentially through the regulation of community-based dispensaries.

There are a few limitations to this study. Although participants represented about 5% of the patient population in the program at the time of the survey there is no way to know how representational this cohort is to the rest of the participants in the MMAD since Health Canada has never released any demographic information about federally authorized users. Additionally, since recruiting was largely done online and through medical cannabis patient lists and groups, it is possible that this more active population has a higher level of dissatisfaction with the federal program. However, the general demographics of participants in this study is similar to those identified by Reinerman in a recent U.S.-based study [19], and many of the patient needs and challenges that came to light in this survey support previous research on Canada's medical cannabis population and associated federal program [3-6]. It is hoped that this survey, which represents the first polling ever conducted solely on federally authorized patients in Canada, will assist policy-makers here and abroad develop more patient-centered strategies for safe access to medical cannabis.

Acknowledgements

The author would like to gratefully acknowledge all of the federally authorized medical cannabis patients who took time to share their experiences by participating in this survey. Additionally, I'd like to thank the McMaster Arts Research Council for funding this study, Andy Hathaway PhD for coordinating the interview component of this research project, and Lynne Belle-Isle PhD Candidate for translating the questionnaire into French.

Abstract

Background: The New South Wales State Government recently proposed a trial of the medical use of cannabis. Australians who currently use cannabis medicinally do so illegally and without assurances of quality control. Given the dearth of local information on this issue, this study explored the experiences of medical cannabis users.

Methods: Australian adults who had used cannabis for medical purposes were recruited using media stories. A total of 147 respondents were screened by phone and anonymous questionnaires were mailed, to be returned by postage paid envelope.

Results: Data were available for 128 participants. Long term and regular medical cannabis use was frequently reported for multiple medical conditions including chronic pain (57%), depression (56%), arthritis (35%), persistent nausea (27%) and weight loss (26%). Cannabis was perceived to provide "great relief" overall (86%), and substantial relief of specific symptoms such as pain, nausea and insomnia. It was also typically perceived as superior to other medications in terms of undesirable effects, and the extent of relief provided. However, nearly one half (41%) experienced conditions or symptoms that were not helped by its use. The most prevalent concerns related to its illegality. Participants reported strong support for their use from clinicians and family. There was almost universal interest (89%) in participating in a clinical trial of medical cannabis, and strong support (79%) for investigating alternative delivery methods.

Conclusion: Australian medical cannabis users are risking legal ramifications, but consistent with users elsewhere, claim moderate to substantial benefits from its use in the management of their medical condition. In addition to strong public support, medical cannabis users show strong interest in clinical cannabis research, including the investigation of alternative delivery methods.

Background

While cannabis has long been part of folk pharmacopeia, there is a burgeoning body of research on its therapeutic potential. This has largely drawn on scientific advances in our understanding of the pharmacology of cannabis, and its complex interactions with the central nervous system, particularly endogenous brain reward pathways [1]. In addition to basic experimental research, case reports, sur-

veys of people using cannabis for medical conditions and prospective clinical trials of cannabis-based medicines are consolidating the evidence that cannabis may play a role in the management of some medical conditions. Authoritative reviews of this evidence indicate that cannabis has therapeutic potential for conditions such as HIV- and cancer-related wasting, nausea and vomiting resulting from

chemotherapy, neurological disorders such as multiple sclerosis and chronic pain [1-4].

While current research reveals exciting therapeutic opportunities, there is an ongoing debate about the virtues of obtaining such benefits from the complex chemical cocktail contained in the whole plant or from one or more components isolated and developed into a synthetic pharmaceutical product. This debate cross-cuts important issues such as the difficulties of reliable dosing when using the natural product, whether the potential harms of smoking cannabis due to its ease of titration overshadow its therapeutic benefits, and whether different medical conditions will respond more favourably to the whole plant or to different constituents in isolation or combination. However, underlying these issues is the reality that most people who use cannabis medicinally do so by using black market supplies of an illicit drug.

As with the opiates, evaluations of the therapeutic potential of cannabis occur in the context of a vigorous political debate on the use of an illicit drug with dependence potential for medicinal purposes. This situation is clearly evident in the United States, where there is an ongoing legal challenge by the Federal Government over the States' rights to allow cannabis to be used by registered medical users. Despite Canada's recent decision to provide a controlled supply of natural cannabis to registered users, and approvals for the marketing of Sativex, a pharmaceutical cannabis extract, in some countries, currently most users would rely on home-grown cannabis, or supplies obtained from friends, families, dealers and medical compassion clubs.

To date, there has been little interest in Australia in formally investigating the therapeutic potential of cannabis or investigating the practices of current medical users. In 1999 the NSW State Government commissioned a Working Party to investigate the issue and recommend research and legislative options. Among their recommendations were: controlled clinical trials of cannabis, investigations into delivery methods other than smoking, surveys of current medical cannabis users and legislative amendments to allow compassionate use [4]. Subsequently, in 2003 the NSW Government announced it would conduct clinical trials, but despite generating significant publicity, there has been no further commitment by the NSW Government on this issue. The 2004 National Drug Strategy Household Survey found widespread public support for medical cannabis use, with 68% supporting a change in legislation to permit use for medical purposes and 74% supporting a clinical trial of medicinal cannabis use [5]. It is not known how many people use cannabis for medicinal purposes in Australia. Those who do use it engage in an illegal behaviour and risk arrest. Those that rely on

black market supplies use a product of unknown source and quality.

Several surveys in the US, UK, Germany and Canada [6-12] have reported perceived improvements in a variety of medical conditions following cannabis use. However, we know very little about the experiences of Australian users, and how they compare to findings in other studies. These authors are aware of only two unpublished Australian studies conducted in northern NSW; in 1998 a survey of 202 users recruited at the Nimbin HEMP Embassy [13], and in 2003 a survey of 48 members of a medical cannabis information service [14].

This paper presents the results of a study of 128 users, which aimed to learn more about their patterns of use, experiences and concerns, and interest in participating in a medical cannabis trial.

Methods

Sample

The sample comprised 128 people who used cannabis for medical purposes. To be eligible for the study, participants had to be living in Australia and to be currently using/have previously used cannabis for medical purposes. While the study targeted residents of Australia's most populous state, NSW (pop: approximately 6.7 million), we did not exclude participants from other parts of Australia (total pop: approximately 20 million).

As it is not known how many Australians use cannabis for medical purposes it was not possible to obtain a representative sample of such users. As this was an exploratory study to see who responded to a general call for participation in the survey, we did not target groups representing people with specific medical conditions (e.g., HIV/AIDS, multiple sclerosis) or hospital departments known to treat patients who may benefit (e.g., oncology, chronic pain clinics). Participants were primarily recruited from opportunistic media stories between November 2003 and August 2004, in newspapers, on radio and television. In addition, the Medical Cannabis Information Service (MCIS) in Nimbin, NSW, offered to tell its members about the survey and the International Association for Cannabis as Medicine (IACM), in Germany, placed the questionnaire on its website.

A total of 147 enquiries were received between December 2003 and August 2004 by telephone and email and approximately 170 questionnaires distributed (some people requested multiple copies to distribute). For example, the media stories generated enquiries from several GPs who said they would inform certain patients of the study. Of the 131 questionnaires returned, 128 were used for analysis (75% of questionnaires sent out). Of the three

Table 1: Conditions/symptoms experienced, duration, and conditions/symptoms requiring cannabis relief (n = 128).

Condition	(%) with condition	Median duration (yrs)	% used cannabis for relief of..*
Depression	60	10	56
Chronic pain	53	10	57
Arthritis	38	9	35
Migraine	22	18	17
Weight loss	21	4	26
Persistent nausea	20	6	27
Spinal cord injury	14	11	13
Spasms (spasticity)	13	8	16
Fibromyalgia	13	13	13
Wasting	13	5	11
ME (chronic fatigue)	13	16	13
Neuralgia/neuropathy	12	8	12
HIV/AIDS	9	15	8
Multiple sclerosis	7	9	7
Cancer	6	10	4
Other neurological disorder	6	5	6
PTSD	5	13	1 person
Irritable bowel syndrome	4	10	1 person
Glaucoma	3	29	2

*These figures do not necessarily equate with the % reporting a particular condition because some people reported using cannabis to relieve the particular symptoms (e.g., chronic pain, nausea) associated with a condition, rather than citing they used cannabis to relieve the condition itself (e.g., arthritis, cancer).

discarded questionnaires, one respondent was a recreational cannabis user and two had never used cannabis.

Questionnaire

The survey comprised an anonymous mail-out questionnaire, adapted from one developed by the MCIS in a recent study of its members [14]. Several issues were covered, including medical conditions/symptoms experienced, patterns of medical cannabis use, symptom relief and effects of use, comparison of cannabis to other medications, source and legal concerns (e.g., arrest), other concerns over use, opinion of family, friends and medical personnel, and interest in participating in a cannabis trial. The final version incorporated comments from researchers and clinicians interested in this issue.

Procedure

The study received ethics approval from the University of New South Wales Social/Health Human Research Ethics Advisory (HREA) Panel. Interested persons were screened for eligibility over the phone and informed of the purpose of the survey; assurances of anonymity and confidentiality were provided. Questionnaires were mailed to participants, completed anonymously and returned in a stamped, self-addressed envelope. Addresses were destroyed when the questionnaire was posted.

Analyses

Data were entered into SPSS (Version 12.0.1). As this was an exploratory study with a small sample size, this paper reports descriptive statistics only. Percentages are presented for categorical data; means (for normally distributed) and medians (for skewed data) are presented for continuous data. While data are usually presented on the overall sample, gender and age differences are presented for some variables, where they are of interest.

Results

Demographics

The sample was 63% male. Participants had a median age of 45 yrs (range 24–88), with almost one third (31%) aged 50 years or over, and one in ten (9%) aged 60 years plus. While the study targeted NSW residents (who represented 58% of participants), responses came from across Australia, especially Queensland (15%) and Victoria (12%). Residents of other States and Territories each comprised less than 3% of participants.

Participants reported a wide range of medical conditions and symptoms associated in the literature with the use of medicinal cannabis (Table 1), most commonly chronic pain (53%) and arthritis (38%). Approximately one in five reported migraine (22%), weight loss (21%) and persistent nausea (20%). However, depression was the most commonly reported condition/symptom (60%). Up to 35 other conditions/symptoms were listed, most commonly

Table 2: Patterns of medical cannabis use (n = 128 unless specified)

post traumatic stress disorder (PTSD) (5%) and irritable bowel syndrome (4%). It is important to note that we did not ask participants to distinguish between primary symptoms/conditions for which they sought treatment (e.g., cancer) and conditions which may have been secondary to this (e.g., depression) or consequent to treatment (e.g., chronic nausea). Multiple conditions (mean = 3.7, SD = 2.1, range = 1–10), of lengthy duration, were the norm, with three quarters (84%) reporting more than one condition and two thirds (67%) at least three conditions. Congruent with this picture, cannabis was used to relieve multiple symptoms (median = 3, range = 1–12), especially chronic pain (57%), depression (56%), arthritis (35%), persistent nausea (27%) and weight loss (26%).

Patterns of medical cannabis use

Participants had first tried cannabis for medical purposes at a median age of 31 years (range = 14–77). More than one quarter (29%) had discovered its therapeutic benefits as a spin-off from recreational use; others had tried it following concerns about the side-effects of their medications (14%), or a belief their medications or treatment were ineffective (13%), or had acted on the recommendation of a medical practitioner (10%) or friend (10%).

Table 2 presents data on patterns of medical use. Most (85%) were currently using cannabis therapeutically, even if sporadically. For those who had stopped, the main reasons were: their inability to obtain a regular supply (9/19 people), its illegality (7/19), cost (7/19) and disliking the side effects or route of use (each 3/19). Of those using intermittently, many reported their use would be more regular if it were more readily availability and cheaper.

Medical use was typically long-term and regular. Use of less than one year was uncommon (12%), with more than half (61%) having used it for at least six years; one in five reported very long-term use (more than 20 years). Most used at least weekly (75%), and more than half (59%) used almost daily or daily. Approximately one in five (22%) specified they used it "as required" for their condition (e.g., when pain was severe). Women tended to report shorter term use than men (52% vs. 31% citing use of 5 years or less).

It was most common for participants' medical use to be stable (22%) or largely unchanged since they started (17%), although it was most common for the amount used to vary according to their condition (35%). About one in ten indicated some increase in dose had been required (12%), while few reported a decrease (5%). Women tended to report more variable (44% vs. 29% of men) or short term use (15% vs. 6% of men); men tended to report an increase in the amount needed (17% vs. 4% of women).

In addition to medical use, three quarters (80%) of participants had used cannabis recreationally. Recreational use was less common among older participants (75% and 97% of recreational users were aged less than 50 years and 65 years, respectively). For almost half (46%), use in the past year had been solely medicinal, but the remainder reported recent recreational use – 29% in the past week, 19% in the past month and a further 6% in the past year.

Route of use

While most people had tried multiple routes for relief, overall smoking was the route most commonly reported (91%). Approximately half the sample (49%) also

smoked tobacco, and two thirds (64.1%) mixed their cannabis with tobacco.

Eating cannabis in cooked recipes was also very prevalent (49%). While vaporisers are not readily available in Australia, 8% had used them. In addition, four people had used tinctures and one used it topically in the bath or as a cream for a skin condition. Overall, smoking was also considered to be the most *helpful* route of use for symptom relief (74%), although concerns about this route of use were widespread. Consistent with Australian research on preferred route of use and age [15], older users (aged 50 years +) typically found joints the most helpful method of use (41% vs. 26% of younger users), while younger users preferred the use of waterpipes (43% vs. 13% of older users).

When asked to comment on the good and bad points of different methods of ingestion the most consistent response was that smoking of any form, particularly with tobacco, was detrimental to respiratory function (and health). This was of particular concern to non-smokers, some of whom did not know how to cook cannabis recipes. Despite attracting the bulk of negative comments, its popularity seemed to lie with its instant effect, its ease of titration and cost-effectiveness compared to the oral route. It seemed to "do the job". Eating was seen to be a much healthier option – it was "safer", tasty when cooked in a recipe, less obvious than smoking and could be done virtually anywhere. Some people liked its slow onset and long-lasting effects, but others claimed difficulties with titration and slow onset made it expensive and ineffective for rapid symptom relief.

Effects of cannabis use

When asked to rate the overall effects of cannabis on a Likert scale ranging from "I feel a lot worse" to "gives me great relief", cannabis was perceived to provide "great relief" (86%) or a little relief (14%). No one believed it had been detrimental to their condition or symptoms.

Positive ratings were ("great" or "good" relief) were also typical for its ability to relieve specific symptoms (Table 3). In addition, several other symptoms were noted, primarily insomnia (13% used for insomnia; of these 82% derived "great" relief).

Approximately three quarters of participants (71%) claimed to have experienced a return of their symptoms or condition on stopping cannabis, especially: pain (53% of those who claimed a return of symptoms), depression or anxiety (30%), insomnia (11%), spasm (10%) and nausea/vomiting or lack of appetite (9%).

Table 3: Symptom relief (n = 128)

Symptom relief required...*	Total (%)	Male (%)	Female (%)
Nausea relief	48	56	44
Of these, received:			
great relief	53	51	62
good relief	44	46	35
no effect	3	3	4
Pain relief	83	83	83
Of these, received:			
great relief	55	49	65
good relief	45	52	35
no effect	0	0	0
Ability to cope emotionally	66	70	60
Of these, received:			
great relief	45	40	54
good relief	54	58	46
no effect	1	2	0
Appetite stimulant	51	55	44
Of these, received:			
great relief	52	55	48
good relief	46	46	48
no effect	2	0	5
Decrease in spasms/tremor	39	36	44
Of these, received:			
great relief	43	43	43
good relief	55	54	57
no effect	2	4	0
Relief through relaxation	83	88	75
Of these, received:			
great relief	72	69	78
good relief	28	31	22
no effect	0	0	0

* No-one reported their condition was made worse

Only one in ten (11%) participants reported symptoms they believed were unrelated to their medical condition upon stopping cannabis, citing symptoms congruent with cannabis withdrawal such as anxiety or mood disturbance (including paranoia), insomnia, loss of appetite, restlessness and vivid dreams.

Comparison with other medicines

Almost two thirds (62%) of respondents claimed that they decreased or discontinued their use of other medicines when they started using cannabis medicinally. This was more common in males (65% vs. 58% of females) and older participants (aged 50 years +) (70% vs. 59% among younger participants). For some people this was a

Table 4: Comparison of cannabis with other medications (n = 128 unless specified).

	Total	Male	Female
Decreased or discontinued use of other medicines (n = 117*)	62%	65	58
Comparison of undesirable effects (n = 125)			
Cannabis produced much worse effects than other medicines	1	0	2
Cannabis produced somewhat worse effects	2	4	0
Undesired effects about the same	8	8	9
Other meds produced somewhat worse effects than cannabis	16	14	19
Other medicines produced much worse effects than cannabis	41	40	43
I have no undesirable effects from cannabis	31	33	28
Other medicines work differently	1	1	0
Comparison of relief provided (n = 118*)			
Other medicines work much better than cannabis	3	0	7
Other medicines work a bit better than cannabis	3	4	0
Other medicines work about the same as cannabis	9	8	9
Cannabis works a bit better than other medicines	13	11	15
Cannabis works much better than others medication	54	58	48
Only cannabis gives me relief from my condition	15	15	15
Other medicines work differently	2	0	4
Can't distinguish – use them together	1	1	2
Use cannabis to relieve side effects of other medicines	1	1	0

*Some people did not use other medications concurrently

substantial change, representing a shift away from chronic, high-dose medication use.

Perhaps not surprisingly, cannabis was typically perceived as superior to other medications in terms of undesirable effects, and the extent of relief provided (Table 4). Thus, cannabis was rated to produce equivalent (8%) or worse side effects (3%) by a minority of therapeutic users. It was considered to work "a bit" or "much better" than other medicines, or to be the only source of relief, by more than three quarters (82%). Two participants made the interesting comment that cannabis worked *differently* to other medicines, so could not be directly compared.

Despite the very positive response to the use of cannabis, nearly one half (41%; 36% of men and 50% of women) found it did not help certain conditions/symptoms. Almost one third (29%) said cannabis was less effective for certain types of pain, or extreme pain, with a further 12% specifying migraine or headache pain. Nearly one in ten (8%) reported no effect on depression or anxiety. More than one in ten (14%) specified that while cannabis could ease their symptoms and enabled them to cope, they realised that it could not cure their underlying condition. Younger participants were more likely than older participants to claim a condition not helped by cannabis (45% vs. 32% of those aged 50 years +).

Supply issues

Participants obtained medical cannabis from multiple sources (median = 1, range = 1–6; 44% had two or more sources), especially friends or family (58%) and dealers (42%). A substantial proportion grew their own (38%) while few (6%) obtained it from a compassion club or cooperative. Among those who purchased cannabis, the median weekly outlay was \$50 (range = \$1–\$500, n = 95).

When asked to comment on the variability of the cannabis they used, those who could obtain a consistent supply of high quality cannabis that suited their needs were in the minority. Typically, participants noticed variability along a number of lines, such as potency, effectiveness, intoxication and side-effects, which made titration difficult. While some noted the importance of factors such as the part of the plant used (e.g., leaf versus head/buds), strain (e.g., *sativa* versus *indica*), soil and climate, the overwhelming responses focussed on hydroponic versus soil-grown cannabis ("bush bud" or home grown cannabis), and home grown cannabis versus purchased cannabis.

Hydroponic cannabis was almost universally unpopular and was avoided where possible – despite its greater potency, it was also considered shorter acting, produced greater tolerance and worse side-effects than other cannabis. By comparison, soil-grown cannabis was perceived to

be less unpleasantly potent, natural ("organic"), less chemically treated, and with fewer side-effects. However, it was also perceived as harder to get. Home grown cannabis was seen as the best method of obtaining a consistent, safe supply of medicinal quality. A common response was that purchased cannabis was not to be trusted, and that unscrupulous growers who were more concerned with yield and greed compromised the quality of their crop with chemicals such as growth hormone and pesticides.

Concerns

A minority (13%) had no concerns over their medical cannabis use. Concerns over potential health effects (32%) or the risk of dependence (21%) were overshadowed by those relating to its illegal status (76%), the fear of being arrested (60%) and cost (51%). Indeed, one quarter (27%) claimed to have been arrested, cautioned or convicted in relation to their medical cannabis use, with this outcome more commonly reported by men (31% vs. 19% of women) and younger users (30% vs. 16% of users aged 50 years +). Other concerns mentioned (15%) were: the stigma of using, issues around parenting, pregnancy and relationships, availability, quality and difficulties in dose adjustment.

Support from others and interest in clinical trial

Most participants had a regular doctor (90%) and about a half had a regular specialist (55%). Virtually all (90%) had informed a clinician of their therapeutic use, typically reporting a supportive response from GPs (75% of those told), specialists (74%) and nurses (81%). Family and friends were largely considered supportive of the participant's use (71%).

Not surprisingly, there was widespread support for Government provision of cannabis to patients in a variety of circumstances. At least three quarters supported the supply of cannabis to any patient who was permitted to use it by being registered under a Government scheme (82%); more specifically, those patients who: could not afford to buy it on a regular basis (82%), could only purchase it on the black market (81%), couldn't ensure a consistent supply (75%), or were worried about quality control issues (77%). More than half endorsed the supply of patients who did not know anyone capable of growing it (72%), were concerned about hydroponically grown cannabis (72%), or who needed a supply quickly (66%).

Although not all participants were NSW residents, there was almost universal interest (89%) in participating in a clinical trial, in which a controlled supply of cannabis was grown and provided to registered medical cannabis users. There was also strong, although lesser, interest in trying alternative delivery methods such as a spray or tablet (79%).

While for some people, the availability of any cannabis-derived product that worked was their prime concern, alternative delivery methods were considered attractive as they obviated the necessity to smoke, removed concern about engaging in illegal behaviour and having to access the black market, and were more portable and acceptable than smoking. The main caveats on an alternative were that it was easy to titrate, quick, efficient, reliable and natural or safe – sprays and vaporisers were mentioned specifically by some as preferable to pills in this regard. A clear theme was the desire to keep the holistic, natural properties of cannabis rather than produce a chemical/synthetic drug with numerous binding and carrying agents. Nevertheless, there was recognition that different medical conditions may require different approaches, such as different active agents (e.g., THC versus other cannabinoids), strains or methods (e.g., slow release pill versus fast-acting spray).

The main reason for not supporting alternatives appeared to be that using the whole plant in its natural state was perceived to be the best method. In addition, for some the ritual of cannabis use was perceived as part of its medicinal benefit. There was also concern at political interference and its potential for exploitation and corruption in a trial.

Discussion

This exploratory study examined the patterns of medicinal cannabis use among a sample of 128 Australian adults who responded to media stories about this issue. Firstly, we need to acknowledge its limitations. As we do not know how many Australians use cannabis medicinally or their characteristics, we relied on the recruitment of volunteers through purposive sampling. Instead of targeting a particular group we used media stories disseminated widely on the radio, television and in newspapers to attract a cross-section of people. Thus, these results may not be representative of the experiences of all medicinal users, and may be affected by selection bias by excluding those who did not have access to these media, who did not wish to or could not contact us or did not return the questionnaire. We also attracted participants whose experiences with medical cannabis were typically positive, so they have little to tell us about people who have not found cannabis helpful or pleasant therapeutically. However, they still provide important information on these people's experiences, and raise important issues regarding the use of black market supplies of the cannabis plant and the development of cannabis-based pharmaceuticals. As the questionnaire was self-completed, there was potential for misunderstanding of the questions. However, the wording was straightforward, contact details were provided in the event of misunderstanding, and the results were remarkably consistent across participants, which encour-

ages us that the questions were understood. Despite being anonymous, several participants provided us with contact details in case further information was needed, and wrote additional comments about their experiences and attitudes. In addition, many of the findings are remarkably consistent with the findings of other local and international studies, as indicated below.

People in this study reported regular, ongoing medical use over quite long periods – with 61% using for more than five years and 20% reporting very long-term use of more than 20 years. However, as Ware and colleagues noted in their study of almost 1000 medical users [10], this was a group of chronically ill people with multiple long-standing conditions. The perceived need for alternative or additional symptom relief may reflect the fact that we recruited a sample of particularly entrenched medicinal cannabis users who were dissatisfied with conventional treatments, that medicinal cannabis use is more likely to be considered an option by people who find conventional treatments and medications unsatisfactory, or that many had been exposed to its perceived medical benefits quite early due to their recreational use. Larger studies addressing a broad cross-section of users may better answer this question.

Consistent with the literature on the conditions for which cannabis has been indicated, chronic pain, arthritis, persistent nausea and weight loss were among the most common conditions for which cannabis relief was sought. However, depression was the most common condition: more than half (56%) used cannabis to relieve depression, and two thirds (66%) used it to cope emotionally, universally obtaining great or good relief. Other studies have also reported cannabis use for the relief of depression, although not at this level [8-10,14]. The relationship between depression and cannabis use is controversial, with recent literature indicating that cannabis use may be implicated in depression and suicidal thoughts and behaviours. This would suggest that regular medicinal use may be contraindicated by placing people at risk of depression or self-harm. However, we do not know the type or aetiology of the depression cited by our participants. Many may have experienced depression and stress associated with their physical condition, which may have been alleviated along with any physical relief. The risk may also be greatest among heavy, younger users and those who may already be vulnerable to mental ill health due to their life circumstances [16-18]. Medical cannabis use patterns may not typically be regular enough to pose a great risk. Regardless, it is important that people considering the use of medical cannabis are aware of the risks of use [19]. A recent paper [20] has suggested that THC and cannabidiol, two major components of cannabis, may help alleviate bipolar disorder, recommending a pharmaceutical

product would be a safer option than crude cannabis, in which the balance of components is variable.

Consistent with local and international research on people with a variety of medical conditions [8-12,14], most participants claimed moderate to substantial benefits from cannabis, both in terms of their overall condition and management of individual symptoms. It was typically considered more effective and less aversive than other medications in managing their condition(s), the symptoms of which commonly re-emerged upon stopping (71%). While their use was often complementary to other medications and treatment, 62% had decreased or discontinued use of other medications when they commenced medicinal cannabis use. Nevertheless, cannabis was not a panacea – it did not help all conditions, particularly certain types of pain, and there was recognition that while it substantially improved quality of life it was not a cure. This is not necessarily surprising, as overall well-being and specific symptoms have multiple causes and can be affected by several factors, and is borne out by recent controlled clinical trials, for example, on chronic pain [21].

As others have reported (e.g., [8-10]) we also found that in addition to medical use, recreational use was common: most (80%) had used cannabis recreationally, with about one half (54%) of these reporting some recent use. Indeed, 29% had discovered its therapeutic potential through their recreational use. One participant raised the issue that part of the therapeutic effect for them was the ritual of use and the "high" experienced [6]. This demonstrates the difficulty of precisely identifying the therapeutic component when people are using the natural plant matter, and will continue to present a challenge for the development of cannabis pharmaceuticals. While some people may find the illegality, route of use and psychoactive effects of natural cannabis undesirable and prefer a manufactured pharmaceutical product, several in this survey claimed to prefer the holistic delivery of all the compounds present when using the natural plant. We need to know more about the effect of the different active chemicals on medical conditions and how their therapeutic potential is mediated by the context of use.

Nonetheless, this was not simply a sample of recreational users, especially as we attracted many older users who used exclusively for medical reasons (75% of those aged 50 years+). They did not fit the recreational user stereotype, were willing to take the risk of using an illicit drug, exposure to the illicit drug market and the possibility of arrest to gain symptom relief. Indeed, the most common concern over medicinal use was its illegality, fear of arrest and cost (all >50%). One quarter (27%) of participants had experienced legal ramifications due to their use. Several people commented that they had no alternative than

using an illegal drug, claiming that other medicines with negative and toxic effects (e.g., opiates) were legally prescribed, and that if nothing else worked for them they had the right to access cannabis without fear or stigma. Several made pleas for medical cannabis use to be treated as a medical, rather than a legal, issue, as their health and quality of life were at stake.

Smoking was the most common method of use; in addition, many were tobacco smokers or mixed cannabis with tobacco. Given the similarities between cannabis and tobacco smoke this is of particular concern for people who are ill, especially those with compromised immune systems. Despite acknowledgement of the risks of smoking and concerns expressed over its effects, it was considered the most helpful route of use. While eating was perceived as much healthier, until satisfactory solutions are achieved on titration and dosing issues, smoking will no doubt continue to be a popular method of obtaining relief.

Cannabis dependence was a concern for one in five participants (21%). This study provided indirect evidence that participants were unlikely to experience withdrawal symptoms on ceasing medical use, but this was only a crude measure. While the risk of dependence is probably low when used medicinally, this risk needs to be weighed up with the other concerns of the patient – for example, it may be low on the list of concerns for those with terminal illness [19].

Finally, participants reported that family and friends were likely to know about and support their medical cannabis use. These data also indicate that the medical profession is encountering, and frequently supporting, patients who use cannabis for symptom relief. Given their central role in the management of illness, it is important that clinicians are educated about the effects of cannabis, in order to assist patients in making informed decisions about their treatment. There was also clearly great interest among participants in a clinical trial and scope to investigate methods of delivery that avoid the health concerns associated with smoking cannabis, keeping in mind that some participants were reluctant to use a pharmaceutical product. In addition to distrust of unscrupulous participants in the black market, some were also distrustful of Government's motives and role in therapeutic research. It is therefore vital that any clinical trials are conducted in a rigorous, independent manner.

Conclusion

Overall, these findings are consistent with those of other surveys, in revealing the perceived effectiveness of cannabis for the relief of symptoms associated with several medical conditions. While a small study, it has several

implications. Firstly, people are risking the use of an illicit drug for its perceived therapeutic effects, and in some cases being arrested. Secondly, they are informing their clinicians about their medical use and frequently receiving support, highlighting the importance of ensuring clinicians are informed about cannabis. Finally, in addition to strong public support, medical cannabis users show strong interest in clinical cannabis research, including the investigation of alternative delivery methods.

ABSTRACT

Background: In 2014 Health Canada replaced the Marihuana for Medical Access Regulations (MMAR) with the Marihuana for Medical Purposes Regulations (MMPR). One of the primary changes in the new program has been to move from a single Licensed Producer (LP) of cannabis to multiple Licensed Producers. This is the first comprehensive survey of patients enrolled in the MMPR.

Methods: Patients registered to purchase cannabis from Tilray, a federally authorized Licenced Producer (LP) within the MMPR, were invited to complete an online survey consisting of 107 questions on demographics, patterns of use, and cannabis substitution effect. The survey was completed by 271 respondents.

Results: Cannabis is perceived to be an effective treatment for diverse conditions, with pain and mental health the most prominent. Findings include high self-reported use of cannabis as a substitute for prescription drugs (63%), particularly pharmaceutical opioids (30%), benzodiazepines (16%), and antidepressants (12%). Patients also reported substituting cannabis for alcohol (25%), cigarettes/tobacco (12%), and illicit drugs (3%). A significant percentage of patients (42%) reported accessing cannabis from illegal/unregulated sources in addition to access via LPs, and over half (55%) were charged to receive a medical recommendation to use cannabis, with nearly 25% paying \$300 or more.

Conclusion: The finding that patients report its use as a substitute for prescription drugs supports prior research on medical cannabis users; however, this study is the first to specify the classes of prescription drugs for which cannabis it is used as a substitute, and to match this substitution to specific diagnostic categories. The findings that some authorized patients purchase cannabis from unregulated sources and that a significant percentage of patients were charged for medical cannabis recommendations highlight ongoing policy challenges for this federal program.

Background

The past two decades have witnessed a resurgence of interest in the therapeutic potential of cannabis, with several nations and jurisdictions developing regulations to allow for access to cannabis for medical purposes (Fischer, Murphy, Kurdyak, Goldner, & Rehm, 2015). One potential salutary consequence of these developments

is the substitution of cannabis for other substances (Allsop et al., 2014; Lucas et al., 2013, 2016). Indeed, examinations of jurisdictions with legal access to medical cannabis have reported reductions in negative health outcomes associated with the use of other substances, such as opioid overdose (Bachhuber, Saloner, Cunningham, & Barry, 2014), and cannabis substitution has been forwarded as a mechanism to help explain these public health benefits. Consistent with this proposal, several large surveys confirm that medical cannabis users report substituting cannabis for other medications (Lucas, 2012a; Lucas et al., 2013, 2016; Reiman, 2009). Although extant surveys have provided broad evidence of cannabis substitution, the extent to which cannabis is

E-mail addresses: plucas@uvic.ca, philippe@tilray.ca (P. Lucas).

used to substitute for distinct classes of substances by distinct patient groups has not been systematically examined from a patient-centred perspective. The present study addresses this knowledge gap by examining the extent to which physician-authorized medical cannabis users report using cannabis as a substitute for specific classes of substances, and by disaggregating this examination according to condition-based patient group. We also add to the nascent literature on medical cannabis use by describing patient characteristics, patterns of use and barriers to access.

In 2001 Canada became one of the first nations to develop a program to allow access to cannabis for medical purposes. The program has undergone numerous convolutions, culminating in the 2014 establishment by Health Canada of the Marihuana for Medical Purposes Regulations (MMPR) (Walsh et al., 2013), and ultimately in the Access to Cannabis for Medical Purposes Regulations in August 2016. One of the primary changes of the MMAR was the authorization of multiple Licensed Producers of cannabis: as of August 2016 >30 federally authorized Licensed Producers provide hundreds of strains of cannabis, as well as cannabis extracts to approximately 67,075 patients (Office of Medical Cannabis, 2016). The ACMPR adds regulations by which patients can produce their own cannabis, an option that was removed in the transition from MMAR and MMPR, and subsequently re-established through a court decision (Allard et al. v. Canada).

In contravention of the MMPR/ACMPR, a large number of patients access cannabis through community-based outlets known as dispensaries or compassion clubs, as well as from friends and other sources. In addition, although many Provincial medical colleges expressly forbid physicians from charging patients for providing patients with medical cannabis prescriptions, 3rd party patient aggregator services have emerged that provide cannabis prescriptions, occasionally in exchange for a substantial fee. To date, the prevalence of this practice among clients of LPs has not been explicitly examined. In addition to providing a more granular examination of cannabis substitution, this study also adds to the growing literature chronicling patterns of medical cannabis use and user characteristics using a novel sampling methodology: whereas prior studies generally queried self-identified medical cannabis users who may not have obtained physician authorization (Lucas, 2012b; Lucas et al., 2013; Walsh et al., 2013), to our knowledge this is the first study since the establishment of the MMPR to include only those medical cannabis users with confirmed physician authorization to access cannabis for therapeutic purposes.

Design and methods

A password protected 107 question online cross-sectional survey was made available in French and English for a 2 week period in July 2015 to patients of Tilray—a licensed producer of cannabis. 1310 participants were notified of the opportunity to participate in this study via direct email to patients that had opted in to receive online communication from Tilray upon registration. Participants were compensated \$10 credit for Tilray cannabis. The study was approved by Institutional Review Board Services, and gathered data on demographics, patient experiences, patterns of use, and cannabis substitution effect. Respondents were not forced to answer a given question in order to proceed to the next and as such the number of recorded responses varies across items. All reported percentages are based on number of responses rather than on the entire sample; we accompany all reported percentages with number of responses.

Findings

The survey was started by 301 participants, and completed by over 90% of respondents ($n=271$). The 30 non-completers only filled out the demographic section of the study, and based on this information did not differ on age, gender, education, income or work status compared to those that completed the survey. The primary demographics of respondents corresponds with the greater Tilray patient population but was more male and Caucasian, single, disabled and of lower income than the general Canadian population, with over-representation in Western Canada and Ontario, and under-representation in Quebec (see Table 1 for demographic characteristics).

While an increasingly common medical treatment, cannabis is often used for symptom relief rather than as a curative agent, therefore it's important to distinguish between the primary conditions for which cannabis is officially prescribed by a physician, and the specific symptoms for which patients report relief. For example, while a patient might report having a prescription for MS, the list of symptoms impacted might include chronic pain, spasticity, and insomnia. In this survey, respondents could select a single primary condition from a drop-down list, but could then select multiple symptoms affected by the medical use of cannabis. In regards to conditions, pain-related conditions were the most common, reported by 53% of participants ($n=144$; chronic pain 36%; ($n=98$), arthritis 12% ($n=32$), headache 5% ($n=14$)). The second most prominent class was mental health (eating disorder, PTSD & psychiatric disorder), reported by 15% ($n=41$). Other prominent conditions included gastrointestinal I disorders (11%, $n=29$), insomnia (7%, $n=18$) and multiple sclerosis (4%, $n=11$).

In regards to symptoms; the most highly endorsed were chronic pain (73%, $n=197$), stress (60%, $n=162$), insomnia (57%, $n=155$), depression (46%, $n=126$) and headache (32%, $n=87$). Gastrointestinal (GI) issues also featured prominently, with 29% ($n=79$) citing appetite loss and another 29% ($n=79$) nausea. Cannabis was perceived to be very effective at symptom relief, with 95% ($n=257$) reporting that it “often” or “always” helped alleviate their symptoms.

Patterns of use

The mean age of initiation was 18.50 (SD = 7.42) for recreational use and 34.13 (SD = 13.74) for medical use, as determined by responses to the question “How old were you when you first used cannabis” followed by “How old were you when you first used cannabis for medical purposes?”. It is notable that participants readily distinguished between their recreational and medical use of cannabis, with recreational cannabis use preceding medical use for 81% ($n=220$) of respondents, with 16% ($n=44$) reporting no history of recreational cannabis use, and 3% ($n=7$) reporting precedence of medical use prior to recreational use.

In regard to frequency, 88% ($n=238$) reported using cannabis at least daily, and the modal amount used per day was 1–2 g, with 29% ($n=79$) using a larger amount.

In regard to methods of use, 90% ($n=243$) had tried joints, 86% ($n=234$) vaporizers, 76% ($n=207$) oral/edibles (such as baked goods, butter, tincture, etc.) and 16% ($n=44$) had used cannabis-infused topical ointments. Regarding primary methods of use, vaporizers proved most popular (38%, $n=102$), followed by joints (25%, $n=67$), oral/edibles (14%, $n=37$), waterpipe/bongs (12%, $n=33$), pipes (11%, $n=30$), and topicals (1%, $n=2$). Regarding preferred method, vaporization was rated most highly by a plurality (44%, $n=119$), with oral/edibles second (23%, $n=63$). Respondents overwhelmingly reported that not all strains/types of cannabis were “equally effective” at relieving symptoms (77%, $n=210$): 82%

^a As of July 31, 2015.^b Statistics Canada. Canadian census, 2011. <https://www12.statcan.gc.ca/census-recensement/2011/dp-pd/prof/index.cfm?Lang=E>.

(n = 222) reported a preferred cannabis type; 25% (n = 68) indicas, 21% hybrids (n = 56), 18% favoring strains high in cannabidiol (CBD) (n = 50), and 18% sativas (n = 48). While many Licensed Producers continue to identify cannabis by these phenotypes (*Cannabis sativa* and *Cannabis indica*) in keeping with classifications found in the black market, there is a growing academic debate about whether these classifications represent real and distinct genetic classifications, with evidence suggesting that the label of indica or sativa is not consistent with the actual genetics of many of these strains (Sawler et al., 2015). However, evidence that cannabinoids and terpenes are found at different ratios within each distinct cannabis phenotype supports the subjective differences between strains commonly reported by patients.

Cannabis substitution effect

Overall, 71% (n = 186) of participants report substituting cannabis for either prescription drugs, alcohol, tobacco/nicotine or illicit substances, with 63% reporting substitution for

prescription medication (n = 166), 25% for alcohol (n = 66), 12% for tobacco/nicotine (n = 31), and 3% for illicit substances (n = 9). To facilitate interpretation of substitution for prescription medications, pharmaceuticals were classed into the following 4 categories: *opioids*, *benzodiazepines*, *antidepressants* and a category of *other medication* that included diverse substances that were less frequently endorsed (e.g., NSAIDs, Methylphenidate). Respondents were allowed to report up to three medications for which they substituted cannabis; of those who explicitly listed prescription substitution 59% (n = 92) reported substituting for a single class of medications, 33% (n = 52) reported substituting for two classes, and 8% (n = 13) reported substituting cannabis for three classes. The most common form of substitution was for opioids (32%, n = 80), followed by benzodiazepines (16%, n = 40), and antidepressants (12%, n = 31) (Table 2). The reasons most frequently ranked as being most important for substituting cannabis for prescribed medications were “less adverse side effect” (39%, n = 68); “cannabis is safer” (27% n = 48), and “better symptom management” (16%, n = 28).

Table 2
Substitution for prescription medications.

Class	n	%
Opioids (Oxy/Oxyneo/Percocet/hydromorphone/morphine/codeine derivatives, etc.)	80	32
Benzodiazepines	40	16
Antidepressants	31	12
Other medication	100	40

Supplementary analyses examined variation across diagnostic groups, and indicated that respondents who used cannabis for pain-related conditions were more likely to substitute cannabis for opioids (42% (n = 57) vs. 20% (n = 23), $\chi^2 = 13.78(1)$, $p < 0.01$), whereas respondents who used cannabis to address mental health were more likely to substitute cannabis for benzodiazepines (31% (n = 12) vs. 13% (n = 28), $\chi^2 = 7.75(1)$, $p < 0.01$) and for antidepressants (26% (n = 10) vs. 10% (n = 21), $\chi^2 = 7.69(1)$, $p = 0.01$) (Fig. 1). Our data suggested no relationship between age, amount of cannabis used, mode of administration, access or affordability on substitution effect.

Access

Although all respondents accessed cannabis from Tilray, 21% (n = 56) also reported purchasing cannabis from another Licensed Producer, 25% (n = 67) purchased from dispensaries, 18% (n = 47) from a friend, and 8% (n = 20) buy from an illicit dealer. In total, 42% (n = 111) of respondents reported accessing from one or more unregulated sources. Regarding cost, 44% (n = 118) spend less than \$250 monthly and 78% (n = 212) spend less than \$500 per month on cannabis, whereas 4% spend \$1000 or more (n = 11). Capacity to “often” or “always” afford to buy enough cannabis to relieve symptoms was reported by 40% (n = 109), leaving 60% (n = 162) who report “sometimes” or “never” affording sufficient cannabis. Similarly, 53% (n = 146) reported choosing between medical cannabis and other necessities (food, rent, other medicines . . .) in the past year due to finances. Only 3% (n = 7) cited having 3rd party insurance coverage, and another 3% (n = 8) reported getting the cost of cannabis covered through Veterans Affairs Canada.

Finding a supportive physician was a reported challenge, with 31% (n = 78) having changed doctors in relation to medical cannabis use, and 55% reporting feeling discriminated against by their doctor because of medical cannabis use (n = 139). Paying a physician or clinic a fee for recommendations to use medical cannabis was reported by 55% (n = 140), with a modal price of between \$300–99 (n = 50) and

94% (n = 131) paying \$100 or more. It is therefore unsurprising that 29% (n = 75) reported that obtaining an authorization to use medical cannabis was “difficult” or “very difficult”.

Interpretation

The finding that patients using cannabis to treat pain-related conditions have a higher rate of substitution for opioids, and that patients self-reporting mental health issues have a higher rate of substitution for benzodiazepines and antidepressants has significant public health implications. In light of the growing rate of morbidity and mortality associated with these prescription medications (Bachhuber et al., 2014; Fischer, Rehm, Goldman, & Popova, 2008), cannabis could play a significant role in reducing the health burden of problematic prescription drug use. Indeed, a recent study of US states that have legalized medical cannabis, found that the number of prescriptions significantly dropped for drugs that treat pain, depression, anxiety, nausea, psychoses, seizures and sleep disorders, with the annual number of doses prescribed for chronic pain falling by more than 11% per physician (Bradford & Bradford, 2016). Additionally, according to Veterans Affairs Canada, a recent significant increase in the use of medical cannabis by patients is paralleled by a nearly 30% decrease in the use of benzodiazepines and a 16% decrease in the use of opioids (Hager, 2016). Moreover, the finding that cannabis might be used to substitute for multiple medications is particularly promising in light of concerns patients may have regarding adherence to complex pharmaceutical regimens, and attendant side effects (Brown & Bussell, 2011; Ingersoll & Cohen, 2008; Sylvestre, Clements, & Malibu, 2006). Indeed, tolerability of side effects was identified as a prominent reason for cannabis substitution.

The finding that medical cannabis is used primarily to treat chronic pain is consistent with past research (Ware et al., 2010; Ware, Wang, Shapiro, & Collet, 2015). However, the extensive self-

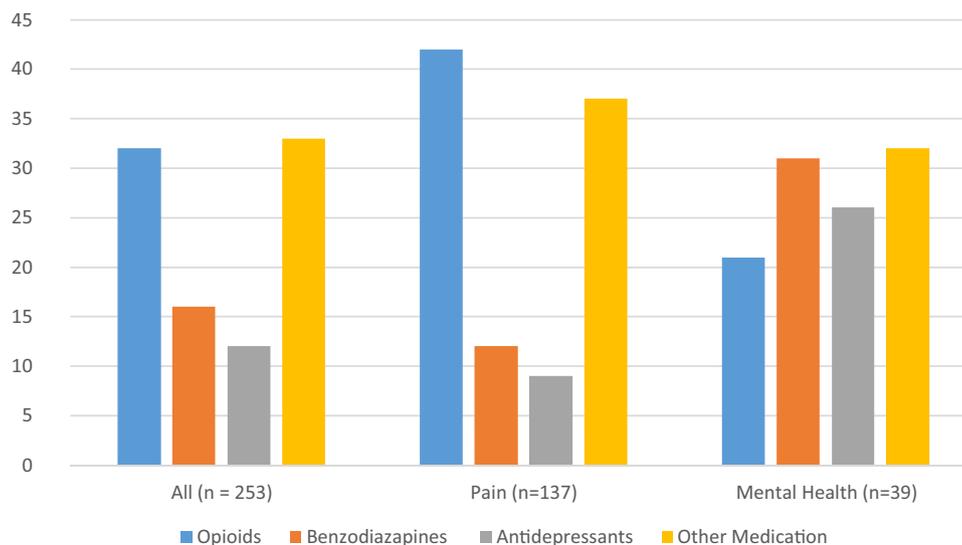

Fig. 1. Substitution by condition.

reported use to treat mental health conditions and associated symptoms represents a novel and interesting trend, and suggests that the conceptualization of cannabis as deleterious to mental health may not generalize across conditions or populations. Studies currently underway to investigate cannabis for the treatment of PTSD, anxiety, and other psychiatric conditions may soon provide more information on these potentially promising treatment options.

Our finding that most patients use 2 grams or less is consistent with past research (Carter, Weydt, Kyashna-Tocha, & Abrams, 2004; Clark, 2013; Hazekamp, Ware, Muller-Vahl, Abrams, & Grotenhermen, 2013). To our knowledge, this is the first patient survey to report vaporization as the primary method of ingestion, and non-smoked forms of ingestion as primary and preferred methods of ingestion. This marks a health conscious shift in medical cannabis use under the MMPR that may be attributed to a few factors: since patients in the MMPR require a physicians support to access medical cannabis, they may be more likely to be focused on safer methods of ingestion than non-MMPR patient populations; improvements in vaporizer technology and associated reductions in cost, patient outreach and education initiatives focused on safe and responsible use by cannabis vendors, and ongoing restrictions on smoking in the public realm.

Cannabis is rather unique as a therapeutic treatment in that many patients report some permeability between recreational and medical use (Walsh et al., 2013). However, unlike opioids where medical use via prescription often precedes recreational use and dependence (Fischer et al., 2008), the pathways between the medical and recreational use of cannabis are reversed, with previous recreational use often a precursor to prescription medical use, while the reverse is rarely the case. Although most respondents in this study had experience with recreational cannabis use prior to initiation of medical use (81%, $n=220$), transition from medical use to recreational use was only reported by 7 participants (<3%), which is suggestive of a low risk of abuse associated with medical cannabis. Additionally, with so many patients reporting use for the relief of mental health conditions like stress, insomnia and depression, much of this medical use is ultimately focused on improving psychological well being and quality of life. This perhaps blurs the lines between traditional biomedical approaches to disease and more holistic approaches (such as yoga or naturopathic medicine) used as adjunct treatments to address the symptoms, side-effects and psychological impacts of long-term illness/disability and/or the modern pressures of every day life. This is supported by previous research that has found that patients who use medical cannabis often cite depression and anxiety as a primary symptoms for which they seek relief, regardless of their actual medical condition (Bonn-Miller, Boden, Bucossi, & Babson, 2014; Ogborne, Smart, Weber, & Birchmore-Timney, 2000; Walsh et al., 2016), as well a growing amount of preclinical research supporting the use of CBD as a potential treatment for both anxiety (Blessing, Steenkamp, Manzanares, & Marmar, 2015) and depression (Linge et al., 2015).

Despite the legal protection and quality control offered through the MMPR, 42% of participants report accessing cannabis from unregulated sources which may be due to restrictions imposed on LPs by the MMPR during that period. At the time of this survey, LPs were only allowed to provide raw cannabis flowers, whereas other sources may have provided a diverse array of extracts and edibles. Since that time regulations have been altered to allow LPs to produce extracts, and to once again produce their own cannabis supply. Future research may determine whether this regulatory revision alters patient behaviour in regards to access through unregulated sources.

In light of consistent evidence that many lower income patients face affordability issues in regards to the cost of medical cannabis (Belle-Isle et al., 2014), the finding that so many patients had to pay high medical fees to gain access medical cannabis is concerning and suggests there may subsequently be an under-representation of low income patients in the MMPR/ACMPR.

Conclusions

The high rate of substitution for prescription drugs among patients with pain-related and mental health conditions suggests that medical cannabis may be an effective adjunct or substitute treatment to prescription drugs used to treat these conditions. Further research into the comparative efficacy of cannabis relative to front-line treatments for these conditions is warranted, and longitudinal research would help elucidate the context of cannabis substitution effect, and the potential impact of cannabis substitution on the quality of life of patients (in-progress, Lucas).

While the MMPR had only been in place for approximately 15 months when this survey took place, the findings that some authorized patients continue to purchase cannabis from unregulated sources and that a significant percentage of patients have had to pay high fees for medical cannabis recommendations highlight ongoing policy challenges for the federal medical cannabis program. As Canada's federal medical cannabis policy continues to evolve (both organically and in response to legal challenges) and as provinces and municipalities seek regulatory solutions to issues like dispensaries, personal production, and private medical cannabis clinics, it will be important to keep tracking the impact of these policy developments on patient access to and experiences with medical cannabis.

Limitations

The relatively low response rate to the survey (21%) leaves open the possibility this could potentially be an unrepresentative sample. It is not possible to confirm the impact of cannabis substitution on quantity of use of prescription drugs, alcohol or illicit drug use. Additionally, all data regarding the cannabis substitution effect in this study were self-reported by patients and did not benefit from biological drug detection to confirm use or non-use of a substance. In light of this potential bias, our characterisation of the therapeutic use of cannabis and/or cannabis substitution effect should be interpreted with caution pending replication by research that employs a more systematic recruitment approach, longitudinal monitoring, and biological drug testing.

However, these limitations are counterbalanced by several methodological strengths, including the large size of the sample, assurance that all participants were using medical cannabis with the support of a physician, and adherence to established standards for reporting Internet-based surveys (Eysenbach, 2004).

Declaration of interest

This study was funded by Tilray, a federally authorised medical cannabis production and research company. Philippe Lucas is currently employed as Vice-President, Patient Research and Advocacy for Tilray; however, his compensation is not tied in any way to the outcomes of this study.

Zach Walsh is currently the Primary Investigator in a Tilray-sponsored randomized clinical trial of medical cannabis and PTSD, but he receives no financial compensation for that study nor for assisting with the analysis and writing of this paper.

Acknowledgements

Funding for this study was provided by Tilray. We would like to thank all of the Tilray patients that have shared their thoughts and experiences with us, as well as Kim Crosby for assisting with some of the data analysis of this survey.

Abstract

Introduction and Aims. Recent years have witnessed increased attention to how cannabis use impacts the use of other psychoactive substances. The present study examines the use of cannabis as a substitute for alcohol, illicit substances and prescription drugs among 473 adults who use cannabis for therapeutic purposes. **Design and Methods.** The Cannabis Access for Medical Purposes Survey is a 414-question cross-sectional survey that was available to Canadian medical cannabis patients online and by hard copy in 2011 and 2012 to gather information on patient demographics, medical conditions and symptoms, patterns of medical cannabis use, cannabis substitution and barriers to access to medical cannabis. **Results.** Substituting cannabis for one or more of alcohol, illicit drugs or prescription drugs was reported by 87% ($n = 410$) of respondents, with 80.3% reporting substitution for prescription drugs, 51.7% for alcohol, and 32.6% for illicit substances. Respondents who reported substituting cannabis for prescription drugs were more likely to report difficulty affording sufficient quantities of cannabis, and patients under 40 years of age were more likely to substitute cannabis for all three classes of substance than older patients. **Discussion and Conclusions.** The finding that cannabis was substituted for all three classes of substances suggests that the medical use of cannabis may play a harm reduction role in the context of use of these substances, and may have implications for abstinence-based substance use treatment approaches. Further research should seek to differentiate between biomedical substitution for prescription pharmaceuticals and psychoactive drug substitution, and to elucidate the mechanisms behind both. [Lucas P, Walsh Z, Crosby K, Callaway R, Belle-Isle L, Kay B, Capler R, Holtzman S. Substituting cannabis for prescription drugs, alcohol, and other substances among medical cannabis patients: The impact of contextual factors. *Drug Alcohol Rev* 2016;35:326–333]

Key words: cannabis, marijuana, substitution effect, substance use, addiction.

Introduction

The medical use of cannabis can be traced back at least 5000 years [1,2], and by the late 19th century, cannabis-based preparations were widely marketed for medical use [3]. A variety of social and technological developments led to the stigmatisation and marginalisation of cannabis by the 1920s [4,5], and by

the 1940s, the international implementation of cannabis prohibition put an end to nearly all research into the use of cannabis for therapeutic purposes (CTP). The past decade has witnessed an increased interest in the therapeutic properties of cannabis, and a growing body of laboratory and clinical research attests to the many uses of cannabis-based medicines for diverse symptoms and conditions [6–9].

Concurrent with increased recognition of the legitimate therapeutic use of cannabis is an international reappraisal of prohibitions for extra-medical cannabis use, with several nations exploring the potential costs and benefits of establishing legal access to cannabis outside of the medical system [10]. Legal access to cannabis might affect the broader social costs related to the use of both licit and illicit psychoactive substances, and a comprehensive analysis of the consequences of cannabis use must recognise potential effects on the use of other psychoactive substances such as prescription drugs, alcohol and illicit substances.

Substitution effect

Substitution of psychoactive substances can be conceptualised within the context of behavioural economics, whereby commodities may have substitution, complementary or independent interrelationships with regard to rates of human consumption. In a seminal investigation of substitution and addictions, Hursh and colleagues [11] noted several factors that may affect substitution of one psychoactive substance for another, including changes in policy that affect availability, and changes to legal risk and associated repercussions. Population-level studies have identified substitution resulting from shifts in the legal risk associated with the use of a particular substance, such as decriminalisation [12].

In regards to psychoactive/pharmacological substitution, Hursh *et al.* [11] add that ‘pharmacological therapies for the treatment of drug abuse can also be conceptualised as alternative commodities that either substitute for illicit drug use (e.g. agonist therapy) or reduce the potency of illicit drugs directly (e.g. narcotic antagonist therapy)’ (p. 25). Prominent examples of the harm-reducing potential of substituting one psychoactive substance for another include the prescription use of methadone as a substitute to injection heroin use [13] and the use of nicotine patches to curb or stop tobacco smoking [14]. Additionally, the cannabis extract nabiximols [Sativex (<http://www.gwpharm.com/Sativex.aspx>)] has been investigated as a potential agonist for cannabis withdrawal in a treatment-seeking cohort, finding that while nabiximols attenuated cannabis, which is a 1:1 THC/CBD buccal spray, withdrawal symptoms, placebo was as effective in promoting long-term reductions in use [15].

The use of cannabis as a substitute for prescription drugs, alcohol and other substances has been identified in a number of studies. Deliberate cannabis substitution has been reported by heroin and pharmaceutical opiate users [16]. A number of smaller studies have also found that cannabis appears to reduce the cravings for other drugs of dependence like crack cocaine [17], alcohol

[18] and opiates [19–21], and may improve some treatment outcomes for substance dependence [22]. A complementary line of research has found that cessation of cannabis use is associated with increased use of other substances like alcohol and cigarettes [15,23].

The effectiveness of cannabis as a substitute for other substances has been proposed to reflect diverse neurochemical and cognitive processes [17]. From a patient perspective, recent surveys of CTP users in Canada and the USA identified less withdrawal, fewer side effects, and better symptom management as primary reasons for cannabis substitution [6,18,24].

Medical cannabis in Canada

In Canada, several court cases have upheld the rights of patients to choose cannabis as medicine (e.g. *R. v. Smith, 2013*; *R. v. Beren and Swallow, 2009*; *Hitzig et al. v. Canada, 2003*; *R. v. Parker, 2000*; *Wakeford v. Canada, 2000*), and the 2001 *Marihuana Medical Access Regulations* established means for Canadians to obtain legal authorisation to possess CTP. Despite widespread concern with the efficiency of the Health Canada programme [25–28], registration has grown from fewer than 500 registrants in 2002 to over 26 000 in 2012 [29]. However, the *Marihuana Medical Access Regulations* have been noted for presenting substantial barriers to access [25–28], and fewer than 10% of the estimated one million Canadian individuals who use CTP are authorised through the federal programme [28,30,31]. The authorised versus unauthorised status of users of CTP represents a legal risk factor that might be expected to influence substitution.

Ability to afford CTP has also been identified as an important factor that affects access [25,31], and may therefore be expected to impact substitution. Additionally, several studies have identified analgesia as a prominent reason for using CTP, and cannabis has several potential advantages relative to widely used opiate analgesics including fewer side-effects, a lower risk of dependence, and no possibility of fatal overdose [20]. Therefore, those who use cannabis to address pain-related conditions might be expected to report relatively higher rates of substitution for prescription drugs for pain. History of problematic substance use might also influence rates of substitution, as individuals working to maintain abstinence from other substances may be more likely to use cannabis as a substitute [19].

In sum, prior research has identified cannabis as a potential substitute for other substances among CTP and community samples, however no studies have examined the extent to which cannabis substitution varies according to theoretically important factors such as authorisation to possess cannabis, affordability

of cannabis, substance use history, medical condition, and age. We expect that higher levels of access associated with authorised status and with greater affordability of CTP will be associated with increased likelihood of cannabis substitution for prescription drugs, alcohol, and illicit drugs, and that younger patients will be more likely to report substitution effect for alcohol and illicit substances due to the higher rates of use of these substances in those under 40 years old in the general population. Finally, we predict that individuals with histories of problematic substance use will report higher rates of substitution for alcohol and illicit substances.

Methods

Participants were 473 self-identified current users of CTP drawn from the Cannabis Access for Medical Purposes Survey (CAMPS) [32], with complete data regarding use of cannabis as a substitute. CAMPS is the largest polling of Canadian medical cannabis patients to date, and involved the administration of multi-part questionnaire of 414 forced choice and open-ended items that queried demographic information, medical conditions and symptoms, and patterns of cannabis use. Participants were surveyed in 2011–2012 online or in person at a medical cannabis dispensary. The study and survey were developed with the assistance of a community research board, and recruitment was assisted by dispensaries, by organisations that serve people who use CTP (e.g. Canadian AIDS Society, Canadian Aboriginal AIDS Network), and by social media and traditional media reporting on the project. The study was reviewed and approved by the Behavioural Research Ethics Board of the University of British Columbia. Respondents were 68% men, 90% European-Canadian and 9% Aboriginal. Ages ranged from 17 to 78 years, with a median age of 40. Participants presented with the range of conditions that is generally consistent with surveys of CTP users, the most prominent conditions being pain (32%), mood (i.e. anxiety and depression; 18%), arthritis (15%), HIV (10%), gastrointestinal disorder (7%) (Table 1; see Walsh *et al.*, 2013 [32] for a detailed account of CAMPS methodology and participant characteristics).

Substitution was measured using three dichotomous items (yes/no), each of which referred to a distinct class of substance. Participants were asked if they had substituted cannabis for: (i) prescription drugs; (ii) alcohol; and (iii) illicit substances. Positive responses branched to a follow-up query asking participants to rank six reasons for substitution as follows: *less adverse side effects from cannabis, less withdrawal symptoms with cannabis, the ability to obtain cannabis versus other drugs, social acceptance of cannabis is greater than other drug, better symptom*

management from cannabis than from alcohol or other drugs, and an *other* category, which was followed by space for an open response. This approach and the selection of items for the substitution reasons are derived from prior studies of substitution [6,18].

Participants were asked to indicate the single primary *condition* treated with cannabis, as well as any number of primary symptoms cannabis use alleviated (Figure 1). We created a dichotomous *pain condition* variable by aggregating respondents who identified the primary condition treated with CTP as spinal pain, non-spinal pain, or arthritis ($n = 220$), and comparing these participants to an aggregation of all other conditions ($n = 241$). A large contingent of these non-pain respondents nonetheless endorsed *pain* among the symptoms for which they used CTP (71%, $n = 171$), therefore, we conducted supplementary analyses comparing those who endorsed treating pain with CTP among a list of symptoms (83%, $n = 390$) with those who did not endorse treating pain with CTP (17%, $n = 82$). We also compared those who used cannabis primarily to treat the *depression* or *anxiety* ($n = 81$) to an

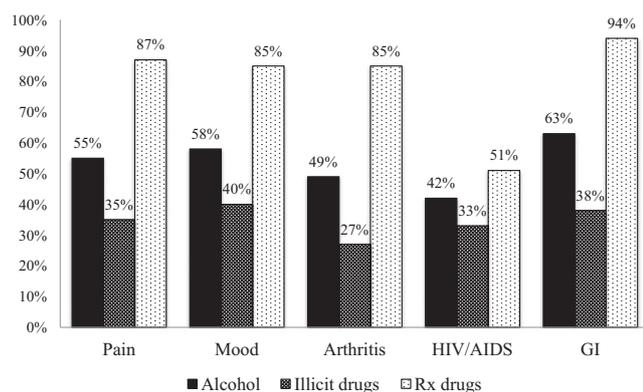

Figure 1. Frequency of substitution across top five reported medical conditions.

aggregation of all other conditions ($n = 379$). Approximately, one-third of respondents had obtained federal authorisation to possess cannabis (32%, $n = 152$), and we used a dichotomous *authorisation* variable to compare authorised versus unauthorised patients. Participants were queried regarding ability to afford CTP, and were divided into those who could *always* or *often* afford CTP (46%, $n = 214$) and those who could *sometimes* or *never* afford CTP (54%, $n = 252$). We also compared respondents with a history of treatment for problematic alcohol or other substance use (15%, $n = 71$) to those with no such history (85%, $n = 402$). Finally, we examined self-reported reasons for substitution and associations between substitution and quantity of cannabis use. Logistic regression analyses were used to examine the associations between these variables and dichotomous indices of (presence/absence) the three types of substitution. All significance tests were two-tailed.

Results

Substituting cannabis for one or more of alcohol, illicit drugs, or prescription drugs was reported by 87% ($n = 410$) of respondents, with 36% ($n = 168$) substituting cannabis for only one class of substances, 25% ($n = 118$) substituting for two classes, and 26% ($n = 124$) substituting for all three classes. Examination by class of drug (Table 2) identified substitution for prescription drugs as the most commonly reported form of substitution (80%), followed by alcohol (52%), and illicit substances (33%). The most commonly endorsed reasons for substitution were ‘less adverse side effects’ (51%, $n = 208$), followed closely by ‘better symptom management’ (49%, $n = 199$).

Amount used

Median weekly amount of cannabis used was 14 g. Comparisons based on a median split of higher versus

lower quantity users indicated that quantity of use was not associated with differences in the observed levels of any of the three forms of substitution; for prescription drugs [odds ratio (OR) = 0.77, 95% confidence interval (CI) = 0.44–1.37], alcohol (OR = 1.44, 95% CI = 0.95–2.19) or illicit drugs (OR = 0.93, 95% CI = 0.60–1.45).

Medical condition

Participants who identified pain-related conditions as the primary reason for using CTP were more likely to report substituting cannabis for prescription drugs (OR = 1.99, 95% CI = 1.23–3.21), but did not differ with regard to rates of substituting cannabis for alcohol (OR = 1.01, 95% CI = 0.76–1.59), or illicit substances (OR = 0.96, 95% CI = 0.65–1.42). Supplementary analyses comparing those who endorsed pain as a symptom treated with CTP to those who listed a non-pain-related primary condition treated with CTP produced a parallel pattern of results: those who used CTP to treat pain were more likely to substitute cannabis for prescription drugs (OR = 1.92, 95% CI = 1.12–3.30), and did not differ from respondents who did not endorse CTP use for pain with regard to substituting cannabis for alcohol (OR = 1.03, 95% CI = 0.64–1.66) or illicit substances (OR = 1.30, 95% CI = 0.77–2.20). Participants who used CTP primarily to treat depression or anxiety did not differ from other participants with regard to prescription drugs (OR = 1.49, 95% CI = 0.77–2.89), alcohol (OR = 1.35, 95% CI = 0.83–2.19), or illicit substances (OR = 1.43, 95% CI = 0.87–2.35).

Authorisation

Comparison of authorised versus unauthorised status indicated that authorised users (Table 2) were marginally less likely to substitute cannabis for alcohol (OR = 0.63, 95% CI = 0.43–0.93), and did not differ with regard to substituting for prescription drugs (OR = 1.45, 95% CI = 0.87–2.41), or illicit substances (OR = 0.92, 95% CI = 0.61–1.39).

Affordability

Respondents who reported substituting cannabis for prescription drugs were moderately more likely to report difficulty affording sufficient quantities CTP (OR = 0.59, 95% CI = 0.37–0.94). Affordability was not related to substitution for alcohol (OR = 0.75, 95% CI = 0.52–1.08) or for illicit substances (OR = 1.01, 95% CI = 0.68–1.49).

Table 2. Patients who report substituting cannabis for alcohol and other drugs by condition, authorisation, affordability, addiction treatment, and age

	Medical condition		Authorisation		Affordability		Addiction treatment history		Age		
	All	Pain	Other	Authorised	Unauthorised	No	Yes	No	Yes	Younger	Older
R _x (%)	80	86**	75**	84	79	84*	76*	80	85	84**	76**
Alcohol (%)	52	53	51	44*	55*	55	48	52	51	62**	41**
Illicit (%)	33	32	33	31	33	33	33	29**	54**	37**	26**

Note: R_x = prescription drugs; affordability: no = *sometimes* or *never* afford cannabis for therapeutic purposes (CTP), yes = *always* or *often* afford CTP; age: younger = <40 years old, older = ≥40 years old; groups differences **P* < 0.05, ***P* < 0.01 (two-tailed).

Addiction treatment history

Comparison according to any history of treatment for problematic substance use indicated that those who had a history of treatment exhibited higher levels of substituting cannabis for illicit substances (OR = 2.16, 95% CI = 1.52–3.06), but did not differ from those without a treatment history with regard to substituting cannabis for alcohol (OR = 1.01, 95% CI = 0.73–1.40) or for prescription drugs (OR = 1.37, 95% CI = 0.84–2.21).

Age

Respondents who substituted cannabis for prescription drugs were younger [M = 38.58 standard deviation (SD) = 12.57] than those who did not engage in this class of substitution [M = 44.26 (SD = 13.90)], (OR = 0.97, 95% CI = 0.95–0.99). Similarly, respondents who substituted cannabis for alcohol were younger [M = 36.65 (SD = 12.99)] than those who did not engage in this class of substitution [M = 42.84 (SD = 12.26)], (OR = 0.96, 95% CI = 0.95–0.98), and respondents who substituted cannabis for illicit substances [M = 36.50 (SD = 12.55)] were younger than those who did not engage in this class of substitution [M = 41.13 (SD = 13.01)] [M = 42.84 (SD = 12.26)], (OR = 0.97, 95% CI = 0.96–0.99).

Discussion

The results of this study are consistent with a growing body of research suggesting that cannabis use may play an important role in the use of prescription drugs, alcohol and illicit substances. Although we identified generally high rates of substitution across all patients, we also identified variability in rates of substitution across substances and contextual factors. Specifically, using cannabis for pain relief was associated with substituting cannabis for prescription medications; having a history of treatment for substance use was associated

with substituting for illicit substances; and younger age was associated with higher rates of substitution across all substances. We also found that respondents who used CTP without authorisation were more likely to use cannabis as a substitute for alcohol, whereas those substituting cannabis for prescription drugs were more likely to have difficulty affording cannabis.

The high rate of substitution for prescribed substances, particularly among patients with pain-related conditions, suggests that further research into cannabis/cannabinoids as a potentially safer substitute for or adjunct to opiates is justified, and adds to research suggesting this phenomenon is robust across samples [6,20]. This includes a study by Bachhuber *et al.* that examined the association between the medical cannabis laws in US states and opiate overdose deaths, which found nearly 25% lower mean annual rates of opioid overdose mortality among states that allowed medical cannabis, noting that the protective influence of medical cannabis regulation grew stronger over time [33]. The recent rise of addiction to pharmaceutical opiates in Canada and around the world and an associated increase in opiate-related morbidity and mortality [34–36] highlights the importance of exploring this context for substitution and its potential public health impacts.

The finding that cannabis was substituted for alcohol and illicit substances suggests that the medical use of cannabis may play a harm reduction role in the context of use of these substances, and could have implications for substance use treatment approaches requiring abstinence from cannabis in the process of reducing the use of other substances. Furthermore, public policies informed by evidence that cannabis might be a substitute for alcohol [12,18,23,37] could have an impact on overall rates of alcoholism, as well as alcohol-related automobile accidents, violence, and property crime [38].

The novel finding that patients under 40 reported a higher rate of substitution than older patients poten-

tially reflects more established patterns of substance use among older patients. In addition, younger patients typically use more psychoactive substances in the first place, leading to greater opportunities for substitution [30]. This finding suggests that older patients might benefit from education regarding the potential of cannabis to serve as a substitute for prescription drugs, alcohol, and illicit substances and indicates that future research on cannabis substitution should consider the age of the sample.

The finding that higher rates of substituting cannabis for prescription drugs was associated with lower ability to afford cannabis warrants consideration, and may reflect increased demand—and therefore higher cost—for cannabis related to use for this purpose. Such an interpretation is consistent with our finding that affordability was inversely associated with substitution of prescription medications, as such medications are subsidised in Canada, making them generally less expensive than cannabis. In contrast, alcohol and illicit drugs may be more expensive than cannabis, and therefore substitution of cannabis for these substances would not be expected to be associated with financial stress. Indeed, as we did not find that cannabis substitution for prescription medications was associated with the use of a greater quantity of cannabis, findings related to economic pressure suggests that affordability might limit cannabis use, adding to research that highlights the importance of affordability for maximising efficient access to cannabis [25,31].

The finding of higher levels of substituting cannabis for alcohol among unauthorised users was surprising, as prior research identified few differences between authorised and unauthorised Canadians who use CTP [32]. We propose that the actual government-regulated authorisation process may have led to a formalisation of medical cannabis use among authorised patients, limiting their reported reasons for the use of medical cannabis to those recognised and approved by their physician and Health Canada. However, further research that directly queries this issue is required to confirm this hypothesis.

Limitations

The limitations of this study are common to online medical surveys, such as the potential for multiple responses from a single respondent, a potentially unrepresentative sample, and lack of physician confirmation of medical conditions. Since no data was gathered on the extent of self-reported substitution, it is not possible to determine how much actual prescription drug, alcohol or illicit drug use was substituted for, and variable time frame for retrospective reporting may impact the reliability of recall. Furthermore, response

bias related to participant self-selection and recruitment through organisations that support medical cannabis patients likely resulted in overrepresentation of individuals who respond favourably to the medical use of cannabis. Additionally, all data regarding the cannabis substitution effect in this study were self-reported by patients and did not benefit from biological drug detection to confirm use or non-use of a substance. In light of this potential bias, our characterisation of the therapeutic use of cannabis and/or cannabis substitution effect should be interpreted with caution pending replication by research that employs a more systematic recruitment approach and biological drug testing. However, these limitations are counterbalanced by several methodological strengths, including the size of the sample, the inclusion of an in-person subsample, and adherence to established standards for reporting Internet-based surveys [39].

Conclusions

Taken together, our findings provide additional evidence for the widespread nature of cannabis substitution and suggest potentially fruitful avenues for further research that elucidates the complex interaction between cannabis use and the use of other substances. In particular, as the therapeutic and recreational uses of cannabis continue to be normalised, research that explicitly investigates contexts and motives for substitution, particularly in younger adults, might help to maximise the health benefits of this emerging phenomenon. Further research is needed to better estimate the extent of substitution, and to specify differences in substitution across prescription drugs (i.e. opiates, benzodiazepines, anti-inflammatories), and other substances such as tobacco and caffeine. To this end, we recommend the development of a psychometrically valid instrument to facilitate the reliable assessment of cannabis substitution across diverse samples, contexts and substances.

Acknowledgements

This research was supported by a grant from the UBC Institute for Healthy Living and Chronic Disease Prevention. The authors would like to thank the hundreds of Canadian medical cannabis patients who took the time to participate in this survey, and would also like to express our gratitude to Ben Atkinson and Megan Hiles for their contribution to data collection and management.

Conflict of interests

Philippe Lucas is currently employed as Vice-President, Patient Research and Services for Tilray, a federally

authorised medical cannabis company. However, he was not employed by Tilray during the preliminary planning, data collection and analysis of this study, and his compensation is not tied in any way to the outcomes of this study. None of the other authors have any conflicts of interest with regard to the contents of this paper.

Cannabis as a substitute for prescription drugs – a cross-sectional study

James M Corroon Jr¹
Laurie K Mischley²
Michelle Sexton³

¹Center for Medical Cannabis Education, Del Mar, CA, ²Bastyr University Research Institute, Kenmore, WA, ³Department of Medical Research, Center for the Study of Cannabis and Social Policy, Seattle, WA, USA

Background: The use of medical cannabis is increasing, most commonly for pain, anxiety and depression. Emerging data suggest that use and abuse of prescription drugs may be decreasing in states where medical cannabis is legal. The aim of this study was to survey cannabis users to determine whether they had intentionally substituted cannabis for prescription drugs.

Methods: A total of 2,774 individuals were a self-selected convenience sample who reported having used cannabis at least once in the previous 90 days. Subjects were surveyed via an online anonymous questionnaire on cannabis substitution effects. Participants were recruited through social media and cannabis dispensaries in Washington State.

Results: A total of 1,248 (46%) respondents reported using cannabis as a substitute for prescription drugs. The most common classes of drugs substituted were narcotics/opioids (35.8%), anxiolytics/benzodiazepines (13.6%) and antidepressants (12.7%). A total of 2,473 substitutions were reported or approximately two drug substitutions per affirmative respondent. The odds of reporting substituting were 4.59 (95% confidence interval [CI], 3.87–5.43) greater among medical cannabis users compared with non-medical users and 1.66 (95% CI, 1.27–2.16) greater among those reporting use for managing the comorbidities of pain, anxiety and depression. A slightly higher percentage of those who reported substituting resided in states where medical cannabis was legal at the time of the survey (47% vs. 45%, $p=0.58$), but this difference was not statistically significant.

Discussion: These patient-reported outcomes support prior research that individuals are using cannabis as a substitute for prescription drugs, particularly, narcotics/opioids, and independent of whether they identify themselves as medical or non-medical users. This is especially true if they suffer from pain, anxiety and depression. Additionally, this study suggests that state laws allowing access to, and use of, medical cannabis may not be influencing individual decision-making in this area.

Keywords: cannabis, marijuana, prescription drugs, pain, analgesics, opioid

Introduction

The past two decades have brought about a prodigious change in state laws and social policies regarding the use of cannabis for medical and other purposes. Twenty-eight states and the District of Columbia currently enforce legalized medical cannabis laws. Eight of these states and the District of Columbia have also legalized cannabis for recreational use.¹ Among other factors, these legislative and policy changes have resulted in shifts in social acceptance and cannabis use patterns in the US population, some of which have been driven by a growing understanding of the medicinal value of cannabis.²

According to the Center for Behavioral Health Statistics and Quality (CBHSQ), past-month use of cannabis has risen steadily each year in the general population from 5.8% in 2007 to 8.4% in 2014. In 2015, an estimated 22.2 million of >265 million Americans aged ≥ 12 years reported having used cannabis in the past month (8.3%).³

In addition to changing use patterns, recent research suggests that physicians' drug prescribing patterns may also be changing in states with legalized medical cannabis. Bradford and Bradford⁴ reported a drop in filled prescriptions in such states between 2010 and 2013 for drugs under Medicare Part D for the treatment of conditions such as pain, anxiety, depression and others. The US Centers for Disease Control and Prevention (CDC) has issued federal guidelines on the long-term use of opiates, noting concerns that there may be negative unintended consequences associated with dose reduction, such as patients switching to the use of heroin.⁵ An alternative for patients with chronic pain is switching to the use of cannabis to navigate dose reduction and to treat their pain and/or comorbid conditions outright.⁶ A recent open-label, prospective study suggests that medical cannabis may decrease opioid use and benefit patients with treatment-resistant pain.⁷

Here, we analyzed self-reported data for frequency of prescription drug substitution with cannabis use across sociodemographic characteristics, prescription drug class, state legalization policies for medical cannabis and global quality of life health scores.

Methods

Survey

The institutional review board (IRB) of Bastyr University approved the protocol. Procedures were in accordance with the ethical standards of the Declaration of Helsinki, as revised in 2008. Documentation of consent was waived in accordance with Department of Health & Human Services regulation 45 CFR 46.117(c) by the IRB of Bastyr University on the basis that the research presents no more than minimal risk of harm. The only record linking the subject with the research would be the consent document, and thus, the principal risk would be potential harm resulting from a breach of confidentiality. A literature review was conducted to identify existing epidemiological surveys of cannabis use.⁸⁻¹³ The authors developed a novel questionnaire by assessing the strengths and weaknesses of existing surveys to meet the goals of this study. Drafts were circulated to physician researchers and cannabis users for feedback in an iterative process. The final survey consisted of 44 structured questions answered by yes/no, multiple choice, open-ended

response fields and rating scales.¹⁴ These included patient-reported outcomes (PROs) using the PROMIS® Global Health 10-item short form (part of a National Institutes of Health [NIH] initiative to produce validated, self-reported item banks for physical, mental, emotional and social health) to measure overall well-being. Study data were collected and managed using Research Electronic Data Capture (REDCap), a secure tool allowing participants to directly enter responses.¹⁵

Subjects were a self-selected convenience sample who accessed the survey through links posted on the Center for the Study of Cannabis and Social Policy and Bastyr University websites, a Facebook page, flyers in Washington State cannabis dispensaries or word of mouth from December 2013 to January 2016. Recruitment strategies included Bastyr University medical students circulating the survey through their own social media, by distributing IRB-approved fliers to local medical cannabis dispensaries in Washington State, through public lectures describing the questionnaire at King County Library Systems locations, in an article written for an online Cannabis magazine and through an article posted to an online group located at momswithms.org. The only inclusion criterion was having used cannabis at least once in the past 90 days. A total of 31 respondents from the 2,864 respondents were deemed ineligible and excluded based on this criterion. Another 14 were excluded for failure to answer the eligibility question. To minimize risk to participants, no identifying information was collected. Individuals were given the opportunity to provide a five-digit code that enabled repeat responses to be identified with only the first response analyzed. A total of 389 (10.4%) individuals failed to provide this code and were included in the final analysis. A total of 45 repeat responders were identified and deleted, leaving a total of 2,774 eligible respondents. Individuals were told that they could skip any question(s) they did not wish to answer. Those who refused to provide a five-digit code were included based on the rationale that fear of lost anonymity is more likely to motivate response refusal than repeat participation.

Data sources and measurement

Prescription drug substitution was evaluated by asking survey respondents, "Have you ever used cannabis as a substitute for prescription drugs (yes/no)?" If the respondent answered in the affirmative, an open-ended response field was available with the instructions, "Please list prescription drugs that you have substituted cannabis for:"

If a specific number of prescription drugs were entered into the open-ended response field, values were coded as the

number of drugs per category. For example, “opiate pain killers (Roxicet, Percocet, Vicodin) and benzos (Xanax)” was counted as three substitutions in the drug category of narcotics/opioids and one substitution in the drug category of benzodiazepines. If a specific number of prescription drugs were not entered, values were coded as the number of drug categories. For example, “opiates and pain killers, muscle relaxants, anti-anxiety meds and depression meds” was counted as one substitution for the following four drug categories: narcotics/opioids, muscle relaxants, anxiolytics and antidepressants.

All nonspecific drug entries mentioning “anxiety” (e.g., “anxiety meds”) were categorized as anxiolytics and then combined with drugs in the benzodiazepines category to form the broader category of anxiolytics/benzodiazepines. Combination drugs were recorded in multiple categories where appropriate, except for combinations of opioids and non-steroidal anti-inflammatory drugs (NSAIDs). Generic values like “pain medicine” were categorized as narcotics/opioids, as opposed to NSAIDs/non-opioid analgesics. Generic values like “prescription headache medication” were categorized as anti-migraine, despite the absence of language confirming the headaches were actually migraines.

Drugs available over the counter (OTC), and entered with specific names, were recorded as prescription drugs. For example, “ibuprofen” was assumed to be prescription ibuprofen, given the nature of the question(s) in the survey.

Type of cannabis use was determined by asking the question, “What kind of user do you consider yourself to be?” Respondents were given four, non-mutually exclusive options: “recreational user”, “medically indicated, recommended by licensed provider”, “medically indicated, self-prescribed” and “religious (e.g., Rastafari)”. For the purposes of this analysis, medical cannabis users were defined as those respondents identified as either “medically indicated, recommended by licensed provider” or “medically indicated, self-prescribed”, including those who were also identified as a “recreational user”.

Data analyses

Data analyses were conducted using SAS University Edition (SAS 9.4; SAS Institute Inc., Cary, NC, USA). Univariate and bivariate comparisons were conducted using PROC FREQ and chi-square tests. Odds ratios (ORs) were used to estimate strength of association using PROC LOGISTIC. Patient-Reported Outcomes Measurement Information

System (PROMIS) scores were calculated using the recommended scoring method that calibrates each score to a US national mean of 50 and standard deviation (SD) of 10.¹⁶ T-scores were calculated for only those respondents who answered all questions of the short form. Mean differences between PROMIS mental health and PROMIS physical health scores were computed using a two-sample *t*-test using PROC TTEST. Statistical significance was assessed using an alpha value of 0.05. Figures were produced using Microsoft Excel for Mac, version 15.27.

Results

Demographics

A total of 2,774 respondents were included in the final study population. A majority of respondents were males (55.72%), aged <36 years (62.71%), Caucasian (86.13%), residing in the US (83.02%) and identifying themselves as medical cannabis users (59.81%; Table 1). All 50 US states and >42 countries were represented in the survey. Just over half of respondents reported residing in the following states: Washington (32.50%), California (8.47%), Oregon (5.89%) or Colorado (4.27%).

A total of 1,248 respondents, or ~46% of respondents, responded affirmatively to the question, “Have you ever used cannabis as a substitute for prescription drugs?” The odds of reporting substituting cannabis for prescription drugs increased with age, up to 65 years of age (Table 2). The odds of reporting substituting were 1.21 (95% confidence interval [CI], 1.04–1.40) greater among females than males and 1.58 (95% CI, 1.00–2.48) greater among Native American/Asian/Pacific Islanders than Caucasians. Geographically, the odds of reporting substituting were greater among those residing in Canada (OR, 1.20; 95% CI, 0.82–1.76) and lesser among those residing in Europe (OR, 0.93; 95% CI, 0.72–1.21) as compared to those residing in the US. These geographical comparisons were not statistically significant.

Substitution for prescription drugs

A total of 1,248 respondents reported a total of 2,473 substitutions of prescription drugs. This represents approximately two drug substitutions per affirmative respondent. The most common classes of drugs substituted were narcotics/opioids (35.8%), anxiolytics/benzodiazepines (13.6%) and antidepressants (12.7%; Figure 1). Substituting cannabis for narcotics/opioids was 2.6 times more frequent than substituting cannabis for anxiolytics/benzodiazepines, the second most commonly substituted drug category.

Medical versus non-medical users

The odds of reporting substituting were 4.59 (95% CI, 3.87–5.43) times greater among self-identified medical cannabis users as compared to non-medical cannabis users. Approximately one-quarter (24.43%) of non-medical users reported substituting cannabis for prescription drugs (Table 2).

The relationship between user type (ie, medical or non-medical) and frequency of reported substitution was assessed independently for males and females and for different categories of age. The odds of substituting were more than six times greater (OR, 6.09; 95% CI, 4.65–7.80) among female medical users than among female non-medical users. Similarly, the odds were 3.7 times (95% CI, 2.91–4.57) greater among male medical users. A trend in the odds of substituting among medical users was also seen with increased age (Table 3).

Comorbidities

We previously reported in an earlier survey that of 1,429 respondents, 61% reported using cannabis for managing pain, 58% reported using cannabis for anxiety and 50% reported using cannabis for depression.⁶ In the current analysis, these same conditions were also the most commonly reported conditions by respondents. Of the 1,040 participants reporting pain and/or intractable pain, 619 (59.52%) reported depression and anxiety as comorbidities. As such, the odds of reporting substituting cannabis for prescription drugs were more than one and a half times greater (OR, 1.66; 95% CI, 1.27–2.16) among those reporting using it to manage pain, anxiety and depression than among those using it to manage only one of the three conditions.

States with legalized medical marijuana

A slightly higher percentage of those who reported substituting resided in states where medical cannabis was legal at the time of the survey (47% vs. 44%, $p=0.47$). This difference was not statistically significant.

PROMIS Global Health

The 10-item short form developed and published by PROMIS was used to arrive at a bottom-line indicator of self-reported health status. By summing the physical and mental health scores separately (using only participants with complete data on each subscale), the standard PROMIS raw score to T-score conversion allowed for comparing our sample with the general population. The distributions are standardized such that a score of 50 represents the mean for the US general population, with an SD of 10 points. A total of 1,186 respondents (43%) provided complete information for the 10-item short form. For mental health, the sample scored 39.34 (SD=5.05; 95% CI, 39.15–39.53). For physical health, the sample scored 40.26 (SD=3.94; 95% CI, 40.11–40.41), placing these respondents below average for global mental health and global physical health as compared with the general population. Those reporting substituting cannabis for prescription drugs scored similar to the overall sample population (mental health, mean: 39.75 [SD=5.32; 95% CI, 39.45–40.05]; physical health, mean: 39.80 [SD=4.00; 95% CI, 39.57–40.02]). In terms of the PROMIS raw scores (i.e., non-T-score-converted scores), those who reported substituting had slightly higher mental health scores (mean difference: 0.31; $p<0.001$) and slightly lower physical health scores

(mean difference: -0.31 , $p < 0.001$) than those who denied substituting (Figure 2).

Sensitivity analysis

A total of 389 respondents failed to provide a 5-digit code anonymously identifying themselves as unique respondents. When excluded from the analysis, the percentage of respondents reporting ever using cannabis as a substitute for prescription drugs increased from 45.55% ($n=1,248$) to 46.28% ($n=1,094$), an increase of 1%.

The odds of reporting substituting among medical users versus non-medical users decreased from 4.59 (95% CI, 3.87–5.43) to 4.54 (95% CI, 3.78–5.45), a decrease of 1.5%. Finally, while the total number of prescription drug substitutions by drug category decreased from 2,473 to 2,160, the per respondent substitution ratio remained two substitutions per respondent.

Discussion

The purpose of this study was to examine whether, and how often, cannabis users report substituting cannabis for prescription drugs. Overall, these PROs underscore four key points: 1) individuals are substituting cannabis for prescription drugs, independent of whether they identify themselves as medical users (medical users are doing so at almost five times the odds of non-medical users) and independent of legal access to medical cannabis; 2) this practice increases in frequency with age, up to 65 years, and is more common in females, particularly female medical users, and Native American/Asians/Pacific Islanders; 3) the most common classes of substitution were narcotics/opioids, anxiolytics/benzodiazepines and antidepressants; and 4) the odds of reporting substituting cannabis for prescription drugs were

more than one and a half times greater among those reporting the use of cannabis to manage pain, anxiety and depression than among those using it to manage only one of these three conditions. Stated differently, pain, anxiety and depression seem to represent a comorbidity triad that is associated with greater substitution frequency.

These data are in line with previous research suggesting that cannabis is commonly used as a substitute for prescription drugs. For example, in 2013 and 2016, Lucas et al^{17,18} found that 68% of 259 and 87% of 410 physician-authorized medical cannabis users in Canada reported substituting cannabis for alcohol and illicit or prescription drugs, respectively. In 2017, Lucas and Walsh¹⁹ found that 63% of 271 such subjects reported substituting cannabis for prescription drugs such as opioids (30%), benzodiazepines (16%) and antidepressants (12%), representing the same top three categories as data presented here. These findings also agree with our previous data showing that medical cannabis users report using cannabis most frequently to manage pain, anxiety and depression.⁶ The present study contributes to a greater understanding of substitution across specific classes of prescription drugs in a largely US-based sample, in a much larger cohort and cross-section, occurring among both medical and non-medical subjects, and in areas without legal access.

While the results of research on the effects of cannabis for medical use have been largely mixed, our previous study indicated that patients reporting using cannabis for managing pain are experiencing adequate symptom relief.⁶ In 2016, Boehnke et al conducted a survey at a medical cannabis dispensary and found a 64% decrease in opioid use among those reporting using cannabis for chronic pain ($n=118$). Respondents also reported a reduction in other classes of drugs, including antidepressants and NSAIDs, as well as a

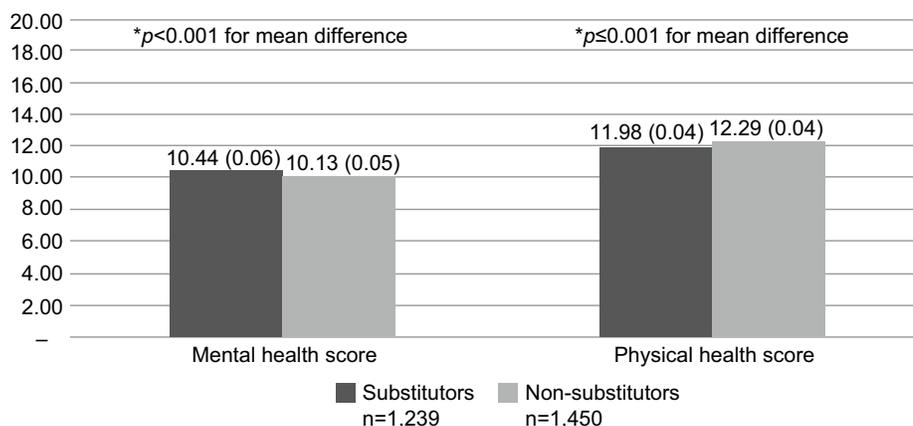

Figure 2 PROMIS Global Health short form: physical and mental health scores (mean [SE]; cannabis substitutors versus non-substitutors, 2016; raw scores [i.e., non-T-score corrected]).

Notes: Maximum score=20 for each domain. High scores reflect better functioning.

Abbreviations: PROMIS, Patient-Reported Outcomes Measurement Information System; SE, standard error.

decrease in the number of side effects of medications.²⁰ This study highlights differences between those with the comorbidities of pain, anxiety and depression and those with only one of the morbidities.

This team previously reported that in a survey of 1,429 medical cannabis users, 61% reported cannabis use for pain, 58% reported cannabis use for anxiety and 50% reported using cannabis to manage depression.⁶ In 2016, Dale and Stacey²¹ reported that those using cannabis for pain were more likely to be substituting for prescription drugs. In 2017, Walsh et al published a review of medical cannabis and mental health to try to better understand how medical cannabis use may impact areas of potential concern for clinicians. “Relaxation and relief of anxiety” and “relief of negative mood” or depression were among the most widely reported conditions in 60 publications included in their analysis.²² Because it is common for chronic pain patients to be prescribed combinatorial pharmacotherapy to address comorbidity with depression and/or anxiety, it is largely unknown how often patients may be discontinuing prescription medications when initiating cannabis use.²¹ Doctors need to have open communication with their patients regarding these matters in order to ensure that the medical community does not repeat the prescribing mistakes made in the past with opioid pharmacotherapy, namely, unchecked use of medical cannabis that leads to adverse events and abuse.²³ Furthermore, these preliminary data can serve to drive prospective research focused on whether cannabis can assist in opioid tapering protocols so that doctors can offer patients science-based guidance.

Importantly, older individuals may be substituting cannabis for prescription drugs at a higher rate than the general population, a finding in line with previous research.⁴ There are very little data on the impact of cannabis use in elderly populations. Our data show a trend toward increased substitution with age, perhaps not surprisingly, as older populations are more likely to be prescribed prescription drugs, particularly psychotropic medications.^{24,25}

We previously reported that medical cannabis users are evaluating cannabis products for the presence of a secondary, non-intoxicating cannabinoid, cannabidiol (CBD), ~40% of the time.⁶ CBD does not have the same action at the cannabinoid receptor as Δ^9 -tetrahydrocannabinol (THC), the primary intoxicating constituent in cannabis. To avoid adverse effects, particularly in elderly populations, the application of CBD-dominant cannabis varieties and preparations may be warranted. There is a need for more research on mental health disorders and cannabis use, particularly with a focus

on CBD rather than THC-dominant cannabis.²² This information is needed for doctors to be able to adequately participate in conversations with their patients, regardless of age, about the role that medical cannabis may play in managing mental health conditions.²⁶

We previously reported on gender differences in cannabis use and effects, highlighting the need for focused research on this topic.²⁷ Importantly, there is evidence of differences in endocannabinoid system function across gender.^{28–30} Here, we report that female users may be more likely to substitute cannabis than male users (OR, 1.21; 95% CI, 1.04–1.40) and that female medical users may be much more likely to substitute cannabis than female non-medical users (OR, 6.09; 95% CI, 4.65–7.80). These findings are interesting given that females reported significantly less frequency and quantity of use in our previous study. In that study, women were more likely to report use for anxiety, nausea, anorexia and migraine headaches than men. Taken together, these findings provide preliminary data for future studies on gender-based differences in cannabis use and effects.

This study showed a nonsignificant difference between the proportion of individuals reporting substituting cannabis for prescription drugs in states with legalized medical cannabis versus states where cannabis remains illegal (47% vs. 44%, $p=0.47$). This finding suggests that state laws allowing access to, and use of, medical cannabis may not be influencing individual decision making in this area. This finding is in contrast to other studies showing that the use of prescription drugs fell in states once medical cannabis laws were implemented.⁴ This finding has public health implications and should be explored further.

As compared with the general population, survey respondents scored below average for global mental health and global physical health on the PROMIS 10-item short form. This association deserves further attention to determine whether individuals with lesser mental/physical health are using cannabis as a medical therapy or whether cannabis use is negatively affecting mental/physical health.

Given the current nationwide epidemic of prescription opioid-related abuse, addiction and death, there is an urgent need for alternatives with efficacy and safer toxicology profiles.³¹ It is important to note that active “substitution” with cannabis may be a conscious decision to reduce harm caused by narcotics.³² Not only may opioid therapy prove ineffective for some patients but it may also induce serious adverse reactions that complicate management, including allodynia or opioid-induced hyperalgesia, also known as “paradoxical pain”.³³ Chronic pain is an “expensive” condition, both

economically and socially, yet existing pharmacotherapeutic interventions are not always adequate.^{34–36} Taken with pre-clinical data on the role of the endocannabinoid system in stress, pain processing and immune homeostasis, it is clear that future investigation is warranted using controlled trials with human subjects to better understand the role that cannabis may play in treating pain, anxiety, depression and other conditions.^{37–46}

Limitations

The study population was a self-selected convenience sample, and it is possible that individuals with favorable opinions of, and experiences with, cannabis are more likely to have responded to the questionnaire than those with negative opinions and experiences. This, when considered with the predominance of males, Caucasians and individuals aged <35 years, indicates that our sample may not be representative of the general population. In addition, PROs are subject to reporting bias.^{47,48}

Another limitation of this study was the method by which prescription drug information was collected. The availability of an open-ended response field enabled narrative responses that made accurate categorization difficult. In some instances, this limitation may have resulted in undercounting. For example, a response of “a variety of SSRIs” was counted as one drug substitution in the drug category antidepressants. In other instances, it may have resulted in overcounting. For example, a response of “opiate pain killers (Roxicet, Percocet, Vicodin)” was counted as three substitutions in the drug category of narcotics/opioids, yet the respondent may have only substituted cannabis for “Vicodin” after previously trying “Roxicet” and “Percocet”. Additionally, drugs that are available both OTC and via prescription (e.g., ibuprofen) were counted as prescription substitutions, given the nature of the question. The substitution count for these OTC drugs would be overestimated if these drugs were not prescribed.

Data for determining the proportion of individuals reporting substituting cannabis for prescription drugs in states with legal versus illegal medical cannabis policies were analyzed as of December 31, 2016. Several states may not have had legal medical cannabis policies at the time an individual completed the survey, but did have such policies at the time of analysis, which may falsely increase the proportion of those reporting substituting in states with legalized medical cannabis.

Conclusion

These data contribute to a growing body of literature suggesting cannabis, legal or otherwise, is being used as a

substitute for prescription drugs, particularly prescription pain relievers. According to the CDC, 259 million prescriptions for pain relievers were written by health care providers in 2012.⁴⁹ In 2015, two million Americans aged ≥12 years had a substance use disorder that involved prescription pain relievers.⁵⁰ The CDC also reports that overdoses from prescription opioids are a “driving factor” in the increase in opiate overdose deaths over the past 15 years. Such deaths have more than quadrupled in the same time period with >20,000 overdose deaths attributable to prescription pain relievers alone.⁵¹

Despite the illegality of cannabis in many states and the lack of professional guidance on dosing, routes of delivery and inadequate standardization or quality control for medical use, individuals are taking it upon themselves to augment, or discontinue, US Food and Drug Administration (FDA)-approved drugs in favor of a largely unregulated herbal one.

Publish your work in this journal

The Journal of Pain Research is an international, peer reviewed, open access, online journal that welcomes laboratory and clinical findings in the fields of pain research and the prevention and management of pain. Original research, reviews, symposium reports, hypothesis formation and commentaries are all considered for publication.

The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Abstract

Introduction: Chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) is a chronic pelvic pain condition largely refractory to treatment. Cannabis (marijuana) use has been reported for a wide variety of chronic pain conditions, but no study has examined prevalence of cannabis use, symptom benefit or side effects, or frequency in CP/CPPS.

Methods: Participants were recruited from an outpatient CP/CPPS urology clinic (n = 98) and online through the Prostatitis Foundation website (n = 244). Participants completed questionnaires (demographics, CP/CPPS, depression, cannabis).

Results: The clinic sample included Canadian patients and the online sample included primarily American patients. Due to differences, groups were examined separately. Almost 50% of respondents reported using cannabis (clinic n = 49; online n = 89). Of the cannabis users, 36.8% of clinic and 75% of online respondents reported that it improved their symptoms. Most of the respondents (from the clinic and online groups) reported that cannabis improved their mood, pain, muscle spasms, and sleep. However, they did not note any improvements for weakness, fatigue, numbness, ambulation, and urination. Overall, the effectiveness of cannabis for CP/CPPS was "somewhat/very effective" (57% clinic; 63% online). There were no differences between side effects or choice of consumption and most reported using cannabis rarely.

Conclusions: These are the first estimates in men suffering from CP/CPPS and suggest that while cannabis use is prevalent, its medical use and benefit are unknown. This is an understudied area and the benefit or hazard for cannabis use awaits further study.

Introduction

Chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) is characterized by pain in the perineum, pelvic, and suprapubic areas or the external genitalia with variable degrees of voiding or ejaculatory disturbances.^{1,2} The prevalence is about

7.1% (range: 2.2%–16%), with a 6.7% median.³ CP/CPPS symptoms do not routinely remit, with 66% of community-based samples experiencing symptoms 1 year later,⁴ and patients showing no changes in pain, disability, or catastrophizing over 2 years later.⁵ CP/CPPS etiology is unclear and medical treatments are largely ineffective.⁶ Medications (antimicrobials, alpha-blockers, anti-inflammatories), as well as phytotherapy, biofeedback, thermal therapies, and pelvic floor training have been examined⁷ and may provide mild benefit,⁶ but most men continue to experience chronic pain.

Physicians may use opioids to manage CP/CPPS pain, but their efficacy is limited and physicians fear tolerance, misuse, and side effects, such as nausea/vomiting or sedation.⁸ Chronic pain patients are turning to alternate forms of symptom relief, yet no research on this is available for CP/CPPS. Cannabis sativa has been used for pain and symptom relief for thousands of years. In Canada and several American states, patients use medical cannabis for severe intractable illnesses. As an addition to opioid treatment for chronic pain, vaporized cannabis results in pain reduction without altering plasma opioid levels.⁹ Moreover, 71% of the available randomized controlled studies concluded that cannabinoids were associated with pain relief, with low adverse effects, and good tolerance.¹⁰ Cannabis may be used in conjunction with or substitute for prescription opiates resulting in reduced opiate use.¹¹ Wide ranging types, quantities, and frequency of cannabis use for pain relief have been reported, with chronic non-cancer pain patients reporting previous use (15%) or current use (10%).¹²

We examined cannabis prevalence among men experiencing CP/CPPS-like symptoms from a tertiary care urology department and from an online group. Although previous work has not examined cannabis use in CP/CPPS, it was expected that use would echo previous pain studies.¹² We also solicited patient self-reports on the side effects or potential benefits, frequency, and indication of future cannabis use.

Methods

Participants/procedure

Identical online and outpatient surveys were administered to an online community-based sample and a tertiary care outpatient CP/CPPS clinic sample. All participants remained anonymous and received no financial compensation. Clinic patients were approached after their appointments and briefed about this Research Ethics Board-approved study. Interested participants then provided written consent and received a package (letter of information, debriefing form, questionnaires, postage-paid return envelope) to complete and mail back. The online sample was recruited through the Prostatitis Foundation.¹³ Participants were a self-selected “availability” sample from site visitors. All participants were required to read and write in English. All questionnaires were in English.

Measures

Demographics

Participants completed questions on demographics (age, CP/CPPS diagnosis, health problems, tobacco use, medication use).

Medical symptoms

The National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI)¹⁴ assessed prostatitis-like symptoms and their impact on daily life (pain, urinary symptoms, quality of life) providing a score range from 0 to 43. The self-administered NIH-CPSI provides a valid, psychometrically robust outcome measure.¹⁴ Confirmation of CP/CPPS cases was based on NIH-CPSI pain/discomfort in perineum and/or with ejaculation and NIH-CPSI total pain score of ≥ 4 (0–21), used in the community^{15–17} and in the general population¹⁸ studies.

Depression

The Patient Health Questionnaire 9 (PHQ-9)¹⁹ is a reliable and valid self-report measure using 9 items to assess depressive symptoms. An item sum was used for the indexation of depression.

Experience with cannabis

We used a 21-question descriptive survey on experience with cannabis; questions were binary (yes/no), multiple choice,

and rating scales. Questions included whether participants had ever used cannabis, the purpose of use, relief of pain/effects with use, potential side effects, usage frequency, and usage method.¹² Participants rated personal experience with different modes of delivery using Likert scale-style responses.

Data analysis

Scores were excluded if $>15\%$ of the items were missing on measures. Participants who provided $\geq 85\%$ of items on a particular measure had the missing items imputed using means replacement procedures.²⁰ As a check on generalizability, primary comparisons between the online and clinic data were computed for age and domains of NIH-CPSI (quality of life pain, urinary), and the PHQ-9. If outcomes differed significantly, online and clinical samples would be examined separately. Due to the exploratory nature, unadjusted t-tests and descriptive analyses (chi-square) were used to evaluate differences between cannabis users and non-users.

Results

The total sample of participants was comprised of an online self-reported CP/CPPS sample ($n = 376$) and a tertiary care outpatient CP/CPPS clinic sample ($n = 100$). Two participants were excluded from the clinic sample and 35% ($n = 132$) of the online sample was excluded due to incomplete data. In the end, we had 244 online and 98 clinic participants. Missing data pattern for the online group was random.

The online group was on average 10 years younger than the clinic group ($p < 0.001$), with an average age of 44.57 (standard deviation 13.96) for the full sample (Table 1). The clinic sample was Canadian and the online sample was primarily American.

The online group reported more depressive symptoms, pain, poorer quality of life, and worse symptom scores (Table 2). For the remaining analyses, samples were examined across groups. Most of clinic (63.3%) and online (79.1%) participants reported a score of 4 or above on prostatitis cut scores ($\chi^2 = 9.24$, $p = 0.013$). While the clinic and online groups did not differ in terms tobacco use ($\chi^2 = 1.17$, $p = 0.340$), the online group (63.1%) consumed more medication for pain, mood, sleep, or spasms than the clinic group (47.4%) ($\chi^2 = 7.00$, $p = 0.01$). There were no group differences when asked if they had ever used cannabis ($\chi^2 = 0.87$, $p = 0.390$) (yes 50% clinic, 44.3% online). Examining only those previously using, 36.8% clinic and 75% of the online groups reported that cannabis improved their symptoms ($\chi^2 = 7.63$, $p = 0.006$).

Participants were questioned whether cannabis use made their symptoms “worse/no better” to “slightly/much better” (Table 3). The large majority of online and half of clinic participants reported that cannabis improved their mood by a

Table 1. Sample demographics

	Online (n= 244)	Clinic (n = 98)
Age (years \pm SD)	42.04 (13.33)	51.56 (12.21)
Continent N (% of column total)		
North America	162 (66%)	
Canada	12 (7%)	98 (100%)
United States	150 (93%)	
South America	6 (2%)	
Europe	54 (22%)	
Australia	4 (2%)	
Asia	15 (6%)	
Africa (Egypt)	3 (1%)	

SD: standard deviation.

“slightly/much better” degree (Fisher’s exact test $p = 0.026$). Across both groups, cannabis’ effects made pain “slightly/much better” ($\chi^2 = 2.48$, $p = 0.619$), as with muscle spasms ($\chi^2 = 0.51$, $p = 0.474$), sleep ($\chi^2 = 0.54$, $p = 0.461$), and a borderline majority for nausea ($\chi^2 = 0.51$, $p = 0.474$). Also a minority of participants reported “slightly/much better” improvement in weakness ($\chi^2 = 3.11$, $p = 0.078$), fatigue ($\chi^2 = 3.40$, $p = 0.065$), numbness ($\chi^2 = 1.16$, $p = 0.281$), ambulating ($\chi^2 = 0.64$, $p = 0.423$), and urination (Fisher’s exact test $p = 0.432$). When asked on overall effectiveness of cannabis for CP/CPPS, most participants (57% clinic, 63% online) reported cannabis as “somewhat/very effective” ($\chi^2 = 7.89$, $p = 0.051$).

There was an even distribution of side effects reported by the groups, with most suggesting “none” to “mild” side effects from cannabis use (70.3% clinic, 70.8% online) ($\chi^2 = 0.05$, $p = 0.972$) (Table 4). Also, if offered a choice, participants reported similar preferences for cannabis method across groups ($\chi^2 = 1.99$, $p = 0.370$), but smoking was a leading choice. There were no differences when asked about the preferred form of cannabis they had used ($\chi^2 = 2.59$, $p = 0.274$), although most participants listed herbal option (buds, sinsemilla, hydroponic). In current cannabis users, frequency did not differ between groups ($\chi^2 = 0.27$, $p = 0.88$), with most respondents using “rarely” (73.3% clinic, 77.3% online).

Discussion

This is the first study to document the initial prevalence and patterns of cannabis use in men suffering from CP/CPPS from an outpatient urology clinic and online. Almost 50% of participants used cannabis and almost 3/4 reported using it for symptom relief. These figures are bigger than those in other studies.¹² The samples were treated as separate during analyses because the online group was younger, reported greater depression, pain, and diminished quality of life. Interestingly, while examining only those having used cannabis, fewer clinic respondents reported benefit compared to the online group. This almost doubling of the reported

Table 2. Psychological and NIH-CPSI differences between clinic and online participants

		N	Mean	SD	p value
Depressive symptoms	Clinic	92	7.15	6.66	<0.001

benefit by the online group may be related to symptom/disease severity differences in this study. The present data cannot describe factors underlying differences in benefit across groups, but this study is consistent with the suggestion that chronic pain is associated with lifetime marijuana use.²¹

Physicians should be aware and question patients on cannabis use. Despite a lack of information on the mechanisms of glycinergic cannabinoids for pain, cannabidiol, a major nonpsychoactive component of cannabis, suppressed chronic inflammatory pain in mice.²² Furthermore, the use of cannabis was not associated with analgesic tolerance in rats.²² It appears that cannabinoids’ anti-inflammatory action

Table 3. Cannabis illness-symptom effects across clinic and online participants

		“Worse/No Better” (n)	“Slightly/Much Better” (n)
Mood	Clinic	50.0% (12)	50.0% (12)

stimulates cannabinoid receptors.²³ However, contrasting results about cannabis side effects discouraged the authors for suggesting its chronic use for pain relief due to associated cognitive deficits and gastrointestinal toxicity.²³

The online group reported greater distress and NIH-CPSI symptoms, but both groups showed trends where most reported improved symptoms like mood, pain, muscle spasms and sleep. However, no improvements were in weakness, fatigue, numbness, or ambulation. Improved symptoms for some patients might reflect the shared effects that pain/muscle spasm can have in regard to improving sleep and ultimately mood. Current research shows that unresolved chronic pain, continuing disease, obesity, and sleeping problems predict the persistence of pain, while issues like mood are weakly associated.²⁴ Of other note, cannabis use was not helpful for urinary symptoms, which can be very bothersome in patients with CP/CPPS.

This survey showed that the side effects of cannabis appear minimal, with most patients reporting “none” to “mild” side effects. More detailed information on the amount of cannabis use, the types used (medical vs. other) would be important to provide a more detailed pattern of examining benefits. If offered a choice on how to use cannabis, participants reported smoking as the preferred methods – this is similar with other studies.²⁵ There were no differences by groups – the herbal form was endorsed by most respondents. In regard to current frequency of use, most participants reported using cannabis “rarely;” further study into usage patterns may shed some light on whether participants use cannabis primarily to manage pain flares or muscle spasms, or to aid with sleep. If usage is associated with intermittent pains, as flares, then that may reflect the rarity of reported use.

Our study has its limitations. This initial survey cannot qualify the benefits/risks of cannabis use in CP/CPPS, and simply suggests rates for further comparison. Sample size was an issue in some analyses because finer detail in questions, such as symptom benefit, had to be collapsed into 2 categories (“worse/no change” and “slightly/much better”) from original categories (“much worse,” “slightly worse,” “no change,” “slightly better,” “much better”). Larger samples

are necessary to gather more accurate patterns of use and benefit.

Although our samples were not randomized or stratified, they represent tertiary care outpatient males diagnosed with CP/CPPS, as well as community-based men with CP/CPPS-like symptoms. More online participants reported a prostatitis cut score. Perhaps the clinic men experienced reduced symptoms under the care of a specialist, but there was no opportunity to verify this in our study. Future research should also collect healthcare utilization and previous treatments prior to the onset of cannabis use. This data would allow contrasts and provide insight into medical comorbidities prior to cannabis use. It would also be interesting to examine the associations between psychological pre-cannabis use pain-associated comorbidities, like catastrophizing, and patterns of use.

Conclusion

This is the first study to examine and report on cannabis usage and benefit in participants with CP/CPPS from a tertiary care and community “availability” sample. The current data suggest that almost 50% of men with CP/CPPS-like symptoms have used cannabis in their lifetimes and that a minority of clinic patients versus most online participants reported cannabis benefit. Future research should examine larger representative samples to further document usage patterns, fuller CP/CPPS symptom benefit, and associated factors with usage in predictive models. The ultimate study would be a randomized controlled trial prospectively evaluating the efficacy and safety of cannabis compared to either placebo or an active comparator.

Who is Using Cannabis as a Medicine and Why: An Exploratory Study[†]

Alan C. Ogborne, Ph.D.*; Reginald G. Smart, Ph.D.*;
Timothy Weber, B.A.** & Carol Birchmore-Timney, M.A.**

Abstract—This article reports on an exploratory study of medical cannabis users. Interviews were completed with 50 self-identified medical cannabis users recruited through notices in newspapers and on bulletin boards. They reported using cannabis for a variety of conditions including HIV-AIDS-related problems, chronic pain, depression, anxiety, menstrual cramps, migraine, narcotic addiction as well as everyday aches, pains, stresses and sleeping difficulties. A majority also used cannabis for recreational purposes, and many were longer-term cannabis users. However, there were some notable exceptions. Almost all smoked cannabis and many did so two to three times a day. Few admitted negative experiences with cannabis, although some problems evident to the researchers were not clearly admitted. Those who told their doctors about their medical cannabis use found doctors noncommittal or supportive. The results raise questions about the definition of medical cannabis use and about policies that might be developed to accommodate such use. Limitations of the study are noted and further research suggested. Research priorities include population surveys, studies involving larger, more representative samples of medical cannabis users and studies of medical cannabis use among people with HIV-AIDS.

Keywords—cannabis, HIV/AIDs, medical marijuana, self medication

Cannabis has a long history of use as a medicine, and during the 19th century extracts of cannabis were recommended by respected physicians for a wide range of medical conditions (Grinspoon & Bakalar 1997). Cannabis was considered to have analgesic, sedative, anti-inflammatory, antispasmodic, anti-asthmatic and anticonvulsant properties and promoted for the treatment of tetanus, cholera, pruritis, uterine dysfunction, labor and menstrual pains, gout, asthma, neuralgia, rheumatism, convulsions and

depression. Early in the 20th century the use of cannabis fell out of favor with the medical profession due to the discovery of newer, more stable and effective drugs. A synthetic form of THC (dronabinol or marinol) has since been developed for the treatment of nausea associated with chemotherapy and AIDS-related anorexia. However, until recently, cannabis has mainly been used illegally as a recreational drug with the intention of getting high rather than treating medical conditions.

Anecdotal and journalistic evidence indicating that cannabis is regaining popularity as a medicine has been accumulating since the 1970s. Personal testimonials from users and statements by lobbyists and some physicians have indicated that cannabis is used by people suffering from glaucoma, multiple sclerosis, epilepsy, mood disorders, and other disorders that cause pain, muscular tension or spasms (Campbell 1996). One study of people using a buyers' club

in California showed that many were using cannabis to treat AIDS-related symptoms or for a variety of chronic pain, neurological and psychiatric disorders (Harris, Mendelson & Jones 1998).

There are two published studies of medical cannabis use among people with HIV/AIDS. The first was a survey conducted during 1993/94 that involved patients of an AIDS clinic in Alabama (Dansak 1997). Of the 72 patients interviewed, 33 (46%) were currently using cannabis and almost all had used it before the onset of AIDS/HIV. Most current users had used cannabis for medical reasons as it had beneficial effects on gastrointestinal conditions such as nausea, vomiting, indigestion and appetite. A few also noted that cannabis helped alleviate depression and two noted that it reduced anxiety.

The second study of medical cannabis use by persons with HIV/AIDS was conducted in Hawaii (Wesner 1996) through an AIDS Newsletter. It reached 374 persons affected with AIDS or HIV but only 35% responded, and it is not clear whether respondents were more likely to have used cannabis than nonrespondents. Of those who did respond, 36.9% had used cannabis as a therapy for AIDS symptoms; of those who had also used prescription anti-emetics, 80% preferred cannabis. A third of those who had used cannabis medically had not discussed this with their doctors.

There are no published surveys of medical cannabis use among people suffering from chemotherapy-induced nausea, multiple sclerosis, epilepsy or other physical conditions for which cannabis is said to be helpful. However, several surveys have shown that cannabis use is common among psychiatric patients who often seem to use cannabis to medicate psychiatric symptoms (Beesley & Russell 1997; Rohnaar & Timmerman 1997; Mathers et al. 1991; Blackwell, Beresford & Lambert 1987).

The prevalence of medical cannabis use is not known except in Ontario, where the results from a province-wide survey of adults aged 18 and over indicate that about 2% had intentionally used cannabis for self-defined medical reasons at least once in the past year. This represents 7.6% of those who had ever used cannabis and 22% of those who had used cannabis in the last year. No comparable figures are available from other Canadian provinces or from other countries. The latest national drug survey in Canada was in 1994 and this showed that 7.6% of the adult population had used cannabis in the past year (Smart & Ogborne 2000). However, no questions about medical cannabis use were included.

The medical use of cannabis raises new and important medical, social policy and legal issues concerning the rights of people to use an illegal substance for medical reasons. In the United States and in Canada there is considerable public support for the medical use of cannabis and for the rights of physicians to recommend cannabis to people who might benefit from it (Lindsmith Centre 1998; Angus Reid Group

1997). Attempts have also been made to establish buyers' clubs to provide cannabis to those with legitimate medical needs, and several recent court rulings have been in favor of the rights of sick people to use cannabis for medical reasons. More information is therefore needed on the nature and extent of medical cannabis use and on motivations, characteristics and experiences of those involved. This is especially so because cannabis is used medically by some of the most vulnerable and sickest people. This article reports a study that explores why people use cannabis for medical reasons, the effects they get, their methods and patterns of use, their experiences with physicians and their encounters with the law. It provides an analysis of interviews with 50 cannabis users in Toronto.¹ These interviews were conducted to (1) assess the feasibility of a larger study involving medical cannabis users and (2) explore opinions and practices concerning the medical use of cannabis. Implications for further research and for social policy are considered in the discussion.

METHODS

Those interviewed were recruited mostly through notices placed in newspapers and on bulletin boards at the Addiction Research Foundation, downtown bookstores, grocery stores, restaurants, and laundromats, AIDS clinics and drop-in centres and an informal buyers' club. These notices invited those who had ever used cannabis for medical reasons to share their experiences in a confidential interview. A few respondents (less than five) were also recruited through contacts with professionals and through the use of snowball sampling. Those who called in response to information about the study and who said that they used cannabis for medical conditions were invited for an interview. Most interviews were conducted at the Addiction Research Foundation. Others were conducted in respondents' homes, at a drop-in centre, or a restaurant; two interviews were conducted by telephone. All those interviewed were paid \$10. All interview questions were open-ended and encompassed a range of topics. In this article, the focus will be on: (1) reasons for the medical use of cannabis; (2) other attempts to treat the conditions for which cannabis was used; (3) routes to cannabis use; (4) methods of use; (5) patterns and amounts of use; (6) sources of supply; (7) negative experiences with cannabis; and (8) experiences with physicians.

RESULTS

Fifty (50) individuals were interviewed over a six-month period. About 70 others inquired about the study but could not be contacted. Twenty others did not show up for interviews. Of the 50 people interviewed 33 (66%) were male. The average age was 38, with a range from 26 to 57.

Arthritis	1

*For which they had received medical or psychiatric treatment (not noted in text).

**Did not seek treatment.

Medical Reasons Reported for Cannabis Use

Table 1 shows the conditions for which respondents said they used cannabis. The majority (n=34) reported using cannabis to treat symptoms of organic illnesses or to treat pains due to accidents or unknown causes. The most common organic illness was HIV/AIDS (n=11). Others (n=9) said they used cannabis for serious psychological problems (clinical depression or chronic anxiety), anorexia (n=2) or symptoms related to narcotic addiction (craving and methadone-related nausea). One person claimed to use cannabis to treat chronic but unexplained nausea. Finally, two reported using cannabis to treat minor medical conditions and cope with everyday stresses.

A wide range of symptoms or conditions were reportedly relieved by cannabis including difficulty sleeping, physical pain, loss of appetite, nausea, seizures, tics and muscle spasms, craving for narcotics, loss of energy, depression and anxiety. Table 2 shows the frequency with which specific symptoms were mentioned. The total number of symptoms exceeds the number of respondents because many reported using cannabis for two or more symptoms or conditions. Typically nausea and loss of appetite were mentioned together as were depression and anxiety.

The reported reasons for taking cannabis varied greatly:

Its mostly for spasms. I use it for relaxing . . . I get a lot of pain running all down my neck. . . . I get a lot of spasms coz of the HIV . . . It [cannabis] helps because it relaxes me and gets rid of the muscle pains in my neck. (male with HIV).²

I can see clearer . . . a little sharper. . . . Sometimes my eyes start . . . pulsating . . . itchiness and stuff and after I do one of those [smoke a joint] . . . no problem. (male with retinitis).

If I have no marijuana I'm no good for nobody. . . . But the moment I smoke a joint I've got self-esteem, it makes me feel good. (male with HIV).

I could not control my focus . . . I have double vision . . . it [cannabis] helps me. . . . The condition of my eyes has improved and he [the doctor] could see this because he made me undergo tests. (male with eye problems related to Graves disease).

. . . to increase my appetite . . . my metabolism burns very fast. Can't gain an ounce . . . can't even maintain weight unless I eat five, six times a day. Can't bring myself to do that unless I smoke a couple of joints. (male with anorexia).

I have really excruciating pain and I find it [cannabis] helps. (female with chronic back pain).

He is currently using medical marijuana for pain relief for lupus and vascularities associated with lupus; capillaries break and it results in sores that are quite painful. A secondary use is to relieve nausea and pain associated with the drugs for lupus. (Interviewer notes on male with lupus).

If I'm seizing I will get someone . . . [and] they'll come by with a couple of joints and . . . take a puff . . . then in a few seconds or a few minutes I got no seizure problems whatever. It's amazing how it works. (male with epilepsy).

I take 30 pills a day . . . I feel nauseated most of the time . . . marijuana takes care of the nausea . . . prescriptions from the doctor . . . don't work as well. (male with HIV).

TABLE 2
Number of Respondents with Symptoms Reported to be Relieved with the Use of Cannabis*

Problems sleeping	28
Loss of appetite	21
Nausea or pain (including menstrual cramps and headaches)	14
Depression	12
Anxiety/tension	11
Ticks and muscular spasms	10
Seizures	4
Loss of energy	3**
Difficulty breathing (asthma related)	2
Craving for heroin	2
Anger	1
Eye irritation and double vision (in Graves Disease)	1

*Number of symptoms exceeds number of respondents because some respondents reported two or more symptoms that were relieved by cannabis.

**Includes one person who developed seizures following the onset of HIV infection.

... if you're feeling really, really bad some days ... eh maybe escape isn't the right word because it's a drug but it gives you some relief to make that go away for a while ... if I am really bad I don't take the Tylenol 3. I would rather take a few tokes. (female with multiple sclerosis).

It's an unexplained nausea ... to the point of vomiting ... I won't eat for three to four days and then I'll still be vomiting like dry heaves. I just like a little bit [of cannabis] ... it's just to make it go away ... (female with nausea).

To induce my appetite because I'm on methadone ... I lost about 25 pounds cause of it ... suppresses your appetite but it also make you nauseous ... I wasn't eating at all for three days at a time ... so I started smoking ... it worked for the nausea when I was pregnant ... and it helps me sleep. (female with nausea and narcotic addiction).

I find [prior to menstruation] my body goes through ... aches and pains and back pains ... and when I smoke marijuana it tends to relieve it ... I'm able to function ... as opposed to going and taking a Midol or going to my family physician ... for a synthetic prescription. (female with menstrual cramps).

I started smoking because that was the only way I could eat and function. Otherwise I had to stay in bed ... [I] was so sick. But when I smoked a joint I can clean the house ... eat ... but as soon as it passed I have to go back to bed. (female with HIV).

Bulimia, anxiety, depression ... what it does [cannabis] is it calms down my system so that I can eat and think rationally. I get all my stuff down and then it's time for bed. (female with anorexia).

[Cannabis] helps me with my nerves and sometimes with pain ... I don't know if I could ... live and be functional without it [cannabis] unless I got something under a doctor's care but because of my liver any pills are bad for me. (female with anxiety and hepatitis).

I use it [cannabis] to alleviate cravings for heroin. It helps me get through the day without using heroin. (male receiving methadone).

Nausea, which you suffer from a lot when you have Crohn's, [also] loss of appetite ... lot of pain it would help with that. Also ... with Crohn's you'd have a lot of like spasms of your stomach or your bowel inside and it would help with that. (male with Crohn's disease).

If I've got a boardroom meeting let's say at 3:00 today, at 1:00 I'll take a "butt" ... I'm very ... lucid. (male with Tourette's Syndrome).

Treatments Other than Cannabis Tried for Main Conditions and Symptoms

Other attempts to treat the symptoms and conditions that motivated self medication with cannabis were quite variable. In some cases it was not clear that alternatives to cannabis had been tried. However, in other cases cannabis was described as superior to other, more conventional, treatments:

[I've tried] Dilantin and phenobarbital but they were not controlling the seizures. ... I've not used any other medication (except cannabis) since 1971. (male with epilepsy).

Two specialists ... gave me pills ... but they didn't make a noticeable difference. ... I've tried health food stuff ... it just takes a little bit [of cannabis] ... to make it [nausea] go away. (female with chronic nausea).

So ... I tried ... Prozac. It did not help me ... it made me a different person ... very introverted ... withdrawn. (female with migraines and insomnia).

I was taking tons of medication ... a major dose of Anafranil [an antidepressant] and ... Rivatrol [an anticonvulsant] and ... they were getting me very lethargic and laid back ... what was happening was it was getting me so stoned and so happy ... my tics didn't go away ... [but] I couldn't give a hoot and henny ... (male with Tourette's Syndrome)

They [doctors] gave me Tylenol 3s and they made me a bit groggy. ... I wanted to work ... I noticed that when I took a

bit of marijuana it alleviated the symptoms and allowed me to function normally. (male with repetitive strain injury).

I was on Serax [a sedative] once for almost a year but I found that taking Serax made me sick. It made my stomach feel real weird. So I discontinued it... marijuana makes you feel strange but it's a good kinda strange . . . it's not the kinda stone where you're walking around and your head feels like it's 15 miles high. (male with HIV).

I tried different pain killers and at first they seemed to be okay but . . . they stopped writing prescriptions for me. I found it [the marijuana] helped. It made me motivated and gave me energy and kept me active. (female with back pain).

I was taking Valium, diazepam . . . like I took it for like three years and then I started smoking marijuana . . . I didn't have the same feelings I had when I was taking the Valium. I felt more calm, more relaxed. . . . It was able to open my appetite to eat. (male suffering from depression).

Well, I suffer from depression and when you're really, really, really depressed a joint works a lot better. . . . I've tried all the antidepressants, like all of them and I've just given up on it. (male with depression).

Cannabis was, however, also sometimes used in combination with drug treatments that respondents found helpful.

I'm a chronic asthmatic. So . . . I'm using it [cannabis] in combination with . . . Beclavent which is a long-term steroid and occasional use of Ventolin, an immediate release asthmatic drug, just for when you're in a crisis situation . . . and I find a little marijuana on the side does help. (male with chronic asthma).

I fell down a flight of stairs . . . and found myself in a lot of pain . . . decided to stop taking the prescribed medication because I ballooned up to 235 pounds. . . . I'm back to taking Tylenol 3s but I've reduced my intake to more than half since I've started smoking [cannabis]. (Female with chronic pain).

Only one person with HIV/AIDS reported being prescribed Marinol[®] (synthetic THC) for HIV/AIDS-related anorexia and nausea. However, he claimed that this had no noticeable effects. Apart from the perceived medical advantages of cannabis, some respondents also valued cannabis because it was relatively inexpensive or "natural":

It [Marinol[®]] is like \$700 for a month's supply of 90 pills and that's the max you can get. . . . So that's why I'd rather buy cannabis on the street with the welfare cheque (male with HIV).

Because it's a natural, organic thing, instead of taking these chemical prescriptions which I don't like. I'm a naturalist and I'd rather do something that grows naturally. (female with anorexia, bulimia and depression).

I would much rather use something natural—a plant product . . . than a chemical or pharmaceutical drug coz I found that they have a lot of side effects. (male with Crohn's disease).

Routes to Cannabis Use

The majority (n=42) of interviewees had at least some experience with cannabis as a recreational drug, and some (n=30) described a long history of recreational use (seven to 35 years). In these cases self-defined, medical cannabis use typically started when recreational use was found to be helpful for medical or psychological problems:

I had lost a lot of weight . . . I was down to like 97 pounds. When I started smoking marijuana I started just smoking it casually . . . to be part of the crowd. But, I noticed the more that I smoked, the hungrier I got and the more that I eat, I found the better I sleep. (male with HIV).

I used to smoke when I was younger but that was when I guess when I started first smoking it was more recreational, with the guys sort of thing, then I stopped for quite a long period of time—I was a very hyper person. So . . . then I decided to smoke it again. (male with insomnia).

When I used to smoke it [cannabis] for recreation I was running a lot of track and field and that's . . . when I noticed when I . . . pulled muscles and so forth the pain wasn't there at all. (male with migraine).

I had tried it for recreational use back as a teenager . . . and I found that . . . there's times when I was feeling bad with my illness and I'd smoke some and I felt better. . . . So, um, I thought that it probably might work for me and . . . It worked better than most of the medicine I was taking. (male with Crohn's disease).

I've been smoking dope for 24 years. Originally, peer pressure, getting high, now I don't even get high, I smoke it to increase my appetite . . . Can't even maintain weight unless I eat five, six times a day. Can't do that unless I smoke a couple of joints. (male with anorexia).

Respondents with no, or very limited previous experiences with cannabis (n=9) started using it medically after reading about it or on the advice of others. Two reported that they first started using cannabis on the advice of a physician:

I was drinking beer at the time . . . a friend asked me if I wanted to try it and . . . was shocked to find out how it made me feel. It was just magic. (male with AIDS).

A friend made me some Sleepy Time tea with cannabis in it. (male with Tourette's Syndrome).

Dr. . . . was seeing me for epilepsy suggested that I smoke a joint before I came for the next visit . . . and I did. . . . he was having trouble controlling the epilepsy. (male with epilepsy).

Around four or five years ago I read and even my doctor had suggested that maybe that this was a good thing . . . because of my . . . problem with wasting. (male with HIV).

Methods of Cannabis Use

Smoking was the primary and the preferred method for using cannabis either because it was inherently enjoyable or

because of its advantages over other methods of use.

I just smoke it. . . . I have tried hash brownies and I've tried marijuana brownies . . . but to me the high is not the same . . . I smoke cigarettes constantly, right? . . . to smoke a joint is the same thing as smoking a cigarette except for you're getting a buzz off a joint (male with HIV).

I've eaten it in the past. . . . I've drunk it in tea. . . . put it in sauces and cooking . . . for me immediate effective relief is smoking . . . eating is too expensive . . . smoking you don't need as much to get the effect what-have-you and it's more immediate too. (male with epilepsy).

It's just easy to do [smoking] . . . you have to put it and just light it up . . . so it's a lot easier. (male on methadone).

Some advantages to eating or drinking cannabis were identified:

In tea form . . . it effects you faster, it's absorbed faster . . . but it is a totally different high. . . . It's more of a body type stone . . . relaxes your body whereas if you smoke it, it still has the same effect but it's more of a head stone as well. (male with Crohn's Disease).

I think it's longer lasting [eating or drinking marijuana] . . . don't have to worry so much about the smell of it. (female with pain from an accident)

I worry about the respiratory side effects and the social aspects—sometimes. . . . my partner doesn't like me to smoke in the house so I step outside and the neighbors can smell it and I'm not always comfortable with that. (male with multiple HIV-related problems).

It [cannabis] can make me lazy. . . . It makes me cough. (male with depression).

What about my lungs and throat and I don't want to be smoking at all. I'm a nonsmoker at heart. (female with chronic pain).

Only two respondents said that they never smoked cannabis. One was the person with Tourette's Syndrome who reported drinking cannabis in tea. The other was a woman who used cannabis in tea or banana bread for menstrual cramps. One respondent had a novel method of using cannabis:

I'm mixing it with alcohol. . . . crushed up as a paste and rub it on my chest as a plaster for like . . . lung infections or colds. (male with migraine).

Patterns and Amount of Cannabis Use

Thirty five (70%) of respondents typically smoked cannabis every day, and among these daily users, the majority smoked two to three times a day. Those using cannabis to stimulate their appetites used it at meal times, while those who ever used cannabis to help them sleep (n=28), used it later in the evenings.

Total daily consumption was, however, quite variable. One person reported smoking up to ten joints a day while another said that she made a joint last all day by only taking a few puffs before meals. Based on reports of the costs of cannabis and typical monthly expenditures the average monthly consumption was between one and two ounces, with a range from less than one quarter ounce to over three ounces. These estimates included daily users but excluded those who reported growing their own cannabis or getting it free.

Thirteen³ respondents reported that, in most cases their use of cannabis was closely associated with symptom relief or avoidance:

I start smoking about two weeks before my period begins. (female with menstrual cramps).

If I can do without it, I do without it. Even if I have my ties back I do without it. I like to keep it for that special moment . . . when I have to make a presentation . . . [at] a board meeting. (male with Tourette's Syndrome).

However, in the majority of cases (n=37) cannabis was also used recreationally and the distinction between medical and nonmedical use was blurred:

It's beautiful when you can sit down and smoke a little joint and just get wasted out of your face . . . yes we like the high. (male with HIV).

Sometimes a friend comes over in the morning of whatever and it's like a beer on a Sunday afternoon. . . . (female with nausea).

For those few (n=13)⁴ who said they did use cannabis recreationally, the cannabis high was either seen as a medical benefit or as a state to be avoided.

I just go with it . . . it makes me feel better you know, once I start feeling better then I know I'm there . . . I just look at it as a pleasant side effect . . . getting a bit high. (male with Crohn's Disease).

The high is the one that gives me the energy. (female with HIV).

Don't like getting high because the disorganization gets worse. (male with migraine headaches).

Sources and Methods of Supply

Almost all respondents obtained cannabis from regular dealers or friends. However, two reported that they grew their own and one reported going to a buyers' club.

It seems more legitimate (going to the buyers' club) than meeting someone on the street . . . and you don't know if you're gonna get ripped off or beaten up. (male with HIV).

Only two reported that they did not have established suppliers of cannabis and went in search of cannabis whenever

they needed it:

I have to go and wait for somebody to show up at these places where they sell . . . it's too far away and sometimes I go there and they're not there. (female with HIV).

I phone people who might know somebody coz nobody I know smokes. So I'm asking them to lean on their friends. (female with chronic pain).

Finally, one respondent said that he got cannabis from his doctor:

He just gets it for me and I have to come in to get it . . . so I never get accosted by anybody. (male with HIV).

Negative Experiences Associated with Cannabis Use

About a third of those interviewed reported being stopped and searched for cannabis or other drugs and drug paraphernalia at some time. These were typically long-term recreational users, but two who saw their use of cannabis use as strictly medical had also been arrested and charged. One won a court case by convincing the judge that the cannabis was used for medical reasons, while the second was preparing to challenge a conviction for possession on the same grounds. A third, strict medical user with AIDS had been contacted by the police following a complaint from a neighbor. However, no arrest was made and the respondent felt that the police were "very humane" when they suggested that he could avoid upsetting the neighbor by smoking on a private balcony.

That cannabis is an illegal drug weighed on the minds of most respondents and they were careful to avoid being arrested. However, medical use was also seen as potentially giving immunity to serious legal consequences:

I'm HIV positive. . . . What are you going to do? Gonna send me to jail? (male with HIV).

Some respondents had been harmed by their use of cannabis, but this was not always acknowledged. One, who saw cannabis and drug use generally in a very positive light, had been severely hurt while riding a bicycle under the influence of cannabis and had since continued a dysfunctional lifestyle involving the heavy use of cannabis and other drugs. Another gave an incoherent account of how cannabis had helped him psychologically, but it appeared that some of his problems (anxiety and depression) were drug-induced. One other respondent, who suffered from depression, also speculated that this may have been made worse by cannabis use.

Having to buy on the street resulted in a financial burden for most interviewees. The appetite stimulant effects of cannabis were negative consequences for two respondents who were not using it for that reason. Most did not see cannabis as having any negative effects. However, the following negative effects were each mentioned by at least

one respondent: rejection by family members, lethargy, apathy, cough or throat irritation from smoking, thirst, loss of concentration, short-term memory loss, paranoia, severe intoxication and depression.

Many interviewees were using cannabis two or more times a day for a long time and they could be expected to experience withdrawal symptoms if they ever stopped using. However, none expressed significant concerns about cannabis dependence:

I am dependent already, it doesn't bother me. cuz I'm still ok and it helps me lead a healthy life. (female with HIV-related anorexia).

No, I'm not concerned about becoming dependent. . . . I know it's slightly habit forming but it's not a chemical addiction like cigarettes. (male with Crohn's Disease).

I do get some withdrawal effect . . . here is a little bit of concern mostly because it's illegal. . . . if I could just get it at the drugstore I wouldn't have much concern. (male with chronic pain).

I think it's more of a psychological addiction than a physical one for me because I've gone days without it. If I became dependent it would be more emotionally than physically. (male with HIV).

Experiences with Physicians

Only twelve respondents said that they had not told their physicians that they were using cannabis for medical or other reasons. Others had told their physicians and found their reactions mostly noncommittal but sometimes clearly positive. Only three said their doctors discouraged them from using cannabis:

Well he [the doctor] doesn't approve of it but in a stupid little way he does approve of it because he knows that from my . . . personal experience telling him of just how much good it's done for me. (male with HIV).

My psychiatrist is very old school. He's telling me that I can become addicted. . . . He would rather see me go through surgery and nerve blocks. (male with chronic pain).

Almost all of those with HIV/AIDS had told their physicians about their use of cannabis and had found physicians to be very understanding and supportive. Physicians were also reported as being sympathetic or supportive of cannabis use by at least one respondent suffering from nausea and weight loss associated with methadone treatment, chronic pain, epilepsy, menstrual cramps, Crohn's Disease, repetitive strain injury, and depression.

SUMMARY AND DISCUSSION

This exploratory study shows that cannabis was being used for a range of medical reasons. Among those interviewed

the most common conditions associated with cannabis use were HIV/AIDS-related problems, chronic pain, depression and anxiety. However, cannabis was also used to treat menstrual cramps, anorexia, narcotic addiction, migraine, Tourette's Syndrome, lupus, Grave's Disease, epilepsy, retinitis, chemotherapy-induced loss of appetite, Crohn's Disease, arthritis and everyday aches, pains, stresses and sleeping difficulties. Specific symptoms that were reportedly relieved by cannabis included sleeping difficulties, nausea, loss of appetite, pain, depression and anxiety, tics and seizures, loss of energy, breathing difficulties, craving for heroin, anger and vision problems. Typically, medical cannabis use followed recreational use and the majority of those interviewed were long-term, and sometimes heavy, recreational users. Most continued to use cannabis recreationally as well as medically. However, the sample also included some people whose use of cannabis was primarily initiated by the desire to treat medical conditions for which other treatments were unsatisfactory.

Almost all interviewees smoked cannabis and only two regularly used it in other forms (in tea or baked in a muffin). The majority used cannabis two to three times every day. Cannabis was usually obtained from friends or regular dealers but one person obtained it from his doctor. Respondents were acutely aware that possession of cannabis was illegal and they took precautions to avoid arrest. About a third, mostly those who used cannabis recreationally, had been stopped by police and searched for drugs. Three of those who had only used cannabis for medical reasons had been involved with the police but only two had been charged and one had won a court case. Few admitted negative experiences associated with cannabis use or expressed concerns about being dependent on it. However, some problems that seemed evident to the researchers were not always clearly acknowledged as related to cannabis (accidents, dysfunctional lifestyle, psychological problems). Most respondents had told their doctors about using cannabis for medical reasons and their doctors were supportive or noncommittal. Doctors were seen as supportive of cannabis use by most respondents with HIV/AIDS.

The present study did not, of course, seek to determine if the reported medical benefits of cannabis were real or imagined or if they should be attributed to placebo effects, other treatments or natural recovery. It is likely that the medical benefits of cannabis were sometimes overstated, especially by long-term recreational users with positive views of cannabis. Although respondents thought that their physicians supported their use of cannabis, it is not known if this was really the case. Some respondents also seemed to ignore negative consequences of cannabis use such as dependence and withdrawal.

Many reported benefits of cannabis were consistent with those reported elsewhere. Cannabis was typically used for its sedative, analgesic, antispasmodic, appetite stimulating, anticonvulsant and euphoric properties. These

properties were well known in the past century when cannabis was used to treat conditions that required medications with these properties. Although scientific evidence in favor of medical cannabis is limited (Gurley, Aranow & Katz 1998), self-treatment with cannabis could become popular as more users publicize their own experiences. This is especially so if the everyday aches and pains and psychological problems are promoted as medical reasons for using cannabis.

The boundaries of medical cannabis use will be of concern if more medical cannabis cases come to court. In the Canadian cases where medical necessity was successfully used as a defense against a charge for the possession of cannabis, the defendants had chronic and serious medical conditions (epilepsy and AIDS) and were strongly supported by their physicians. Others who are able to convince the courts that their use of cannabis brings relief to otherwise untreatable conditions may also do well in court. However, those who use cannabis for less serious conditions that can be successfully treated by other means may not fare so well, especially without a supportive physician.

The boundaries of medical use are also of concern if new policies on medical cannabis use are developed. If such use encompasses use for self-diagnosed conditions then policies might be needed to ensure that all those who want to use cannabis for these conditions have access to quality-controlled cannabis products. If on the other hand, medical use is to be defined as use with the approval of a physician, more restrictive access will be needed.

At present there are no completely satisfactory ways to deal with the issues of medical cannabis use. Apart from the difficulty of defining "medical," there are presently many uncertainties about the objective benefits of cannabis as a medicine as well as legitimate concerns about side effects and the risks associated with cannabis smoking. Many issues could eventually be resolved through scientific research, including research on alternative methods of delivery such as nasal sprays. In the meantime, there are humanitarian reasons for devising ways to ensure that the seriously ill who find cannabis helpful can have access to a quality-controlled product.

Studies of this sort always have limitations. The sample was small and drawn from one area of one city. Respondents were self-selected. The sampling strategy may have excluded those who were very sick and those who feared being identified as cannabis users. It may also have been biased towards HIV/AIDS cases as notices were put in AIDS clinics. A wider distribution of notices to psychiatric, neurological, pain and cancer treatment centres, clinics, or self-help groups may have attracted a wider range of users or a greater representation of some types. However, the study had limited resources and initially there was a concern that large numbers would come forward for interviews, but this was not the case. It took four months before

50 interviews were completed and only about 120 calls about the study were received.

It is clearly important to learn more about the extent of medical cannabis use in the general population and in populations at high risk. The present study suggests that priority should be given to studies of cannabis use among people with HIV/AIDS. Issues of concern should be the nature and extent of cannabis use as well as biomedical studies that assess the effects of cannabis on biological systems. Studies of interactions between cannabis and the drugs used in HIV/AIDS treatment should also be given priority.

NOTES

1. The notice soliciting the interview referred to marijuana and not cannabis on the assumption that most medical

users would refer to cannabis this way. The name cannabis will be used throughout this paper except when quoting respondents who referred to cannabis as marijuana.

2. All quotes use respondents own words. However, redundant words and phrases and those not directly relevant to a particular topic have been omitted. Words in brackets were added by the authors to clarify respondents statements.

3. Approximate number. Some accounts of use patterns were difficult to interpret.

4. See previous footnote.

Abstract

Background: There are indications that marijuana is increasingly used to alleviate symptoms and for the treatment of a variety of medical conditions both physical and psychological. The purpose of this study was to describe the health concerns and problems that prompt some adolescents to use marijuana for therapeutic reasons, and their beliefs about the risks and benefits of the therapeutic use of marijuana.

Methods: As part of a larger ethnographic study of 63 adolescents who were regular marijuana users, we analyzed interviews conducted with 20 youth who self-identified as using marijuana to relieve or manage health problems.

Results: Thematic analysis revealed that these teens differentiated themselves from recreational users and positioned their use of marijuana for relief by emphasizing their inability to find other ways to deal with their health problems, the sophisticated ways in which they titrated their intake, and the benefits that they experienced. These teens used marijuana to gain relief from difficult feelings (including depression, anxiety and stress), sleep difficulties, problems with concentration and physical pain. Most were not overly concerned about the risks associated with using marijuana, maintaining that their use of marijuana was not 'in excess' and that their use fit into the realm of 'normal.'

Conclusion: Marijuana is perceived by some teens to be the only available alternative for teens experiencing difficult health problems when medical treatments have failed or when they lack access to appropriate health care.

Background

There is lively public debate surrounding the use of medical marijuana. While some remain sceptical about the therapeutic value of marijuana, there is a growing body of research that emphasizes its salutary effects. The literature points to the use of marijuana among adults to alleviate a

variety of symptoms including pain, nausea, muscle spasm, insomnia, anorexia and anxiety as well as the treatment of a variety of medical conditions that are both physical and psychological [1-5]. However, less is known about adolescents' use of marijuana for therapeutic purposes.

Background Literature

For individuals who set out to "feel better" through the use of marijuana, use has also been referred to as "self-medication," a hypothesis which posits that people do not misuse substances solely for the experience of being "high;" rather, they do so as a means of gaining relief from psychological and emotional pain [6]. In contrast to the adult literature on marijuana use where therapeutic use is linked to treatment of specific symptoms and illnesses, in the adolescent literature there is less clarity about how to define non-recreational uses of marijuana.

A motivationally-driven approach is one way that researchers have attempted to understand marijuana use among adolescents [7]. It is proposed that different reasons for using marijuana may shape patterns and contexts of use, which in turn may be associated with different problems related to use. Social motives for marijuana use, for example, have been associated with patterns of recreational use (e.g., sensation seeking). Coping motives have been used to classify adolescents using marijuana for non-recreation purposes. Differences have been observed among youth using marijuana for social and coping reasons that support the motives framework. In contrast to youth aged 16–24 years using marijuana for social reasons, users of the same age reporting coping motives have been observed to have lower mental health, higher psychopathology, more psychosocial distress and more stressful life events than non-cannabis-using youth [8].

Although there is a large body of literature related to recreational use of marijuana among adolescents [9,10] less is known about other motivations for the use of marijuana in this population. Several hypotheses have emerged related to non-recreational uses of marijuana among adolescents. The "self-medication hypothesis" [11-14] is most closely associated with the therapeutic use of marijuana. Instrumental use is another term applied to taking drugs for specific pharmacological effects of the substance rather than for pleasure or recreational purposes. For example, Glassner [15] examined the notion of instrumental drug use in a qualitative study of young drug users, and found that marijuana was used for its calming effects, to relieve tension, and to gain self-confidence. Further, support for a typology of drug related beliefs that included relief-oriented beliefs [16] was demonstrated in a study of cannabis use in a sample of 285 French high school students [17]. In this study, four 'positive' relief-oriented beliefs were identified related to how the substance creates relaxation and calms anxiety, reduces suffering, relieves boredom, and makes one feel better. The presence of relief-oriented beliefs was the only predictor of cannabis dependence.

Associations between marijuana and psychological problems have also lead researchers to consider other possible

explanations, including whether marijuana use may reinforce psychiatric symptoms or increase the risk of developing a psychiatric illness later in life [18-21]. A full understanding of marijuana use and its potential adverse effects, however, will require further research.

The trend toward the use of marijuana for therapeutic purposes among adults raises questions regarding how this may influence young people's use of marijuana for similar reasons. Recent studies suggest that adolescents are aware that marijuana is sometimes used to gain relief from physical and psychological pain [22-24]. Furthermore, there is evidence suggesting that adolescents may be using marijuana for reasons that are analogous to adults who use marijuana for therapeutic reasons. For example, young marijuana users with coping motives report more stressful life events (e.g., death of a family member or friend), personal injury and illness than socially motivated marijuana users and non-users [8]. There is also indirect evidence that adolescents with mental health conditions might be seeking relief through marijuana use. In a sample of 992 adolescents in drug treatment programs in four U.S. cities, more than half had at least one comorbid mental disorder. In total, 72.5% of these youth were dependent on marijuana [25]. Among youth entering outpatient treatment programs for cannabis use disorders, 76% were reported to have concurrent mental health conditions [26]. Finally, in a sample of homeless young people in the UK who used a variety of drugs including marijuana, participants were found to be self-medicating to deal with the stress and problems they encountered including depression, loneliness, and physical problems such as aches and pains [13].

As part of a larger study to understand the culture of frequent marijuana use among young people, we were struck by the extent to which some participants spontaneously described using marijuana to gain relief from symptoms. In order to develop these emergent findings, we conducted a focused ethnography in which we examined the ways in which youth use marijuana to seek relief.

Methods

This study was designed to understand and describe adolescents' experiences in using marijuana for therapeutic reasons, and explore how their constructions of these experiences are influenced by social norms. Compared to other types of ethnographic studies, focused ethnographies occur on a smaller scale and seek to examine a specific problem or phenomenon [27]. Typically, focused ethnographies are time-limited, involve a limited number of participants drawn from a specific population who have experience and understanding directly related to the area of inquiry, and are conducted through selected episodes of participant observation and/or interview [28]. In this focused ethnography, both in-depth interviews and participant observation were employed.

We drew data from a larger ethnographic study of frequent marijuana use among adolescents conducted in two rural and one urban location in British Columbia (BC), Canada. In the study communities, as is the case in much of BC, marijuana is readily accessible to youth despite the fact that it is illegal to grow, sell or possess. The use of marijuana for medical reasons is legally supported in Canada in limited circumstances; individuals meeting the criteria are provided with cannabis or given a license to grow a limited quantity for personal use.

Ethical approval for this study was obtained from the University Behavioral Research Ethics Board. Given the sensitivity of the topic and because we successfully argued that teens were able to provide consent for research participation, we did not require parental consent. As a courtesy, we provided the youth with a parent/guardian information letter which outlined the study's focus as pertaining to attitudes about marijuana use in general. Participants were told that they could take the letter home if they so chose. Prior to the interviews, written consent was obtained from the participants. Confidentiality was ensured at the outset and participants were informed that all identifying information would be removed from the data.

Sample

In the larger study, participants were recruited by means of information fliers posted at high schools which invited youth to share their "views on marijuana use and teens." Youth who expressed interest in participating were screened for eligibility by the research team. Eligibility criteria included being 13–18 years of age and reporting having smoked marijuana at least once in the previous week. In total, 63 young people participated in the study. Although many youth described "feeling better" after they smoked marijuana, a subset [$n = 20$] explicitly described experiences of using marijuana on a regular basis specifically to manage, reduce or eliminate unpleasant and uncomfortable feelings or other health problems. They constructed marijuana as a treatment for health problems, often suggesting it had significantly greater benefit than other medical treatments they had been offered. None of these students were legally provided with cannabis for medical treatment or given a licence to grow marijuana for medicinal use. Characteristics of this sub-set of participants are presented in Table 1. The majority of youth using marijuana for relief were male, and the average age of initiation of marijuana was 13 years of age. Youth in this subset were of diverse ethnic backgrounds. Most [$n = 12$] indicated that they were "Canadian" or "Caucasian;" More specifically, 2 participants identified as First Nations, 6 individuals were part First Nations, 3 of UK descent and 3 were of European background including Italian, Croatian, and Ukrainian. Compared to those who

* some participants used marijuana for more than one reason

used marijuana for the purpose of relief, those recruited to this study who smoked marijuana for recreational purposes ($n = 43$) smoked marijuana less frequently (average of 11 days in the last 30 days) and used marijuana more often with others.

Data Collection

The primary source of data was in-depth, semi-structured interviews with youth to glean accounts of their experiences with marijuana. We used a short questionnaire prior to beginning the qualitative interview to collect demographic data and to assess history of marijuana use and current use. The questionnaire included items related to marijuana use including age of initiation, use in the last month, frequency and quit attempts. We also collected data on the time of day that individuals usually used marijuana.

The interviews were conducted using an interview guide. Broad discussion categories included: history and pattern of use, the reasons for their use, what they knew about marijuana, the sources of that information as well as contextual factors related to their use. Open-ended questions were posed in relation to each of these topics, as required during the interviews. Many of these youth were at ease when talking about their use of marijuana and needed little prompting. When youth described the use of marijuana to help them feel better, participants were asked to elaborate further on their experiences.

The tape-recorded interviews took place in privacy within the school setting and lasted from 1 to 2 hours. Participants were offered a \$20 honorarium. Field notes were used to record impressions of responses to the interview

and the interviewer's assessment of the quality of the interview. In addition, field notes were maintained to record pertinent observations within the school and in the larger community (e.g., noting school policies regarding marijuana use at school and the presence of graffiti related to marijuana in close proximity of the school; visiting favourite outdoor settings where some indicated that they preferred to smoke marijuana along with hemp shops where they purchased pipes and bongs and other paraphernalia).

Data Analysis

All data including transcribed interviews and field notes were reviewed several times by the research team paying close attention to young people's descriptions of experiences with the use of marijuana to address uncomfortable feelings or health problems, and the circumstances that surrounded this use. Close readings of the interviews by the investigative team involved highlighting potentially important comments, raising questions about the data, and identifying prominent dimensions of participants' experiences. During team meetings, interview data were discussed and emergent categories were identified to capture experiences related to marijuana use. These categories were organized into a coding framework and used to code the data. All coding was completed by one of the authors who completed a majority of the interviews (BMM). To code the data, we used [29] the NVivo software program designed for qualitative analysis of textual data. The program was also used to retrieve data coded under each category for a more nuanced analysis by the investigative team. Through reflective questioning of these data and detailed comparisons, themes were identified and discussed in team meetings.

Results

The Context of Using Marijuana for Relief

The teens situated their use of marijuana for relief of health problems in the context of difficult life events and illness experiences marked by a lack of supportive family networks, unexpected and sometimes traumatic losses of close friends or family members, and difficulties at school. Many indicated that they had few people to turn to help them; for some their parents were having difficulty coping with their own situations of unemployment, substance use, and marriage breakdowns and offered little support. Those living in households with a parent and step-parent had difficulty coping with unresolved feelings towards their estranged biological parent. Finally, several teens who made frequent moves with their families experienced social isolation at school and were subject to being bullied and teased.

Experiences with the medical system to address their health problems consistently fell short of the teens' expecta-

tations; their problems were either not taken seriously or the solutions offered were not helpful. For example, youth who reported they had been prescribed drugs such as Ritalin, Prozac or sleeping pills, stopped using them because they did not like how these drugs made them feel or found them ineffective. Despite visits to doctors, prescribed treatments and, for a few, hospitalizations, many of these teens perceived that they did not receive the help they needed from doctors.

A final contextual feature to these teens' lives were their observations of others' use of marijuana to deal with difficult circumstances or symptoms, including, in a few cases, parents and other significant adults in their life. For example, one young man reported that his mother was using marijuana while receiving cancer treatment. As he observed, "It helped her sleep and calmed her down." Others described how they were given advice from other teens about how marijuana could "help." Together these circumstances created a context where teens routinely turned to marijuana to manage physical and psychological problems in their lives. Marijuana was readily available, used by others in their network, and was perceived to provide an effective solution not offered to them from the medical system.

Regular Relief: Patterns of Using Marijuana for Persistent Problems

Most of the participants who consistently used marijuana for relief, smoked it when alone, often several times a day. For some, their day began and ended with using marijuana; they smoked before leaving home for school and prior to going to bed. Some indicated that they needed to smoke marijuana during the school day to manage symptoms, and when this occurred it was often in the company of friends. A few participants smoked marijuana for relief in adult company that included relatives and "older" friends who supported their need to use marijuana to manage symptoms.

There were two patterns of marijuana use for relief: intermittent and chronic. With intermittent use, youth routinely relied on marijuana to deal with short-term problems such as stressful situations or limited periods of physical pain. One 14 year old male described non-daily use occurring whenever he had a "really bad day." In the case of chronic use, daily marijuana was used for the relief of identified conditions such as depression, ADHD and to routinely settle at night or manage sleeplessness. Young people's descriptions of marijuana use for relief were imbued with language common to using pharmaceuticals. A number of these youth indicated how they carefully titrated their intake; others described their use as "moderate," involving a "few puffs," or just a "certain amount." Through experience, they had learned to hone

ways of using the right amount of marijuana to achieve a state of relief. As one male elaborated, he regulated his intake by mixing his marijuana with tobacco so as to get "just enough" marijuana to relieve regular states of agitation and high levels of stress. Along with skills at monitoring their intake of marijuana, these youth confidently shared in-depth knowledge of the strength and associated effects of different strains of marijuana.

Explaining the Need to Use Marijuana for Relief

The young people in the sub-sample were particularly articulate in describing their "need" to use marijuana. They were adamant and confident that marijuana provided relief from their health problems. The decision to smoke marijuana was stated in a straight forward fashion (e.g., "I started it to make myself feel better") and justified because they had a "reason for it." Participants also framed their marijuana use in a positive manner; in so doing, gave credence to the claim that this was the right course of action. As one girl elaborated on her daily use, "Pot helps me be me." Several described unpleasant physical sensations such as feeling "jittery" associated with the absence of marijuana. For these youth, regular marijuana use allowed them relief from these unpleasant symptoms so that they were able to feel "normal." One 18-year old male who used marijuana everyday indicated, "If anything, it makes you more normal." Of note, he had first started to use marijuana at the age of 13, and smoked it regularly for 5 years typically 4 times a day.

For these youth, the purpose of smoking marijuana was not specifically about getting high or stoned, nor was marijuana used for "pleasure." In fact, participants tended to differentiate their own use from peers who were recreational users who smoked marijuana when they were "partying" or "socializing." As one 16-year old male described his use, "I don't get a strong sense of euphoria, I just calm down a bit, that's just how it is for me." However, there were a few instances when female participants did smoke "to get high" for the purpose of "escaping reality," a strategy used to remove themselves temporarily from the challenging circumstances that accompanied their daily lives. The participants also distinguished themselves from the "stoner" stereotype, whose preferred activities were watching movies or listening to heavy metal music while smoking marijuana.

Some explanations of using of marijuana to feel better were further bolstered with a focus on use for described "health" reasons. As one 16-year old female indicated, her daily use of marijuana was "more of a health thing, than to get high." She reflected on her history of "mild depression" and her difficulties with antidepressants that had resulted in insomnia and a loss of appetite. She suggested that these health issues would re-surface in the absence of

marijuana, thereby providing solid rationale for her continued use of marijuana. One male situated his marijuana use within a perspective that medications are used to help deal with problems.

I bet you if I had never been put on Ritalin at a younger age, I might not have had the same opinion of drugs growing up, you know, because I was taught growing up that you take drugs to help you out with your problems, you know. [18 years, non-daily use]

Often, marijuana was compared to other substances in a way that suggested marijuana was the best option, further supporting ongoing use of marijuana for relief purposes. Some constructed marijuana as a "natural" substance that was preferable and considered "safer" than many pharmaceutical alternatives. One 14-year old female discovered that marijuana was a better option than dealing with the side effects of pharmaceuticals stating, "Well, my body, I have to be careful what pills I take. I have bad reactions to some medications. My body rejects it and I get really sick." Interestingly, one 18-year old who smoked twice a day on 21 days during the last month, went as far to describe himself as a "healthy marijuana user" adding, "It's not good for you, but then again, neither is MacDonald's and a lot of other things." The health claims in these descriptions served to explain the ongoing use of marijuana for relief.

Painful Lives: Types of Symptoms and Distress Requiring Relief

In the interviews the teens directly linked their use of marijuana with the management of difficult feelings (including depression, anxiety and stress), sleep problems, problems with concentration and physical pain. Each of these will be described in the following sections.

Difficult Feelings

Although some teens described using marijuana to deal with instances of being angry, experiencing a significant disappointment (e.g., with exam results), being afraid, or to forget the past, the most frequent uses were associated with dealing with depression, and managing stress and anxiety.

Depression

Six participants indicated they were using marijuana specifically to deal with depression and several others reported knowing teens that were doing the same. Dealing with difficult personal circumstances was a common theme for this group of teens and was linked to the loss of significant people in their lives, a family history of depression, financial worries at home, "fights" with parents, abuse, and too much "shit" in their lives. Several reported receiving treatment for depression in the form of antide-

pressants and counseling, sometimes over extended periods, yet with little relief. For others, these options were not available in part because "nobody wanted to listen" to them. As a last resort, these teens had opted to try smoking marijuana. In a relatively short time, marijuana helped them to feel better about themselves, happier and more like the person they "wanted to be" as well as alleviate other problems associated with depression (poor appetite, difficulty concentrating, poor sleep).

Not all participants agreed about the use of marijuana for depression. One 16-year old male used marijuana to deal with his unhappiness surrounding the conflict between his mother and father, and worried that he might be using pot too frequently. He reasoned that being happy all of the time was not natural, and that there was nothing wrong with being sad and confused sometimes. As a result, he tried to limit using marijuana to weekends with friends. Others believed that marijuana should only be used for certain types of depression because of the possibility of becoming more depressed by smoking pot:

I think it depends on the level of depression that you have. If it's like depressed because you are sick, then pot is helping you. It's making you happier. But if you're depressed about killing yourself, I don't think that it's a good idea to smoke pot just because it could bring you down more. It's hard to say, though, it's different for every person, right? That just how it makes me feel. [Female, 17 years, daily use]

Stress and anxiety

The use of marijuana to manage stress and anxiety was described by 12 teens in our sample. Dealing with bullying at school, heavy demands of school work, taxing shifts at work, and just "giving as much as you can" along side difficult relationships with parents or guardians, and receiving threats from neighbors all took its toll on these youth. For some, these experiences contributed to high levels of stress and anxiety, and for others uncomfortable levels of anger – both were difficult to manage. Although some had friends they could turn to, marijuana provided an additional source of stress relief that was ready at hand.

Lots of people know me, know I do pot and they think that I'm a pot head but really the thing they don't realize is that I have a reason for it. It's for my stress and an antidepressant. I get really upset. It [pot] helps me feel better about myself, because you know people don't do that [help me], like my friend [name] can, but nobody else can. [Female, 14 years, non-daily use]

There was general agreement among the teens that marijuana calmed them down, and helped them feel "not so nervous" and "not so uptight about everything." One teen

recognized, however, that despite the fact that marijuana could be a very effective stress reliever, it might not work for everyone:

Well as far as pot goes, the good thing is that it's definitely a stress reliever, hands down. I know lots of people who would be just a complete wreck if they weren't smoking pot but then there's also people who are a complete wreck because they do smoke pot, so it's kind of a hard thing. [Male, 16 years, non-daily use]

Sleep problems

Nine teens in our sample described using marijuana to help them sleep. The "trouble" they had with sleeping was a constant problem that many had experienced for years. One 16-year old, who also experienced mild depression, indicated that she "stopped sleeping for two years." Not only did the problem affect their school performance, but it was deeply disturbing to them. As another female described,

I have a really hard time sleeping. I can lay there for about four to five hours, just laying there. And I just finally had it, and I just feel like screaming I don't want to wake anyone up. So I go downstairs and ask my gran or my brother [for some marijuana] or I have a roach or two sitting around. [16 years, non-daily use]

Although one teen indicated that she had spoken to her mother about her problems sleeping, others indicated that the adults in their lives did not offer any support.

I have trouble going to sleep and waking up...My mum wanted to get the doctor to put me on sleeping pills but he said at such a young age it would cause like an addiction to them...I've had these problems since elementary school...I just, I can't go to sleep at night and then I like to sleep during the day. [Female, 14 years, non-daily use]

Many teens turned to pot and found almost immediate benefits in helping them sleep. Likened to a "magic sleeping pill" by one young male, the teens found it calmed their "busy minds," helped them relax and fall asleep quickly.

Focus/concentration

Three teens reported using marijuana to improve their concentration. They explained that they had difficulty focusing at school and that this affected their school performance. As one male explained:

Personally, I'm a very fast paced guy and my mind is always rushing, hard to gather my thoughts. I think a lot faster than I can speak. I get distracted very easily.

In social studies last year, I would talk and wouldn't do any work. But if I had just a little bit of pot, I could really focus my work. I could sit there and I'd work all day and finish everything and have no homework and be done by the end of class. [16 years, non-daily use]

These young people believed they could "think better" when they used marijuana because it allowed them to focus their thinking, and, slow it down in a way that was preferable. All suggested that these cognitive changes were linked to improved school performance. One teen, who self-identified as having "attention deficit, hyperactive disorder" shared the difficulties he experienced on Ritalin. He began smoking pot when he was 12 years of age and still on Ritalin.

Usually my mind is in over gear, right? I'm usually going about a mile a minute and my hands are moving way too fast, and I'm really fidgety. But if I have a puff of marijuana in a moderate use, by moderate I mean one to three to four puffs, depending on the quality....being toned down a bit I find really helps me....If I try to do homework at home without smoking pot, I just can't focus. I'll be looking at my schoolwork and for me with my ADHD this is how it's always been for me. Like school was just a constant story of this scenario before I smoked marijuana. [17 years, non-daily use]

Physical Pain

Five teens indicated they used marijuana to obtain pain relief, and several others shared similar stories about other youth. One male used marijuana to deal with pain associated with rehabilitation after a muscle injury, another used marijuana following an accident where he sustained 3rd degree burns and yet another because of plates in his back due to a car injury. Others suggested that marijuana reduced muscle pain after a hard day of skiing and helped with headaches, and that girls used marijuana for menstrual cramps. One 17-year old male used it daily and explained that marijuana "numbs your systems or senses [and] relaxes your muscles."

Considering the Risks of Using Marijuana for Relief

In spite of experiencing personal benefits from using marijuana for relief, some participants wrestled with their use of marijuana. One girl noted her own problematic use of marijuana that had quickly evolved into relying on it to deal with the regular stress in her life. As she pondered, she commented knowingly that it would be preferable to use it only when her stress level was "really" high.

I mean I started it, and I'm doing it for the wrong reasons...I think if I cut back and only did it when I was *really* stressed out or something, then, you know, really cut back, I think it would be okay. [14 years, non-daily use]

Although knowing that it was "harmful" to her body, she added that she found it difficult to quit using marijuana. Most youth were aware of the health consequences associated with marijuana use in general and their own use in particular. They noticed physical symptoms such as decreased stamina and shortness of breath with physical activities, while others worried about weakened immune systems and how it affected their energy level. Some recognized that they were addicted to marijuana. One male who had been using marijuana for six years framed it as something that he would address at a later date. "I'm trying to get through school and then worry about my dependency issue with marijuana."

Others noted that their marijuana use was linked to difficulties that they were having at school. One male concluded, "I think it brings marks down in one way and sometimes you don't understand things maybe as easily." Others recognized how their use had affected their memory. For a number of the participants, their knowledge of the risks of smoking marijuana was limited and, at times, incorrect. For example, as one 14-year old male who had started smoking marijuana in the past year to relieve muscle pain noted, "It's bad for your lungs, just it's 400 times lower than tobacco."

In what appeared to be an effort to minimize their use in the face of health risks, the teens emphasized that they were not using marijuana "in excess." One 18-year old summed up six years of using marijuana by saying, "I don't feel that I have a problem," adding that "it doesn't really have that many side effects." Some suggested that the benefits of smoking marijuana outweighed the risks. As noted, for those with difficulties sleeping at night, not being able to function the following day when sleep deprived was agonizing; marijuana use at night was preferable and provided a solution to that quandary. However, one male pondered both sides of his use of marijuana in dealing with his depression and was less optimistic:

Well, in some ways, it's helped me and some ways it hasn't. It's good when it's there, but when it's not, it kind of makes me sad. So it's hard like to try to keep up with staying happy all the time. [18 years, daily use]

Several participants made reference to the contradictions that they saw in their world regarding other licit substances and used that argument to make sense of and praise the benefits of marijuana over the risks.

And the thing is that if it's already used, they're already growing it for people that need it for medical help, then like why not.... Like no one has ever overdosed on marijuana, but people die everyday from alcohol, everyday from cigarettes and everyday from vast

amounts of things that the government has legalized, but they just won't legalize marijuana for some reason. It's never killed anyone, never really hurt anyone, it saves people's lives and they could make a good amount of money from it and drop crime rates, why don't they do it? [Male, 14 years, non-daily use]

Discussion

The findings of this study provide one of the first in-depth descriptions of youths' use of marijuana for non-recreational purposes, adding to the growing body of research on the use of drugs to self-medicate among young people. Teens involved in regular and long-term use of marijuana for relief constructed their use of marijuana as essential to feeling better or "normal" in situations where they perceived there were few other options available to them. Unlike the spontaneity typically involved in recreational use, these youth were thoughtful and prescriptive with their marijuana use – carefully monitoring and titrating their use to optimize its therapeutic effect. The findings also point to important contextual factors that further support youth's use of marijuana for relief that extend beyond the availability of marijuana and dominant discourses that construct marijuana as a natural product with medicinal properties.

Of key importance in the findings are the unmet health needs of these youth. Health issues such as depression, insomnia, and anxiety were significant problems that interfered with these youths' ability to function at school, maintain relationships with family and friends, and feel that they could live a normal life. The level of distress associated with these health concerns, along with the lack of effective interventions by health care providers and family members appeared to leave them with few alternatives. Researchers have reported that when adolescents in rural communities experience barriers to seeking health care, they think they can take care of the problems themselves [30]. Similarly, our study participants believed that their best option was to assume responsibility for treating their problems by using marijuana. Unpleasant side effects with prescribed medications and long, ineffective therapies resulted in little hope that the medical system could be counted on as beneficial. In contrast, marijuana provided these youth with immediate relief for a variety of health concerns. Nevertheless, the regular use of marijuana put youth at risk. Cannabis use has been identified as a risk factor for mental illness such as psychosis, schizophrenia [21,31,32] and psychiatric symptoms such as panic attacks [33]. Teens who smoked marijuana at least once per month in the past year were found to be three times more likely to have suicidal thoughts than non-users [34], and there is evidence that exposure to cannabis may worsen depression in youth [35]. Marijuana use among youth has also been associated with other sub-

stance use and school failure [36]. What is interesting is that the findings of this study suggest that youth have little awareness of some of these risks; rather, some are using marijuana to counteract these very problems (e.g., depression, school failure). Teens' perceptions that their health concerns were not addressed suggest that more attention is needed to assess these issues and ensure that other options are available to them. Parents and health care providers need to make a concerted effort to not only understand the pressures and influences on youth [37], but also gain a better understanding of the effect of youths' health problems on their ability to engage in healthy lifestyle choices.

Underlying problems related to youth health concerns also need to be addressed. In many situations, the participants' symptoms appeared to be directly related to their life circumstances. Along with the challenges inherent in being an adolescent in today's complex world, some teens were also trying to deal with significant losses (death of a close friend or family member), extremely difficult family relationships, disappointments with friends, school and sports, and a fragile family and peer support network. The risk of substance use increases substantially when youth are attempting to deal with these kinds of situations in isolation. Although marijuana provided the youth with temporary relief, the underlying situation often went unattended – leading the teens into a regular pattern of use. Appropriate guidance and targeted support from counselors and health care providers must be sensitive to meeting the needs of youth as they work through such situations and life altering events. In addition, adults working with youth must find better ways to talk with young people about how they are coping with their health issues, including their marijuana use. Based on the experiences of youth in this study, there is a wide range of support that may benefit youth including counseling, stress management, social skills training, anger management, study skills, pain management, and sleep hygiene. The youth in this study had minimal access to these types of resources.

The influence of the policy environment in Canada related to medical marijuana cannot be dismissed. The youth in this study were familiar with medical marijuana and its sanctioned use among those with serious illnesses; some knew individuals in their social network who were medical marijuana users. In addition, we acknowledge that the availability of marijuana in the study settings provided teens with opportunities to try marijuana to relieve symptoms. In locales where it is more difficult to access marijuana and penalties for possession of marijuana are harsh, teens with similar symptoms may use other approaches.

Despite presenting themselves as being sophisticated users of marijuana, with a rich knowledge of marijuana

acquired through direct experience, conversations and observations of others, the youth in our study did not appear to be well informed about the therapeutic use of marijuana. Targeted education for youth regarding the risks of marijuana and its appropriate use as a therapeutic agent is warranted, including the risks of legal sanctions. However, as Tupper [38] has suggested regarding drug education, fear-based approaches are unlikely to be effective when the reality of youths' observations and experiences suggest that few serious consequences stand in direct contrast to the "facts" teachers often provide. Alternative approaches are required that acknowledge the complexity of the issues that inform understandings of marijuana. Tupper suggests that drug education be framed using the metaphor of "drugs as tools" to allow "more nuanced understandings of the benefits and harms of drugs, depending on who is using them, in what circumstances, and for what purpose" (p. 235). This approach may be useful in education focused on marijuana.

This study was conducted in three locations in the province of British Columbia (BC) Canada and as such may not be generalized to other contexts. The province of BC is known for its illicit marijuana production [39]. And, in general the BC public is tolerant of marijuana use and support decriminalizing recreational use. In other contexts, teens might turn to other substances such as alcohol. The findings of this study provide a snapshot of these teens' use of marijuana. Further research is required to examine how this therapeutic use evolves over time.

Conclusion

In summary, this study highlights youths' efforts to address their health problems and their experiences in using marijuana for relief. Marijuana may be perceived by some teens to be the only available alternative for those experiencing difficult physical or emotional problems when medical treatments have failed or when they lack access to appropriate health care. As has been noted in other studies of substance use [40], understanding why adolescents use particular substances is key in developing appropriate educational and intervention programs.

Cannabinoid-related agents in the treatment of anxiety disorders: current knowledge and future perspectives

Simone Tambaro and **Marco Bortolato**

Department of Pharmacology and Pharmaceutical Sciences, School of Pharmacy, University of Southern California, Los Angeles (CA), USA

Abstract

Rich evidence has shown that cannabis products exert a broad gamut of effects on emotional regulation. The main psychoactive ingredient of hemp, Δ^9 -tetrahydrocannabinol (THC), and its synthetic cannabinoid analogs have been reported to either attenuate or exacerbate anxiety and fear-related behaviors in humans and experimental animals. The heterogeneity of cannabis-induced psychological outcomes reflects a complex network of molecular interactions between the key neurobiological substrates of anxiety and fear and the endogenous cannabinoid system, mainly consisting of the arachidonic acid derivatives anandamide and 2-arachidonoylglycerol (2-AG) and two receptors, respectively termed CB₁ and CB₂. The high degree of interindividual variability in the responses to cannabis is contributed by a wide spectrum of factors, including genetic and environmental determinants, as well as differences in the relative concentrations of THC and other alkaloids (such as cannabidiol) within the plant itself. The present article reviews the currently available knowledge on the herbal, synthetic and endogenous cannabinoids with respect to the modulation of anxiety responses, and highlights the challenges that should be overcome to harness the therapeutic potential of some of these compounds, all the while limiting the side effects associated with cannabis consumption.

Keywords

cannabis; anxiety; CB receptors; endocannabinoids; Δ^9 -tetrahydrocannabinol; cannabidiol

INTRODUCTION

Anxiety is generally defined as an emotional state characterized by maladaptive and excessive emotional responsiveness to potentially dangerous circumstances. The pathological expression of anxiety leads to enduring emotional perturbations with a consistent apprehension towards the possibility of future, vaguely defined negative events [1]. According to the current classification of anxiety disorders in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) [2], the main diagnostic entities in this category are:

- *generalized anxiety disorder* (GAD), featuring general irritability, anxiety attacks, chronic apprehension/anxious expectation and secondary phobic avoidance.

- *panic disorder*, characterized by brief (2-10 min) spells of overwhelming anxiety or fear, accompanied by somatic and cognitive symptoms;
- *social anxiety disorder* (or social phobia), defined as extreme agitation in social contexts and avoidance of social situations;
- *obsessive-compulsive disorder* (OCD), characterized by recurrent and intrusive anxiogenic thoughts (obsessions), and stereotyped behaviors (compulsions) aimed at the reduction of the distress caused by the obsessions.
- *post-traumatic stress disorder* (PTSD), in which a prior intense trauma results in a long-lasting anxious response, with re-experiencing/flashback phenomena, avoidance and emotional numbing.

In keeping with their different clinical features and phenomenological presentations, these disorders are underpinned by divergent neurobiological alterations and respond to partially different pharmacotherapeutic strategies (outlined in Table 1). A fundamental contribution in our understanding of the neural bases of anxiety disorders and in the development of novel therapies has been afforded by animal models and testing paradigms for anxiety-like behaviors (summarized in Table 2).

Over the last decades, converging epidemiological, clinical and preclinical data have pointed to a key implication of cannabis and its endogenous system in the regulation of anxiety. In the following sections, we will present a brief synopsis on cannabinoids and the available classes of related agents, with a specific focus on their anxiolytic potential, and the scientific challenges that should be overcome to fully establish the applicability of such drugs in the therapy of anxiety disorders.

HERBAL AND SYNTHETIC CANNABINOIDS

Herbal cannabinoids

The three species included in the *Cannabis* genus (or sub-species, depending on the taxonomic classification; see [3], for a detailed discussion on the issue), *sativa*, *indica* and *ruderalis*, feature at least 85 unique terpenophenolic compounds, collectively named *phytocannabinoids* [4]. The main classes of phytocannabinoids are outlined in Figure 1. Quantitative analyses of cannabis constituents are usually performed by chromatographic techniques (generally Gas Chromatography, but also Thin-Layer Chromatography, or High-Performance Liquid Chromatography), often coupled with Mass Spectrometry. A detailed description of the instrumental methods used for classification and source tracing of Cannabis products (including DNA identification for forensic and intelligence purposes) is beyond the scope of this review, but can be found in [5-7].

The chemical fingerprinting of hemp products has revealed that the two most abundant phytocannabinoids are Δ^9 -tetrahydrocannabinol (THC, also named dronabinol) and cannabidiol (CBD):

The main psychoactive constituent of Cannabis, THC is a highly lipophilic alkaloid produced mainly in the leaves, flowers and glandular trichomes of the plant. Most of the pharmacological effects elicited by hemp products, including emotional and cognitive changes, analgesia, hypothermia and appetite stimulation, are considered to be reflective of the action of THC as a partial agonist of cannabinoid CB₁ and CB₂ receptors (see below). Additionally, THC has been shown to act as an acetylcholinesterase inhibitor [8-10].

In contrast with THC, CBD is not psychotropic, but has nevertheless been shown to play a role in the modulation of behavioral effects of cannabis [11]. In fact, the THC: CBD ratio is

the main criterion to define different cannabis chemotypes [12] and has been posited to contribute to the variability in neurobehavioral outcomes of marijuana or hashish consumption [13,14]. Interestingly, most cannabis strains encountered in the illegal markets generally have elevated amounts of THC [15].

The different characteristics of THC and CBD are underpinned by their distinct mechanisms of action. Whereas THC has nanomolar affinity for both CB₁ (K_i = 25.1 nmol/L) and CB₂ (K_i = 35.2 nmol/L) receptors, CBD exhibits much lower affinity for either target [16-20]; however, the latter phytocannabinoid was recently found to act as a highly potent antagonist/inverse agonist of both CB receptors [21], possibly due to a non-competitive mechanism of receptor blockade [22]. Additionally, CBD has been shown to exert some of its actions through other receptors, including the vanilloid receptor VR₁ and the serotonin receptor 5-HT_{1A} (for a general overview of the topic, see [11]).

The other main phytocannabinoids, including cannabigerol (CBG), cannabichromene (CBC) and cannabinol (CBN) (Fig. 1) [4,23], have been shown to exert antibiotic and antiinflammatory properties, but have not been strongly associated with the behavioral effects of Cannabis; nevertheless, the recent discovery that CBG is a highly potent agonist for α_2 adrenoceptor and a blocker of serotonin 5-HT_{1A} receptor [24] underscores the potential importance of these and other alkaloids in the psychoactive profile of cannabis.

Synthetic cannabinoids

In addition to phytocannabinoids, several classes of synthetic CB receptor agonists have been developed; among these families, the best characterized are the synthetic analogs of THC - such as the bicyclic compounds CP 47,497, CP 55,244, CP 55,940 and the benzopyrans HU-210 and nabilone (Fig. 2) - and the aminoalkylindole derivatives - including WIN 55,212-2, JWH-015, JWH-018, JWH-073, JWH-081 and JWH-398 (for a general review, see [23]). Of these agents, only nabilone has been approved for clinical use as an antiemetic treatment and an adjunct analgesic for neuropathic pain [25]. Other more potent synthetic cannabinoids, such as CP 47,497, HU-210 and most JWH compounds, have regrettably gained great popularity in the market of recreational substances during the last decade, under the generic brand names of “Spice” or “K2”. Unlike THC, which is a partial agonist of CB₁ receptors, these agents are full, high-potency CB₁ receptor activators [26,27], thereby eliciting greater psychotropic effects than THC (as CB₁ receptors are the key mediators of the psychotropic actions of cannabis). This characteristic, together with their legal status (recently revoked across most Western countries, including USA as of March 2011) and lack of available testing procedures for the detection of urinary metabolites, has unfortunately contributed to the great diffusion of “Spice” blends in Central and Western Europe, as well as Australasia.

ENDOCANNABINOIDS AND THEIR RECEPTORS

Following the identification of THC in the 1960s [28], extensive research was devoted to the identification of its biological targets and endogenous counterparts. Both objectives were met around 30 years later, with the characterization of the two major cannabinoid receptors, CB₁ [29] and CB₂ [30] as well as the discovery of two most prominent endocannabinoids N-arachidonylethanolamine (commonly named anandamide from the Sanskrit *nanda*, bliss) [31] and 2-arachidonoylglycerol (2-AG) [32,33] (Fig. 3).

CB receptors

Although CB₁ and CB₂ receptors only share 44% sequence identity (68% in the transmembrane domains), they are both coupled to G_{i/o} proteins [34] and activated by both anandamide and 2-AG. In line with their metabotropic nature, CB receptors mediate their

intracellular response through a number of changes affecting signaling cascades, such as inhibition of adenylyl cyclase, activation of G-protein-activated inwardly rectifying potassium channels (GIRKs) and phosphorylation of extracellular signal-related kinases (ERKs) [35,36]. The distribution pattern of CB₁ and CB₂ receptors is strikingly divergent, indicating diverse physiological functions: CB₁ is the most abundant metabotropic receptor in the brain, and is primarily distributed in the synaptic terminals of neurons across all the major structures that regulate emotional responsiveness, perception and memory, including prefrontal cortex, amygdala, septo-hippocampal system, striatum, thalamus, brainstem nuclei etc. [37-41]. CB₁ receptors are typically located on presynaptic terminals [42,43], but they have also been identified in postsynaptic locations [44,45]. Presynaptic CB₁ receptors are posited to serve critical functions for the regulation of synaptic plasticity and neurotransmitter release; in particular, they mediate the depolarization-induced suppression of inhibition (DSI) and depolarization-induced suppression of excitation (DSE), consisting in the reduction of γ -amino-butyric acid (GABA) or glutamate release, respectively, from presynaptic boutons following stimulation of the postsynaptic terminals [46-49]. In general, CB₁ activation has been shown to inhibit the neurotransmission of other mediators, including glycine, acetylcholine, norepinephrine and serotonin [50], but the underpinnings of these phenomena have not been completely elucidated. Additionally, CB₁ receptors have been implicated in short- and long-term synaptic depression, in relation to phasic or tonic endocannabinoid release (for a review on these topics, see [51]).

The function of CB₁ receptors may vary depending on the specific interactions that they entertain with other molecular targets. For example, CB₁ receptors have been found to associate with other G-protein complex receptors, such as dopamine D₂, orexin Ox1, μ opioid and adenosine A_{2a}, to form heteromeric complexes (reviewed in [52,53])

The key role of CB₁ receptors as mediators of neurochemical homeostasis in the brain is maintained through a complex regulation of their expression. For example, these receptors are subjected to a rapid internalization (via clathrin-coated pits) following their binding with full agonists; on the other hand, the receptors are also recycled, with a process that requires endosomal acidification and dephosphorilation [54].

While CB₂ receptors are abundantly expressed in most peripheral organs (and particularly in immune cells, where they regulate cytokine secretion and modulate cell trafficking) [55], their distribution in the brain appears to be sparse and particularly confined to microglial cells; nevertheless, recent evidence has revealed the presence of CB₂ receptors in several areas of the brain [56-58]. Interestingly, a number of studies suggest that neuronal CB₂ receptors may be mainly located in postsynaptic terminals [58,59]; nevertheless, the functional role of these targets in the brain remains largely elusive and awaits further characterization.

The existence of cannabinoid receptors other than CB₁ and CB₂ has been postulated based on ample experimental evidence [60-62]. Interestingly, a number of investigations have pointed to GPR55 as a novel putative cannabinoid receptor [63,64]; nevertheless, evidence on the specificity of this receptor for endocannabinoid is still inconclusive [65].

Endocannabinoids

Both anandamide and 2-AG are derivatives of arachidonic acid, an unsaturated C₂₀ fatty acid with 4 double bonds, which also serves as the precursor for synthesis of other eicosanoids, including prostaglandins and leukotriens. Anandamide is found in picomolar concentrations and acts as a high-affinity partial agonist for both CB₁ and CB₂ receptors. It is synthesized on demand by enzymatic hydrolysis of the membrane phospholipid N-arachidonoyl phosphatidylethanolamine (NAPE), a process catalyzed by several

phospholipases [66-68]. Following release and activation of CB receptors, anandamide is rapidly removed from the synaptic cleft by a carrier-mediated system [69-72] and subsequently hydrolyzed by the membrane enzyme fatty acid amide hydrolase (FAAH) [73-75]. FAAH serves the catabolism of other substrates, including oleoylethanolamine (OEA) and palmitoylethanolamine (PEA). Both these compounds do not activate CB1 receptors [76], although they may reduce or slow down anandamide degradation by competing with it for FAAH activity.

In comparison with anandamide, 2-AG is much more abundant (occurring in nanomolar concentrations across most tissues) and acts as a full agonist of both CB receptors. It is produced from 1,2-diacylglycerol (DAG) by diacylglycerol lipase (DAGL) [77] and degraded mainly by the cytosolic serine hydrolase monoacylglycerol lipase (MAGL) [78], although other enzymes are known to contribute to this process [79].

The divergent neurochemical profiles of anandamide and 2-AG underscore their different physiological roles. Although our current understanding of the different functions entertained by each endocannabinoid is still rudimentary, the development of FAAH and MAGL inhibitors [80,81] has been instrumental to elucidate the implication of each mediator in synaptic and neurochemical regulation. While 2-AG is known as the retrograde mediator of DSI [82,83] and DSE [84-87], a number of studies suggest that anandamide may serve as an activity-dependent regulator of monoaminergic transmission [88-90]. Recent evidence points to a potential biological antagonism between anandamide and 2-AG [91,92]; on the other hand, emerging evidence points to a similar role of anandamide and 2-AG in the regulation of anxiety (albeit in relation to different receptors) and pain [93]. The development of JZL195, a potent FAAH/MAGL inhibitor, has in turn revealed that the behavioral effects of CB₁ receptor agonists can be only recapitulated by the combination of both endocannabinoid-mediated functions [94].

Other lipids have been indicated as putative endocannabinoids, including 2-arachidonoylglycerylether (noladin ether) [95] and O-arachidonylethanolamine (virodhamine) [96] (Fig. 3). Additionally, recent evidence has identified that CB receptors may be modulated by peptidic ligands, such as hemopressin and its derivatives [97,98].

EFFECTS OF CANNABIS AND CANNABINOID AGENTS ON ANXIETY

Cannabis, THC and CB₁ receptor agonists

The employment of cannabis for its medicinal, relaxing and mood-enhancing properties has been documented across most ancient civilizations. Originally introduced in Chinese pharmacopoeia during the third millennium BCE [99,100], cannabis became a popular remedy throughout Asia and Europe in the following centuries [99,101]. The inclusion of cannabis in the medical treatises by Dioscorides and Galen secured the herb a stable reputation in the Roman Empire and the Arabic world [101]. Until the early 20th century, the plant remained a valuable therapy for a large number of diseases [102]; however, growing concerns about the psychoactive and narcotic effects of cannabis led to a progressive restriction and ultimate ban of its usage in the United States and several European countries [100,103]. Despite its illicit status, cannabis remains one of the most popular recreational drugs, particular among adolescents and young adults, in view of its mood-enhancing and euphoriant characteristics [104-106].

Most psychological and behavioral effects of marijuana and other hemp products are induced by THC through activation of CB₁ brain receptors. In fact, although THC and most synthetic cannabinoids are known to activate both CB₁ and CB₂ receptors, their actions on

anxiety-like behaviors and emotional regulation are efficiently countered by selective CB₁ receptor antagonists, such as rimonabant (see next section) [107].

The studies on the psychological effects of cannabis and THC have unfolded a highly complex and often contradictory scenario, fostering a long-standing debate on the potential harms and benefits of its products. An important aspect of this discussion (particularly in consideration of its legal aspects and the potential therapeutic applications of hemp derivatives), revolves around the distinction between use and misuse of cannabis. In particular, whereas the abuse and dependence liability of cannabis is generally well-recognized [108,109], the definition of these phenomena has been heavily criticized as reflective of political agendas rather than scientific bases. For instance, the diagnosis of substance abuse, according to the criteria listed by the DSM–IV TR, is based on the manifestation of at least one of four symptoms: interference with major professional or personal obligations; intoxication in hazardous settings; substance-related legal problems; continued use in the face of persistent social or interpersonal problems [110]. The applicability of some of these standards to marijuana and other cannabis derivatives, however, has been questioned [99], also in view of their lower potential to induce physical harm in comparison with other legal substances, such as alcohol and tobacco [111].

While the controversies surrounding cannabis are far from subdued (and are often permeated and masked by conflicting ideological credos), standardized studies on cannabinoids have highlighted that the psychological and behavioral outcomes of this substance are highly variable and range from relaxation, euthymia and heightened sociability to panic, paranoid ideation and psychosis [112-116]. A corollary of this observation is that the high comorbidity rate between cannabis use disorders and psychiatric conditions [100-105] may indicate that cannabis consumption is either a concurring cause or a “self-therapeutic” strategy for anxiety and mood disorders [117-123]. The latter interpretation is supported by the observation that anxiety-spectrum disturbances and traumas in early developmental stages are a strong predictor for later cannabis use disorders [124-127]; furthermore, several lines of evidence suggest that the anxiolytic effects of THC may partially account for the high prevalence of cannabis use in patients affected by PTSD [128-131] and OCD [132]. Accordingly, recent clinical studies have shown that THC elicits therapeutic effects in OCD [133] and trichotillomania, an impulse-control disorder characterized by compulsive hair-pulling [134]. Nevertheless, prospective analyses show that cannabis use and dependence increase the risk for development of panic disorder [135], suggesting that the effect of cannabis may vary with respect to the nosological entities within the spectrum of anxiety disorders. Of note, chronic consumption of cannabis has been hypothesized to exacerbate depressive or anxious manifestations, and reduce the therapeutic efficacy of anxiolytic agents [122,136-138]; an interesting theoretical implication of this finding is that long-term exposure to cannabinoid agents may lead to profound alterations of synaptic plasticity and neurochemical homeostasis and alter the pathophysiological trajectory of anxiety and mood disorders. Thus, while cannabis may be initially used as a self-therapy for certain anxiety disorders, the prolonged exposure to this substance in vulnerable individuals may in turn alter or aggravate the clinical course of these conditions and render the patients refractory to standard treatments.

The ability of cannabis to either exacerbate or attenuate emotional reactivity is highly influenced by numerous factors, including its chemotype, as well as the influence of genetic, developmental and contextual variables. Unfortunately, little is still known about the susceptibility factors that govern the behavioral outcomes of cannabis in patients affected by anxiety-spectrum disorders. Indeed, several components have been shown to play a role in this link, including genetic background, age, gender, environmental stress and concurrent

use of other drugs; a detailed analysis of these determinants is outside the scope of the present work, but the interested reader should refer to [139].

Aside from the influence of vulnerability factors, the available evidence indicates that cannabis, THC and other CB₁ receptor agonists exercise a bidirectional influence on anxiety responses as a function of the dosage. The majority of users report that consumption of modest amounts of cannabis and CB₁ receptor agonists results in euphoria, relaxation, heightened perception, sociability and creativity, moderate to high doses have been reported to elicit phobia, agitation, panic, dysphoria, psychotic manifestations and cognitive impairments [112-116,124,140-143]. In line with these premises, early studies showed a robust anxiolytic efficacy of low-dose nabilone in comparison with placebo [144,145]. Additionally, the few available reports on the clinical outcomes of recreational cannabinoids show that a moderate consumption of “Spice” blends is generally associated with euphoria and disinhibition [146], but the abuse of these substances is conducive to high levels of anxiety, panic, paranoid ideation and mood disturbances [147-151].

The biphasic effects of cannabinoids on anxiety-related responses have been extensively documented in rodents. In agreement with human evidence, preclinical studies have elucidated that the acute administration of low doses of CB₁ receptor agonists elicits anxiolytic-like in approach/avoidance tasks [152-156]; conversely, high concentrations of the same compounds are generally associated with the opposite outcomes [157-162] (for complete reviews of the topic, see [163,164])

The bidirectional action of CB₁ receptors on anxiety responses may be related to the modulatory role of these targets on GABA and glutamate release across amygdala and other forebrain areas [41,165,166]. As these two major neurotransmitters affect anxiety in an opposite fashion, different doses of cannabinoids and synthetic CB₁ receptor agonists may indeed produce highly divergent effects, in relation to their ability to affect the homeostasis and the balance of GABA and glutamate (for a review on these issues, see [163]). Furthermore, CB₁ receptors have been shown to play critical roles in the regulation of most neurochemical substrates of anxiety, including the neurotransmitters serotonin, norepinephrine and acetylcholine, as well as stress hormones, colecystokynin and opioid peptides [50,163].

In line with this concept, the infusion in the periaqueductal grey of arachidonyl-2-chloroethylamide (ACEA), an anandamide synthetic analog with high CB₁ receptor selectivity, elicited anxiolytic-like effects in rats in an elevated plus maze, with a bell-shaped dose-response curve [167], the highest doses being associated to no significant behavioral change. Novel categories of compounds have been patented for potential efficacy as selective CB₁ receptor modulators, including sulfonyl-benzamides [168] and tetrasubstituted imidazole derivatives [169]. To the best of our knowledge, however, no findings on the action of these compounds in anxiety regulation have been reported to date.

CB₁ receptor antagonists/inverse agonists

The cannabinoid CB₁ receptor antagonists/inverse agonist rimonabant was introduced into clinical practice by Sanofi-Aventis in 2006 as a treatment for obesity [170] and smoking cessation [171]. The majority of preclinical studies found that these compounds are anxiogenic at high doses [158,159,172,173] and ineffective at low doses [174,175]. The anxiogenic properties of CB₁ antagonists, were unequivocally confirmed by clinical data on the psychiatric side effects of rimonabant. The significant increase in anxiety, depression and suicidality in patients under treatment with rimonabant [176-179], in particular, led to the withdrawal of the drug from the European market in October, 2008. As a consequence, several pharmaceutical companies announced the interruption of their clinical research on

CB₁ receptor antagonists, including taranabant (from Merck) and otenabant (from Pfizer), both in Phase 3 of development. Some of the anxiogenic properties of rimonabant and analogs have been speculated to be due to their activity as inverse agonists; as a result, the therapeutic use of newly-developed neutral CB₁ antagonists has been proposed, with the hypothesis that these compounds would not elicit the untoward psychological effects observed with rimonabant and its analogs [180,181]; this idea is supported by recent findings, showing that unlike CB₁ receptor inverse agonists, the neutral antagonists of this targets fail to facilitate the acquisition or consolidation of fear [182].

CB₂ receptor ligands

Few studies have actually evaluated the role of CB₂ receptor in anxiety and stress response. While this receptor was posited to be mainly expressed mainly in immune cells and peripheral areas, its identification in the brain under pathological conditions, such as Alzheimer's disease, multiple sclerosis and amyotrophic lateral sclerosis spinal cord [183-185], led to a number of studies aimed at the assessment of its potential role in brain function and behavioral regulation. Some of these investigations indicated that the suppression of CB₂ receptor in the brain, through intracerebroventricular injection of antisense nucleotide sequences, elicited anxiolytic effects in rodents [186]. In contrast, Garcia-Gutierrez and Manzanares [187] recently described that the overexpression of CB₂ receptors reduced anxiogenic-related behaviors in the light-dark box and elevated plus maze. These premises point to the possibility that CB₂ receptor ligands may also play a role in the modulation of anxiety disorders. This hypothesis, however, awaits further examination with proper pharmacological tools.

CBD

Several studies suggest that THC and CBD may exert opposite actions on brain function and psychopathology [188], possibly in relation to the action of CBD as a potent CB₁ receptor antagonist/inverse agonist [21] (see above). Several lines of preclinical work have shown that CBD reduces the effects of THC on several behavioral functions [189-191]. In line with these data, CBD has been found to reduce the anxiety and improve the sensation of well being induced by an acute, high THC dose in healthy volunteers [192].

In contrast with these data, a number of studies have shown that CBD pretreatment potentiated the behavioral effects induced by THC [193-195]. These actions may signify the ability of CBD to inhibit cytochrome P450-mediated drug metabolism [196,197], which may increase THC blood and brain concentrations [193,195].

Notably, the behavioral outcomes of CBD do not appear to be only due to potential pharmacodynamic/pharmacokinetic competition with THC; indeed, recent studies have shown that CBD exerts inherent anxiolytic effects, both in rodent models [157,198-201] and, more recently, in patients affected by social phobia [202,203]. The anxiolytic action of CBD may be linked to 5-HT_{1A} receptor, but not through benzodiazepine receptors [204]. Of note, the anxiolytic action of CBD also appears to be bidirectional, as only low to moderate doses, but not high doses, have been associated with exert anxiolytic effects [200,205].

The anxiolytic action of CBD do not appear to be mediated by benzodiazepine receptors [204], but rather by 5-HT_{1A} serotonin receptors in the bed nucleus of the stria terminalis [206], a critical component of the amygdaloid complex involved in the regulation of stress response.

Accordingly, CBD has been shown to reduce amygdalar responses to fearful stimuli [207]; this mechanism may be essential for the anxiolytic effects of this compound in social phobia [203]. Furthermore, CBD has been shown to elicit antipanic effects through the activation of

5-HT_{1A} receptors in the dorsal periaqueductal gray, a critical area for the modulation of emotional reactivity to stress [208,209].

Endocannabinoid transport blockers

The systemic administration of the endocannabinoid transport blocker AM404 (Fig. 4) was shown to elicit anxiolytic-like behaviors in the elevated plus maze and defensive withdrawal in adult rats, as well as an attenuation of ultrasonic vocalizations in rat pups [175]. The same compound was shown to attenuate marble burying (a paradigm for compulsivity testing) in mice, suggesting that this compound may have some potential efficacy for OCD [206]. Interestingly, the anxiolytic effects of AM404 were shown to be contributed by both CB₁ and 5-HT_{1A} receptors [152,210], in a fashion similar to the potent CB₁ receptor agonist CP 55,940 [160]. Additionally, AM404 has been suggested to act as a FAAH inhibitor [211], although evidence in this respect is controversial [72]. Indeed, despite the identification of potential candidate endocannabinoid binding sites [212], no final evidence is currently available on the existence and/or molecular identity of the endocannabinoid transporter.

Although the possibility of targeting the endocannabinoid carrier for the development of anxiolytic compounds is appealing and has been targeted by a patent proposing these compounds as a pharmacological support for psychotherapy [213], the elusive molecular identity of the transporter itself has greatly limited the studies. Furthermore, preliminary data indicate that AM404 elicits reward in animals and is self-administered by squirrel monkeys [175,214], raising the possibility that endocannabinoid transport blockers may be addictive.

FAAH inhibitors

The prototypical FAAH inhibitor URB597 (Fig. 4) has been shown to reduce anxiety-like behaviors in rats, in a rimonabant-sensitive fashion [155,163,215-217]. In addition to its anxiolytic-like properties, URB597 was found to exert also antidepressant-like effects in several animal models with high face and predictive validity, such as the forced swim, tail suspension and chronic mild stress paradigms [89,210,216,218]. The anxiolytic action of FAAH inhibitors has been suggested to depend on the enhancement of anandamide in the dorsolateral periaqueductal gray [219]; interestingly, however, only low doses of URB597 in the prefrontal cortex were found to elicit anxiolytic-like effects, through CB₁ receptor activation. However, higher doses ceased to elicit anxiolysis, in view of their interaction with TP_{1V} vanilloid receptors [220]. Furthermore, the anxiolytic and antidepressant actions of FAAH inhibitors were observed only under conditions of high environmental aversiveness, but not under normal conditions [163,218,221]. Importantly, the psychotropic effects of FAAH inhibitors are partially distinct from those associated with cannabinoids, in that they appear to fail to reproduce the hedonic and interoceptive states produced by CB receptor agonists [89] and to induce self-administration in squirrel monkeys [222]. Taken together, these data suggest that FAAH inhibitors may be promising tools in the therapy of anxiety and mood disorders with a safer profile than cannabinoid direct agonists. This idea has been recently endorsed by several authors in recent articles and patents, featuring novel categories of highly selective and potent FAAH inhibitors [223-225] [226]. However, it should be noted that recent data have recently shown that URB597 induce a number of side effects in rats, including social withdrawal, working memory deficits [227] and impairments in auditory discrimination and reversal of olfactory discrimination [228].

MAGL inhibitors

The role of 2-AG in emotional regulation has been difficult to ascertain until the recent development of highly selective monoacylglycerol lipase (MAGL) inhibitors [35,223]. Several lines of evidence have suggested that 2-AG plays a pivotal role in the

pathophysiology of anxiety and defensive behaviors. The prototypical MAGL inhibitor, JZL184 (Fig. 4), has been shown to enhance the levels of 2-AG, but not anandamide; this effect is due to its extremely high selectivity for MAGL over FAAH and other brain serine hydrolases. Recent evidence has shown that this compound exerts anxiolytic-like effects in the elevated plus maze and in marble burying, at doses that do not affect locomotor activity [93,229,230]. Similarly to the effects described for FAAH inhibitors (see above), the anxiolytic effects of this compound were observed in highly aversive (or anxiogenic) contextual settings [229]. The neurobiological role of 2-AG in anxiety is still poorly understood, although several studies have shown that environmental stressors alter its biosynthesis and degradation in key brain structures controlling emotional regulation, including periaqueductal grey, amygdala and hippocampus [231,232]. Interestingly, recent evidence has shown that the anxiolytic properties of JZL184 appear to be mediated by CB₂, rather than CB₁ receptors [93], pointing to a potential implication of this receptor in the role of 2-AG in anxiety regulation.

CURRENT AND FUTURE DEVELOPMENTS

In light of the limitations of our current pharmacological armamentarium for anxiety disorders, the ability of cannabinoids to modulate emotional responses is extremely attractive for the development of novel anxiolytic agents [217]. At the same time, great concern arises from the protean role of cannabinoids on the regulation of these responses, as well as their misuse liability and other side effects. The identification of operational strategies for the employment of cannabinoids in the therapy of anxiety disorders is therefore a fundamental goal in psychiatry research.

As outlined above, clinical evidence strongly suggests that acute administration of low doses of CB₁ receptor agonists results in anxiolytic effects, while excessive activation of these targets elicits opposite outcomes, following a reverse U-shaped dose-response pattern. Hence, a primary strategy to harness the anxiolytic properties of cannabinoids could consist in the employment of partial, low-affinity CB₁ agonists, which may ensure a relatively high therapeutic index and the stabilization of the activation of this target within a range associated with mood enhancement and/or anxiolysis. This idea is indirectly supported by the mirroring observation that anecdotal reports on highly potent, high-affinity synthetic cannabinoids (such as those contained in “Spice” blends) trigger greater psychoactive effects than the partial CB agonist THC [26]. This concept indicates a potential evolution in the search for direct CB agonists, in sharp contrast with the previous trend aimed at the identification of high-affinity CB receptor activators.

An alternative strategy to achieve a similar therapeutic goal may lie in the combination of CB₁ receptor agonists with low dosages of antagonists (preferably neutral, in order to avoid potential side effects linked to CB₁ inverse agonism); this intriguing approach, which has been indicated in a recent patent [233], is based on the likely mechanism of action of Sativex®, a cannabinoid mouth spray containing THC and CBD (in a ratio of 1.08:1) and marketed for the treatment of neuropathic pain, spasticity and overactive bladder, in consideration of the action of CBD as a CB₁ receptor antagonist. However, recent preliminary clinical studies have shown that this formulation did not significantly reduce anxiety (in fact, it was reported to induce a mild, yet not significant increase of this symptom) [234,235], and that CBD did not appear to elicit a significant opposition to the effect of dronabinol [235], plausibly indicating that a higher concentration of this ingredient (or lower relative amount of THC) may be necessary to elicit anxiolytic effects.

A third, highly promising avenue for the development of cannabinoid-based anxiolytic therapies may be afforded by FAAH inhibitors. Unlike endocannabinoid transport blockers

and direct CB receptor agonists, these compounds exhibit a number of highly desirable properties for anxiolytic agents: first, they appear to maintain their anxiolytic and antidepressant effect not only under conditions of acute administration, but also following long-term treatment [93,210]; second, they appear to elicit their effects only in conditions of highly aversive environmental circumstances (i.e., similar to those that would in fact require an anxiolytic treatment); third, they have no apparent addiction liability [89,222]. The neurobiological bases of this phenomenon are not completely understood, and may be related to the involvement of other FAAH substrates, such as OEA or PEA; however, recent investigations suggest that the lack of 2-AG enhancement ensuing FAAH inactivation may contribute to the lack of reinforcing properties of URB597 [236], potentially suggesting a different role of anandamide and 2-AG in the modulation of reward; this idea is actually consistent with the recent finding that 2-AG induces self-administration in monkeys [237].

A key problem concerning the potential application of cannabinoid-related agents and cannabinoids is the relatively little information about their long-term effects following chronic administration. Indeed, the subjective effects of cannabis have been shown to be typically different in chronic users as compared to occasional marijuana smokers [238,239]. Prolonged consumption of cannabis has been shown to induce affective sequelae, including alexithymia and avolition [113,240-242]. Interestingly, tolerance has been shown to the effects of THC [243,244], while no information is available on endocannabinoid-related agents. Long-term administration of cannabinoids has been shown to result in a number of neuroplastic adaptive processes, including CB receptor down-regulation [245,246]. Some of these phenomena may indeed be critical in shaping the different emotional responsiveness to cannabis throughout life and reflect a potential pathophysiological loop which may compound the severity of pre-existing anxiety and affective disorders.

Finally, another important step for the employment of cannabinoid-based anxiolytic therapies will be the analysis of the vulnerability factors implicated in the differential responses and long-term sequelae induced by cannabis consumption. For example, numerous meta-analyses and longitudinal studies have established that cannabis consumption in adolescence is conducive to an increased risk for psychotic disorders [247-250]. This association is particularly significant in the presence of other genetic factors, such as the Val¹⁰⁸Met allelic variant of the gene encoding Catechol-O-methyltransferase (COMT) [251,252], one of the main enzymes for the degradation of the neurotransmitter dopamine. Interestingly, it has been shown that the synergistic effect of COMT haplotype and cannabis in adolescence is more robust in conjunction with predisposing environmental variables, such as the exposure to urbanicity and psychosocial stress [253]. Another gene that may modulate the behavioral responsiveness to cannabinoids is *Nrg1*, which encodes for the synaptic protein neuregulin 1. Indeed, the heterozygous deletion of this gene ablates the development of tolerance to the anxiogenic effects of CB receptor agonists [254,255]. These findings suggest that the employment of a pharmacogenetic approach may be a critical screening instrument to identify which patients may be treated with cannabis for medical purposes without risks of neuropsychiatric side effects. Notably, the role of genes in the mental sequelae of cannabis may also be contributed by epigenetic factors, in consideration of the recent finding that THC induces expression of histone deacetylase 3 [256].

While studies on the biological determinants of different responses to cannabis are still at their preliminary stages, advances in this area may be essential to allow a personalized approach for the employment of cannabinoid-based therapies in anxiety and mood disorders.

Table 1
Current pharmacological strategies for the treatment of anxiety disorders

1	Generalized anxiety disorder
a.	Benzodiazepines
b.	Buspirone
c.	Selective serotonin reuptake inhibitors
2	Panic attack
a.	High-potency benzodiazepines
b.	Tricyclic antidepressants
c.	Selective serotonin reuptake inhibitors
d.	Monoamine oxidase inhibitors
3	Post-traumatic stress disorder
a.	Selective serotonin reuptake inhibitors
b.	Low-dose antipsychotic agents
4	Obsessive-compulsive disorder
a.	Tricyclic antidepressants
b.	Selective serotonin reuptake inhibitors

Table 2
Paradigms for testing of anxiety-like behaviors in rodents

1	Unconditioned anxiety
	a. Tests for social anxiety
	i. Maternal separation-induced ultrasonic vocalizations (for pups)
	ii. Social interaction
	b. Tests based on approach/avoidance conflict
	i. Novel open field
	ii. Defensive withdrawal
	iii. Elevated plus maze
	iv. Elevated T-maze
	v. Zero maze
	vi. Light/dark box
	vii. Emergence test
	c. Tests based on antipredator defensive behavior
	i. Mouse defense test battery
	ii. Predator urine exposure test
	iii. Predator exposure test
	d. Other tests
	i. Novelty-induced feeding suppression
	ii. Marble burying
	iii. Defensive burying
2	Conditioned anxiety
	a. Tests on conditional fear
	i. Fear- conditioned freezing
	ii. Fear-potentiated startle
	iii. Conditional fear-induced analgesia
	b. Operant conflict test
	i. Geiller-Seifter test (conditioned suppression of eating)
	ii. Vogel test (conditioned suppression of drinking)

Cannabidiol as a Potential Treatment for Anxiety Disorders

Abstract Cannabidiol (CBD), a *Cannabis sativa* constituent, is a pharmacologically broad-spectrum drug that in recent years has drawn increasing interest as a treatment for a range of neuropsychiatric disorders. The purpose of the current review is to determine CBD's potential as a treatment for anxiety-related disorders, by assessing evidence from preclinical, human experimental, clinical, and epidemiological studies. We found that existing preclinical evidence strongly supports CBD as a treatment for generalized anxiety disorder, panic disorder, social anxiety disorder, obsessive–compulsive disorder, and post-traumatic stress disorder when administered acutely; however, few studies have investigated chronic CBD dosing. Likewise, evidence from human studies supports an anxiolytic role of CBD, but is currently limited to acute dosing, also with few studies in clinical populations. Overall, current evidence indicates CBD has considerable potential as a treatment for multiple anxiety disorders, with need for further study of chronic and therapeutic effects in relevant clinical populations.

Introduction

Fear and anxiety are adaptive responses essential to coping with threats to survival. Yet excessive or persistent fear may be maladaptive, leading to disability. Symptoms arising from excessive fear and anxiety occur in a number of neuropsychiatric disorders, including generalized anxiety disorder (GAD), panic disorder (PD), post-traumatic stress disorder (PTSD), social anxiety disorder (SAD), and obsessive–compulsive disorder (OCD). Notably, PTSD and OCD are no longer classified as anxiety disorders in the recent revision of the Diagnostic and Statistical Manual of Mental Disorders-5; however, excessive anxiety is central to the symptomatology of both disorders. These anxiety-related disorders are associated with a diminished sense of well-being, elevated rates of unemployment and relationship breakdown, and elevated suicide risk [1–3]. Together, they have a lifetime prevalence in the USA of 29 % [4], the highest of any mental disorder, and constitute an immense social and economic burden [5, 6].

Currently available pharmacological treatments include serotonin reuptake inhibitors, serotonin–norepinephrine reuptake inhibitors, benzodiazepines, monoamine oxidase inhibitors, tricyclic antidepressant drugs, and partial 5-hydroxytryptamine (5-HT)_{1A} receptor agonists. Anticonvulsants and atypical antipsychotics are also used to treat PTSD. These medications are associated with limited response rates and residual symptoms, particularly in PTSD, and adverse effects may also limit tolerability and adherence [7–10]. The substantial burden of anxiety-related disorders and the limitations of current treatments place a high priority on developing novel pharmaceutical treatments.

Cannabidiol (CBD) is a phytocannabinoid constituent of *Cannabis sativa* that lacks the psychoactive effects of Δ^9 -tetrahydrocannabinol (THC). CBD has broad therapeutic properties across a range of neuropsychiatric disorders, stemming from diverse central nervous system actions [11, 12]. In recent

years, CBD has attracted increasing interest as a potential anxiolytic treatment [13–15]. The purpose of this review is to assess evidence from current preclinical, clinical, and epidemiological studies pertaining to the potential risks and benefits of CBD as a treatment for anxiety disorders.

Methods

A search of MEDLINE (PubMed), PsycINFO, Web of Science Scopus, and the Cochrane Library databases was conducted for English-language papers published up to 1 January 2015, using the search terms “cannabidiol” and “anxiety” or “fear” or “stress” or “anxiety disorder” or “generalized anxiety disorder” or “social anxiety disorder” or “social phobia” or “post-traumatic stress disorder” or “panic disorder” or “obsessive compulsive disorder”. In total, 49 primary preclinical, clinical, or epidemiological studies were included. Neuroimaging studies that documented results from anxiety-related tasks, or resting neural activity, were included. Epidemiological or clinical studies that assessed CBD’s effects on anxiety symptoms, or the potential protective effects of CBD on anxiety symptoms induced by cannabis use (where the CBD content of cannabis is inferred via a higher CBD:THC ratio), were included.

CBD Pharmacology Relevant to Anxiety

General Pharmacology and Therapeutic Profile

Cannabis sativa, a species of the *Cannabis* genus of flowering plants, is one of the most frequently used illicit recreational substances in Western culture. The 2 major phyto-cannabinoid constituents with central nervous system activity are THC, responsible for the euphoric and mind-altering effects, and CBD, which lacks these psychoactive effects. Preclinical and clinical studies show CBD possesses a wide range of therapeutic properties, including antipsychotic, analgesic, neuroprotective, anti-convulsant, antiemetic, antioxidant, anti-inflammatory, antiarthritic, and antineoplastic properties (see [11, 12, 16–19] for reviews). A review of potential side effects in humans found that CBD was well tolerated across a wide dose range, up to 1500 mg/day (orally), with no reported psychomotor slowing, negative mood effects, or vital sign abnormalities noted [20].

CBD has a broad pharmacological profile, including interactions with several receptors known to regulate fear and anxiety-related behaviors, specifically the cannabinoid type 1 receptor (CB₁R), the serotonin 5-HT_{1A} receptor, and the transient receptor potential (TRP) vanilloid type 1 (TRPV1) receptor [11, 12, 19, 21]. In addition, CBD may also regulate, directly or indirectly, the peroxisome proliferator-activated receptor- γ , the orphan G-protein-coupled receptor 55, the equilibrative nucleoside transporter, the adenosine transporter,

additional TRP channels, and glycine receptors [11, 12, 19, 21]. In the current review of primary studies, the following receptor-specific actions were found to have been investigated as potential mediators of CBD’s anxiolytic action: CB₁R, TRPV1 receptors, and 5-HT_{1A} receptors. Pharmacology relevant to these actions is detailed below.

The Endocannabinoid System

Following cloning of the endogenous receptor for THC, namely the CB₁R, endogenous CB₁R ligands, or “endocannabinoids” (eCBs) were discovered, namely anandamide (AEA) and 2-arachidonoylglycerol (reviewed in [22]). The CB₁R is an inhibitory G_{i/o} protein-coupled receptor that is mainly localized to nerve terminals, and is expressed on both γ -aminobutyric acid-ergic and glutamatergic neurons. eCBs are fatty acid derivatives that are synthesized on demand in response to neuronal depolarization and Ca²⁺ influx, via cleavage of membrane phospholipids. The primary mechanism by which eCBs regulate synaptic function is retrograde signaling, wherein eCBs produced by depolarization of the postsynaptic neuron activate presynaptic CB₁Rs, leading to inhibition of neurotransmitter release [23]. The “eCB system” includes AEA and 2-arachidonoylglycerol; their respective degradative enzymes fatty acid amide hydroxylase (FAAH) and monoacylglycerol lipase; the CB₁R and related CB₂ receptor (the latter expressed mainly in the periphery); as well as several other receptors activated by eCBs, including the TRPV1 receptor, peroxisome proliferator-activated receptor- γ , and G protein-coupled 55 receptor, which functionally interact with CB₁R signaling (reviewed in [21, 24]). Interactions with the TRPV1 receptor, in particular, appear to be critical in regulating the extent to which eCB release leads to inhibition or facilitation of presynaptic neurotransmitter release [25]. The TRPV1 receptor is a postsynaptic cation channel that underlies sensation of noxious heat in the periphery, with capsaicin (hot chili) as an exogenous ligand. TRPV1 receptors are also expressed in the brain, including the amygdala, periaqueductal grey, hippocampus, and other areas [26, 27].

The eCB system regulates diverse physiological functions, including caloric energy balance and immune function [28]. The eCB system is also integral to regulation of emotional behavior, being essential to forms of synaptic plasticity that determine learning and response to emotionally salient, particularly highly aversive events [29, 30]. Activation of CB₁Rs produces anxiolytic effects in various models of unconditioned fear, relevant to multiple anxiety disorder symptom domains (reviewed in [30–33]). Regarding conditioned fear, the effect of CB₁R activation is complex: CB₁R activation may enhance or reduce fear expression, depending on brain locus and the eCB ligand [34]; however, CB₁R activation potentially enhances fear extinction [35], and can prevent fear reconsolidation. Genetic manipulations that impede

CB₁R activation are anxiogenic [35], and individuals with eCB system gene polymorphisms that reduce eCB tone—for example, FAAH gene polymorphisms—exhibit physiological, psychological, and neuroimaging features consistent with impaired fear regulation [36]. Reduction of AEA–CB₁R signaling in the amygdala mediates the anxiogenic effects of corticotropin-releasing hormone [37], and CB₁R activation is essential to negative feedback of the neuroendocrine stress response, and protects against the adverse effects of chronic stress [38, 39]. Finally, chronic stress impairs eCB signaling in the hippocampus and amygdala, leading to anxiety [40, 41], and people with PTSD show elevated CB₁R availability and reduced peripheral AEA, suggestive of reduced eCB tone [42].

Accordingly, CB₁R activation has been suggested as a target for anxiolytic drug development [15, 43, 44]. Proposed agents for enhancing CB₁R activation include THC, which is a potent and direct agonist; synthetic CB₁R agonists; FAAH inhibitors and other agents that increase eCB availability, as well as nonpsychoactive cannabis phytocannabinoids, including CBD. While CBD has low affinity for the CB₁R, it functions as an indirect agonist, potentially via augmentation of CB₁R constitutional activity, or via increasing AEA through FAAH inhibition (reviewed in [21]).

Several complexities of the eCB system may impact upon the potential of CBD and other CB₁R-activating agents to serve as anxiolytic drugs. First, CB₁R agonists, including THC and AEA, have a biphasic effect: low doses are anxiolytic, but higher doses are ineffective or anxiogenic, in both preclinical models in and humans (reviewed in [33, 45]). This biphasic profile may stem from the capacity of CB₁R agonists to also activate TRPV1 receptors when administered at a high, but not low dose, as demonstrated for AEA [46]. Activation of TRPV1 receptors is predominantly anxiogenic, and thus a critical balance of eCB levels, determining CB₁ *versus* TRPV1 activation, is proposed to govern emotional behavior [27, 47]. CBD acts as a TRPV1 agonist at high concentrations, potentially by interfering with AEA inactivation [48]. In addition to dose-dependent activation of TRPV1 channels, the anxiogenic *versus* anxiolytic balance of CB₁R agonists also depends on dynamic factors, including environmental stressors [33, 49].

5-HT_{1A} Receptors

The 5-HT_{1A} receptor (5-HT_{1A}R) is an established anxiolytic target. Buspirone and other 5-HT_{1A}R agonists are approved for the treatment of GAD, with fair response rates [50]. In preclinical studies, 5-HT_{1A}R agonists are anxiolytic in animal models of general anxiety [51], prevent the adverse effects of stress [52], and enhance fear extinction [53]. Both pre- and postsynaptic 5-HT_{1A}Rs are coupled to various members of the G_{i/o} protein family. They are expressed on serotonergic neurons in the raphe, where they exert autoinhibitory function, and

various other brain areas involved in fear and anxiety [54, 55]. Mechanisms underlying the anxiolytic effects of 5-HT_{1A}R activation are complex, varying between both brain region, and pre- *versus* postsynaptic locus, and are not fully established [56]. While in vitro studies suggest CBD acts as a direct 5-HT_{1A}R agonist [57], in vivo studies are more consistent with CBD acting as an allosteric modulator, or facilitator of 5-HT_{1A} signaling [58].

Preclinical Evaluations

Generalized Anxiety Models

Relevant studies in animal models are summarized in chronological order in Table 1. CBD has been studied in a wide range of animal models of general anxiety, including the elevated plus maze (EPM), the Vogel-conflict test (VCT), and the elevated T maze (ETM). See Table 1 for the anxiolytic effect specific to each paradigm. Initial studies of CBD in these models showed conflicting results: high (100 mg/kg) doses were ineffective, while low (10 mg/kg) doses were anxiolytic [59, 60]. When tested over a wide range of doses in further studies, the anxiolytic effects of CBD presented a bell-shaped dose–response curve, with anxiolytic effects observed at moderate but not higher doses [61, 90]. All further studies of acute systemic CBD without prior stress showed anxiolytic effects or no effect [62, 65], the latter study involving intracerebroventricular rather than the intraperitoneal route. No anxiogenic effects of acute systemic CBD dosing in models of general anxiety have yet been reported. As yet, few studies have examined chronic dosing effects of CBD in models of generalized anxiety. Campos et al. [66] showed that in rat, CBD treatment for 21 days attenuated inhibitory avoidance acquisition [83]. Long et al. [69] showed that, in mouse, CBD produced moderate anxiolytic effects in some paradigms, with no effects in others.

Anxiolytic effects of CBD in models of generalized anxiety have been linked to specific receptor mechanisms and brain regions. The midbrain dorsal periaqueductal gray (DPAG) is integral to anxiety, orchestrating autonomic and behavioral responses to threat [91], and DPAG stimulation in humans produces feelings of intense distress and dread [92]. Microinjection of CBD into the DPAG produced anxiolytic effects in the EPM, VGC, and ETM that were partially mediated by activation of 5-HT_{1A}Rs but not by CB₁Rs [65, 68]. The bed nucleus of the stria terminalis (BNST) serves as a principal output structure of the amygdaloid complex to coordinate sustained fear responses, relevant to anxiety [93]. Anxiolytic effects of CBD in the EPM and VCT occurred upon microinjection into the BNST, where they depended on 5-HT_{1A}R

Effective doses are in bold

Receptor specific agents: AM251 = cannabinoid receptor type 1 (CB₁R) inverse agonist; WAY100635 = 5-hydroxytryptamine 1A antagonist; SR141716A = CB₁R antagonist; rimonabant = CB₁R antagonist; capsazepine = transient receptor potential vanilloid type 1 antagonist; naloxone = opioid antagonist; flumazenil = GABA_A receptor antagonist

Anxiolytic effects in models used: CER = reduced fear response; CFC = reduced conditioned freezing; CFC extinction = reduced freezing following extinction training; EPM = reduced % time in open arm; ETM = decreased inhibitory avoidance; L-DT = increased % time in light; VCT = increased licks indicating reduced conflict; NSF = reduced latency to feed; OF = increased % time in center; SI = increased social interaction

Anticompulsive effects: MBT = reduced burying

Panicolytic effects: ETM = decreased escape; GABA_A blockade in dISC = defensive immobility, and explosive escape; PAG-E-Stim = increased threshold for escape; PS = reduced explosive escape

WR = Wistar rats; SM = Swiss mice; L-E HR = Long-Evans hooded rats; i.p. = intraperitoneal; dIPAG = dorsolateral periaqueductal gray; i.c.v. = intracerebroventricular; PL = prelimbic; IL = infralimbic; BNST = bed nucleus of the stria terminalis; CeA = amygdala central nucleus; SNpr = substantia nigra pars reticularis; CUS = chronic unpredictable stress; GSCT = Geller-Seifter conflict test; CER = conditioned emotional response; EPM = elevated plus maze; VCT = Vogel conflict test; CFC = contextual fear conditioning; RS = restraint stress; ETM = elevated T maze; PAG E-stim = electrical stimulation of the dIPAG; L-DT = light-dark test; SI = social interaction; OF = open field; MBT = marble-burying test; PS = predator stress; NSF = novelty suppressed feeding test; GABA_A = γ-aminobutyric acid receptor A; dISC = deep layers superior colliculus; REM = rapid eye movement; NA = not applicable

activation [79], and also upon microinjection into the central nucleus of the amygdala [78]. In the prelimbic cortex, which drives expression of fear responses via connections with the amygdala [94], CBD had more complex effects: in unstressed rats, CBD was anxiogenic in the EPM, partially via 5-HT_{1A}R receptor activation; however, following acute restraint stress, CBD was anxiolytic [87]. Finally, the anxiolytic effects of systemic CBD partially depended on GABA_A receptor activation in the EPM model but not in the VCT model [61, 62].

As noted, CBD has been found to have a bell-shaped response curve, with higher doses being ineffective. This may reflect activation of TRPV1 receptors at higher dose, as blockade of TRPV1 receptors in the DPAG rendered a previously ineffective high dose of CBD as anxiolytic in the EPM [66]. Given TRPV1 receptors have anxiogenic effects, this may indicate that at higher doses, CBD's interaction with TRPV1 receptors to some extent impedes anxiolytic actions, although was notably not sufficient to produce anxiogenic effects.

Stress-induced Anxiety Models

Stress is an important contributor to anxiety disorders, and traumatic stress exposure is essential to the development of PTSD. Systemically administered CBD reduced acute increases in heart rate and blood pressure induced by restraint stress, as well as the delayed (24 h) anxiogenic effects of stress in the EPM, partially by 5-HT_{1A}R activation [67, 73]. However intra-BNST microinjection of CBD *augmented* stress-induced heart rate increase, also partially via 5-HT_{1A}R activation [85]. In a subchronic study, CBD administered daily 1 h after predator stress (a proposed model of PTSD) reduced the long-lasting anxiogenic effects of chronic predator stress, partially via 5-HT_{1A}R activation [77]. In a chronic study, systemic CBD prevented increased anxiety produced by chronic unpredictable stress, in addition to increasing hippocampal AEA; these anxiolytic effects depended upon CB₁R activation and hippocampal neurogenesis, as demonstrated by genetic ablation techniques [81]. Prior stress also appears to *modulate* CBD's anxiogenic effects: microinjection of CBD into the prelimbic cortex of unstressed animals was anxiogenic in the EPM but following restraint stress was found to be anxiolytic [87]. Likewise, systemic CBD was anxiolytic in the EPM following but not prior to stress [65].

PD and Compulsive Behavior Models

CBD inhibited escape responses in the ETM and increased DPAG escape electrical threshold [68], both proposed models of panic attacks [95]. These effects partially depended on 5-HT_{1A}R activation but were not affected by CB₁R blockade. CBD was also panicolytic in the predator–prey model, which

assesses explosive escape and defensive immobility in response to a boa constrictor snake, also partially via 5-HT_{1A}R activation; however, more consistent with an anxiogenic effect, CBD was also noted to decrease time spent outside the burrow and increase defensive attention (not shown in Table 1) [75, 86]. Finally, CBD, partially via CB₁Rs, decreased defensive immobility and explosive escape caused by bicuculline-induced neuronal activation in the superior colliculus [89]. Anticompulsive effects of CBD were investigated in marble-burying behavior, conceptualized to model OCD [96]. Acute systemic CBD reduced marble-burying behavior for up to 7 days, with no attenuation in effect up to high (120 mg/kg) doses, and effect shown to depend on CB₁Rs but not 5-HT_{1A}Rs [71, 74, 88].

Contextual Fear Conditioning, Fear Extinction, and Reconsolidation Blockade

Several studies assessed CBD using contextual fear conditioning. Briefly, this paradigm involves pairing a neutral context, the conditioned stimulus (CS), with an aversive unconditioned stimulus (US), a mild foot shock. After repeated pairings, the subject learns that the CS predicts the US, and subsequent CS presentation elicits freezing and other physiological responses. Systemic administration of CBD prior to CS re-exposure reduced conditioned cardiovascular responses [63], an effect reproduced by microinjection of CBD into the BNST, and partially mediated by 5-HT_{1A}R activation [79]. Similarly, CBD in the prelimbic cortex reduced conditioned freezing [70], an effect prevented by 5-HT_{1A}R blockade [87]. By contrast, CBD microinjection in the infralimbic cortex *enhanced* conditioned freezing [70]. Finally, El Batsh et al. [80] reported that repeated CBD doses over 21 days, that is chronic as opposed to acute treatment, *facilitated* conditioned freezing. In this study, CBD was administered prior to conditioning rather than prior to re-exposure as in acute studies, thus further directly comparable studies are required.

CBD has also been shown to enhance extinction of contextually conditioned fear responses. Extinction training involves repeated CS exposure in the absence of the US, leading to the formation of a new memory that inhibits fear responses and a decline in freezing over subsequent training sessions. Systemic CBD administration immediately before training markedly enhanced extinction, and this effect depended on CB₁R activation, without involvement of TRPV1 receptors [65]. Further studies showed CB₁Rs in the infralimbic cortex may be involved in this effect [82].

CBD also blocked reconsolidation of aversive memories in rat [76]. Briefly, fear memories, when reactivated by re-exposure (retrieval), enter into a labile state in

which the memory trace may either be reconsolidated or extinguished [97], and this process may be pharmacologically modulated to achieve reconsolidation blockade or extinction. When administered immediately following retrieval, CBD prevented freezing to the conditioned context upon further re-exposure, and no reinstatement or spontaneous recovery was observed over 3 weeks, consistent with reconsolidation blockade rather than extinction [76]. This effect depended on CB₁R activation but not 5-HT_{1A}R activation [76].

Summary and Clinical Relevance

Overall, existing preclinical evidence strongly supports the potential of CBD as a treatment for anxiety disorders. CBD exhibits a broad range of actions, relevant to multiple symptom domains, including anxiolytic, panicolytic, and anticomulsive actions, as well as a decrease in autonomic arousal, a decrease in conditioned fear expression, enhancement of fear extinction, reconsolidation blockade, and prevention of the long-term anxiogenic effects of stress. Activation of 5-HT_{1A}Rs appears to mediate anxiolytic and panicolytic effects, in addition to reducing conditioned fear expression, although CB₁R activation may play a limited role. By contrast, CB₁R activation appears to mediate CBD's anticomulsive effects, enhancement of fear extinction, reconsolidation blockade, and capacity to prevent the long-term anxiogenic consequences of stress, with involvement of hippocampal neurogenesis.

While CBD predominantly has acute anxiolytic effects, some species discrepancies are apparent. In addition, effects may be contingent on prior stress and vary according to brain region. A notable contrast between CBD and other agents that target the eCB system, including THC, direct CB₁R agonists and FAAH inhibitors, is a lack of anxiogenic effects at a higher dose. Further receptor-specific studies may elucidate the receptor specific basis of this distinct dose response profile. Further studies are also required to establish the efficacy of CBD when administered in chronic dosing, as relatively few relevant studies exist, with mixed results, including both anxiolytic and anxiogenic outcomes.

Overall, preclinical evidence supports systemic CBD as an acute treatment of GAD, SAD, PD, OCD, and PTSD, and suggests that CBD has the advantage of not producing anxiogenic effects at higher dose, as distinct from other agents that enhance CB₁R activation. In particular, results show potential for the treatment of multiple PTSD symptom domains, including reducing arousal and avoidance, preventing the long-term adverse effects of stress, as well as enhancing the extinction and blocking the reconsolidation of persistent fear memories.

Human Experimental and Clinical Studies

Evidence from Acute Psychological Studies

Relevant studies are summarized in Table 2. The anxiolytic effects of CBD in humans were first demonstrated in the context of reversing the anxiogenic effects of THC. CBD reduced THC-induced anxiety when administered simultaneously with this agent, but had no effect on baseline anxiety when administered alone [99, 100]. Further studies using higher doses supported a lack of anxiolytic effects at baseline [101, 107]. By contrast, CBD potently reduces experimentally induced anxiety or fear. CBD reduced anxiety associated with a simulated public speaking test in healthy subjects, and in subjects with SAD, showing a comparable efficacy to ipsapirone (a 5-HT_{1A}R agonist) or diazepam [98, 105]. CBD also reduced the presumed anticipatory anxiety associated with undergoing a single-photon emission computed tomography (SPECT) imaging procedure, in both healthy and SAD subjects [102, 104]. Finally, CBD enhanced extinction of fear memories in healthy volunteers: specifically, inhaled CBD administered prior to or after extinction training in a contextual fear conditioning paradigm led to a trend-level enhancement in the reduction of skin conductance response during reinstatement, and a significant reduction in expectancy (of shock) ratings during reinstatement [106].

Evidence from Neuroimaging Studies

Relevant studies are summarized in Table 3. In a SPECT study of resting cerebral blood flow (rCBF) in normal subjects, CBD reduced rCBF in left medial temporal areas, including the amygdala and hippocampus, as well as the hypothalamus and left posterior cingulate gyrus, but increased rCBF in the left parahippocampal gyrus. These rCBF changes were not correlated with anxiolytic effects [102]. In a SPECT study, by the same authors, in patients with SAD, CBD reduced rCBF in overlapping, but distinct, limbic and paralimbic areas; again, with no correlations to anxiolytic effects [104].

In a series of placebo-controlled studies involving 15 healthy volunteers, Fusar-Poli et al. investigated the effects of CBD and THC on task-related blood-oxygen-level dependent functional magnetic resonance imaging activation, specifically the go/no-go and fearful faces tasks [109, 110]. The go/no-go task measures response inhibition, and is associated with activation of medial prefrontal, dorsolateral prefrontal, and parietal areas [111]. Response activation is diminished in PTSD and other anxiety disorders, and increased activation predicts response to treatment [112]. CBD produced no changes in predicted areas (relative to placebo) but reduced activation in the left insula, superior temporal gyrus, and transverse temporal gyrus. The fearful faces task activates the amygdala, and other medial temporal areas involved in

Table 2 Human psychological studies

Study	Subjects, design	CBD route, dose	Measure	Effect
Karniol et al. [99]	HV, DBP	Oral, 15, 30, 60 mg, alone or with THC, acute, at 55, 95, 155, and 185 min	Anxiety and pulse rate after THC and at baseline	↓ THC-induced increases in subjective anxiety and pulse rate No effect at baseline
Zuardi et al., [100]	HV, DBP	Oral 1 mg/kg alone or with THC, acute, 80 min	STAI score after THC	↓ THC-induced increases in STAI scores
Zuardi et al. [98]	HV, DBP	Oral 300 mg, acute, 80 min	VAMS, STAI and BP following SPST	↓ STAI scores ↓ VAMS scores ↓ BP
Martin-Santos et al. [101]	HV, DBP	Oral 600 mg, acute, 1, 2, 3 h	Baseline anxiety and pulse rate	No effect
Crippa et al. [102]	10 HV, DBP	Oral 400 mg, acute, 60 and 75 min	VAMS before SPECT	↓ VAMS scores
Bhattacharyya et al. [103]	15 HV, DBP	Oral 600 mg, acute, 1, 2, 3 h	SPECT STAI scores VAMS scores	↓ STAI scores ↓ VAMS scores
Crippa et al. [104]	SAD and HC, DBP	Oral 400 mg, acute, 75 and 140 min	VAMS before SPECT SPECT	↓ VAMS scores
Bergamaschi et al. [105]	SAD and HC, DBP	Oral 600 mg, acute, 1, 2, 3 h	VAMS, SSPS-N, cognitive impairment, SCR, HR after SPST	↓ VAMS, SSPS-N and cognitive impairment, no effect on SCR or HR
Das et al. [106]	HV, DBP	Inhaled, 32 mg, acute, immediately following, before, after extinction	SCR and shock expectancy following extinction	CBD after extinction training produced trend level reduction in SCR and decreased shock expectancy
Hindocha et al. [107]	Varying in schizotypy and cannabis use, DBP	Inhaled, 16 mg, acute	Baseline VAS anxiety	No significant effect of CBD

HV = healthy volunteers; DBP = double-blind placebo; SAD = social anxiety disorder; HC = healthy controls; THC = Δ^9 -tetrahydrocannabinol; STAI = Spielberger's state trait anxiety inventory; VAMS = visual analog mood scale; BP = blood pressure; SPST = simulated public speaking test; SCR = skin conductance response; SPECT = single-photon emission computed tomography; SSPS-N = negative self-evaluation subscale; HR = heart rate; VAS = visual analog scale, CBD = cannabidiol

Table 3 Neuroimaging studies

Study	Subjects, design	CBD route, dose, timing	Measure	Effect of CBD
Crippa et al. [102]	10 HV, DBP	Oral 400 mg, acute, 60 and 75 min	SPECT, resting (rCBF)	↓ rCBF in left medial temporal cluster, including amygdala and HPC, also ↓ rCBF in the HYP and posterior cingulate gyrus ↑ rCBF in left PHG
Borgwardt et al. [108]	15 HV, DBP	Oral 600 mg, acute, 1–2 h	fMRI during oddball and go/no-go task	↓ Activation in left insula, STG and MTG
Fusar-Poli et al. [109]	15 HV, DBP	Oral 600 mg, acute, 1–2 h	fMRI activation during fearful faces task	↓ Activation in left medial temporal region, including amygdala and anterior PHG, and in right ACC and PCC
Fusar-Poli et al. [110]	15 HV, DBP	Oral 600 mg, acute, 1–2 h	fMRI functional connectivity during fearful faces task	↓ Functional connectivity between L) AMY and ACC
Crippa et al. [104]	SAD and HC, DBP	Oral 400 mg, acute, 75 and 140 min	SPECT, resting (rCBF)	↓ rCBF in the left PHG, HPC and ITG. ↑ rCBF in the right posterior cingulate gyrus

CBD = cannabidiol; HV = healthy controls; DBP = double-blind placebo; SAD = social anxiety disorder; HC = healthy controls; SPECT = single-photon emission computed tomography; rCBF = regional cerebral blood flow; fMRI = functional magnetic resonance imaging; HPC = hippocampus; HYP = hypothalamus; PHG = parahippocampal gyrus; STG = superior temporal gyrus; MTG = medial temporal gyrus; ACC = anterior cingulate cortex; PCC = posterior cingulate cortex

emotion processing, and heightened amygdala response activation has been reported in anxiety disorders, including GAD and PTSD [113, 114]. CBD attenuated blood-oxygen-level dependent activation in the left amygdala, and the anterior and posterior cingulate cortex in response to intensely fearful faces, and also reduced amplitude in skin conductance fluctuation, which was highly correlated with amygdala activation [109]. Dynamic causal modeling analysis in this data set further showed CBD reduced forward functional connectivity between the amygdala and anterior cingulate cortex [110].

Evidence from Epidemiological and Chronic Studies

Epidemiological studies of various neuropsychiatric disorders indicate that a higher CBD content in chronically consumed cannabis may protect against adverse effects of THC, including psychotic symptoms, drug cravings, memory loss, and hippocampal gray matter loss [115–118] (reviewed in [119]). As THC acutely induces anxiety, this pattern may also be evident for chronic anxiety symptoms. Two studies were identified, including an uncontrolled retrospective study in civilian patients with PTSD patients [120], and a case study in a patient with severe sexual abuse-related PTSD [121], which showed that chronic cannabis use significantly reduces PTSD symptoms; however, these studies did not include data on the THC:CBD ratio. Thus, overall, no outcome data are currently available regarding the chronic effects of CBD in the treatment of anxiety symptoms, nor do any data exist regarding the potential protective effects of CBD on anxiety potentially induced by chronic THC use.

Summary and Clinical Relevance

Evidence from human studies strongly supports the potential for CBD as a treatment for anxiety disorders: at oral doses ranging from 300 to 600 mg, CBD reduces experimentally induced anxiety in healthy controls, without affecting baseline anxiety levels, and reduces anxiety in patients with SAD. Limited results in healthy subjects also support the efficacy of CBD in acutely enhancing fear extinction, suggesting potential for the treatment of PTSD, or for enhancing cognitive behavioral therapy. Neuroimaging findings provide evidence of neurobiological targets that may underlie CBD's anxiolytic effects, including reduced amygdala activation and altered medial prefrontal amygdala connectivity, although current findings are limited by small sample sizes, and a lack of independent replication. Further studies are also required to establish whether chronic, in addition to acute CBD dosing is anxiolytic in human. Also, clinical findings are currently limited to SAD, whereas preclinical evidence suggests CBD's potential to treat multiple symptom domains relevant to GAD, PD, and, particularly, PTSD.

Conclusions

Preclinical evidence conclusively demonstrates CBD's efficacy in reducing anxiety behaviors relevant to multiple disorders, including PTSD, GAD, PD, OCD, and SAD, with a notable lack of anxiogenic effects. CBD's anxiolytic actions appear to depend upon CB₁Rs and 5-HT_{1A}Rs in several brain regions; however, investigation of additional receptor actions may reveal further mechanisms. Human experimental findings support preclinical findings, and also suggest a lack of anxiogenic effects, minimal sedative effects, and an excellent safety profile. Current preclinical and human findings mostly involve acute CBD dosing in healthy subjects, so further studies are required to establish whether chronic dosing of CBD has similar effects in relevant clinical populations. Overall, this review emphasizes the potential value and need for further study of CBD in the treatment of anxiety disorders.

Cannabis in the Treatment of Dystonia, Dyskinesias, and Tics

© The American Society for Experimental NeuroTherapeutics, Inc. 2015

Abstract Cannabis has been used for many medicinal purposes, including management of spasms, dystonia, and dyskinesias, with variable success. Its use for tetanus was described in the second century BCE, but the literature continues to include more case reports and surveys of its beneficial effects in managing symptoms of hyperkinetic movement disorders than randomized controlled trials, making evidence-based recommendations difficult. This paper reviews clinical research using various formulations of cannabis (botanical products, oral preparations containing Δ^9 -tetrahydrocannabinol and/or cannabidiol) and currently available preparations in the USA (nabilone and dronabinol). This has been expanded from a recent systematic review of cannabis use in several neurologic conditions to include case reports and case series and results of anonymous surveys of patients using cannabis outside of medical settings, with the original evidence classifications marked for those papers that followed research protocols. Despite overlap in some patients, dyskinesias will be treated separately from dystonia and chorea; benefit was not established beyond individual patients for these conditions. Tics, usually due to Tourettes, did respond to cannabis preparations. Side effects reported in the trials will be reviewed but those due to recreational use, including the dystonia that can be secondary to synthetic marijuana preparations, are outside the scope of this paper.

Keywords Cannabis · Marijuana · THC · Cannabidiol · Dystonia · Dyskinesias · Chorea · Tics

Introduction

Endocannabinoid receptors (CB₁R and CB₂R) are plentiful in the basal ganglia [1], implying they play a role in normal motor function and that pharmaceutical (or recreational) cannabis formulations, which are agonists at both sites, might alleviate symptoms of movement disorders. CB₁R are expressed in γ -aminobutyric acid (GABA)ergic neurons of the caudate and striatum, presynaptic terminals in the globus pallidus externa and interna, substantia nigra pars reticulata and pars compacta, and are present in glutamatergic projections to and from the cortex and the subthalamic nucleus. In addition to GABAergic and glutamatergic pathways, dopaminergic inputs are also influenced by endocannabinoids. In general, the cannabinoid signals would be upregulated if a disease was marked by hypokinesia, such as in Parkinson disease (PD), as the cannabinoid ligands act overall to suppress movement, and would be decreased in hyperkinetic movement disorders such as Huntington disease (HD). However, paradoxical responses can occur during degeneration as the receptors in various parts of the basal ganglia die (Table 1).

The complexity of feedback loops in this region, with indirect actions of the endocannabinoid system modulating other inhibitory, excitatory or dopaminergic transmission, partially explains this. In addition, in degenerative diseases such as HD and PD, progressive loss of specific structures, along with their endocannabinoid receptors occurs. The receptor loss will dampen any effects of CB_{1/2}R agonists such as Δ^9 -tetrahydrocannabinol (THC) and cannabidiol (CBD). Other endocannabinoid receptors, such as transient receptor potential vanilloid-type 1, may be successfully stimulated in early

Table 1 Cannabis formulations used in various movement disorders

Generic name	Trade name	Use	Dosage and component(s)	Reference
PD				
Cannabis extract	Cannador Not stated	Dopa-induced dyskinesias/dystonia Tremor/dystonia dopa-induced dyskinesias	Δ^9 -THC 2.5 + CBD 1.25 100–600 mg/daily 0.03 mg/kg/daily 25mgTHC/kg//daily 75 mg/daily	[7, 10*, 16, 17*, 18*]
Rimonabant (CBD antagonist)	SR141716	Dopa-induced dyskinesias	Experimental	[20]
Inhaled botanical marijuana	–	Parkinson tremor and dyskinesias	1 cigarette 2.9 % THC Survey of unsupervised smoked marijuana 0.5gm/cig	[13*,14, 15, 19]
Nabilone	Cesamet	Levodopa-induced dyskinesias	Synthetic cannabinoid 0.03 mg/kg 0.03 mg/kg	[10*, 16]
Dystonia				
Dronabinol	Marinol	Cervical dystonia Dystonia and tics in MS	7.5 mg twice daily 2.5 mg twice daily	[5*, 11]
CBD or cannabis extract	None	Primary dystonias	10 mg/kg/day up to 75 mg/day 100 mg CBD	[7, 18*, 23]
Inhaled botanical marijuana		Spasms Hemidystonia (in Wilson disease)	Not stated 1 MJ Cigarette/dy 3–4 g/day	[6, 8, 9]
HD				
Nabilone	Cesamet	Motor score no improvement, some in chorea and NPI	1–2 mg/day	[23*†, 24*]
CBD or cannabis extract	None		10 mg/kg/day, mean 700 mg	[21*‡]
Tourette syndrome				
Botanical smoked marijuana			0.5–2.0 cigarettes/day One “cone”/night survey (self-prescribed)	[25–27]
THC capsule	None	Tics and vocalizations	2.5 mg Δ^9 -THC, maximum 10 mg/day	[28†, 29 ‡]

If no evidence classification is indicated, it means it was class IV. PD = Parkinson disease; Δ^9 -THC = Δ^9 -tetrahydrocannabinol (the principal psychoactive agent); CBD = cannabidiol (a lesspsychoactive resin extract constituent of the plant *Cannabis Sativa*); MS = multiple sclerosis; HD = Huntington disease; NPI = Neuropsychiatric index

*Class I

† Class II

‡ Class III

stages of HD, but medications do not exist yet to test this. In fact, CB₁R antagonists, similarly experimental at this stage, might be beneficial for hypokinetic symptoms such as hypokinesia in PD.

Contradictory and confusing efficacy has been reported when cannabis medications (or smoked phytocannabinoids) are used to treat movement disorder symptoms [2, 3]. Although the loss of receptors plays some role, more likely currently available cannabis preparations, which contain different amounts and combinations of cannabinoids (at least 60 have been described) with variable potency and psychoactive content (present in Δ^9 -THC but not CBD) with different, usually low, doses, make standardized comparisons impossible. Scoring methods, other than counting individual tics or choreiform movements, add to the researcher's difficulty in measuring

efficacy. The potency, especially Δ^9 -THC content, is kept deliberately low to limit side effects (or patient recognition in those experienced with marijuana), which contributes to treatment failure. Studies are small with problematic recruitment for a substance that will require limitation of activities such as driving, use of a stigmatized medication, and of short duration (sometimes single dose) to avoid abuse or addiction [4]. Even obtaining study drug status in the USA requires working with the various government agencies, and is only becoming easier in the face of a serious epidemic of opiate overuse and toxicity. The Drug Enforcement Agency continues to classify medical cannabis as a Schedule I drug (that with no therapeutic use).

Investigation into cannabis' medicinal use began with promising case reports and anonymous surveys, followed by limited clinical research often conducted outside the USA,

which has not proved sufficient to allow many evidence-based recommendations. Although overlap exists in individuals, in this review dyskinesias, dystonia, and chorea will be considered separately. Although tremor was studied in patients suffering from multiple sclerosis, there is no information on essential tremor. Tics will be considered separately, as the mechanism differs.

Dystonia

Dystonia involves overactivity of muscles required for normal movement, with extra force or activation of nearby but unnecessary muscles, including those that should be turned off to facilitate movement, and is often painful in addition to interfering with function. It can be primary, as in torticollis and blepharospasm/orofacial dyskinesias or dystonias (Meige syndrome) or as part of another condition such as HD and tardive dyskinesia after dopa-blocking drugs. The globus pallidus and substantia nigra pars reticularis contain CB₁R, with cannabinoids acting as neuromodulators and enhancing GABA release and reducing its reuptake [5].

In 1981, Marsden described improvement in a patient with torticollis who smoked cannabis [6]. An open-label series followed [7], and self-reported improvement with smoking marijuana was described in 2002 in a patient with central pain and dystonia and in a patient with Wilson disease [8, 9]. Cannabidiol showed improvement of 20–50 % by videotape review in 5 patients [9], but higher doses exacerbated tremor and hypokinesia in 2 patients with PD and levodopa-induced dystonia. Nabilone, a synthetic oral form of Δ^9 -THC, which is available in the USA for other indications, was not found to be effective in 1 administration of escalating doses of 0.03 mg/kg using a dystonia rating scale; however, 3/15 patients felt better for several days after its use [10]. Another currently available oral form of Δ^9 -THC, dronabinol, did not improve symptoms of cervical dystonia, as demonstrated by the Toronto Western Hospital Spasmodic Torticollis Rating Scale in a 3-week treatment trial [5]. Finally, response to dronabinol 2.5 mg twice daily in a case report of dystonia (and tics) in a patient with multiple sclerosis who had previously reported symptom improvement after smoking marijuana [11].

Side effects described in these studies included hypotension and sedation at higher doses of nabilone [10], insomnia and tachycardia from dronabinol [5], and hypokinesia and tremor of PD [10].

Dyskinesias from Levodopa (in Advanced PD)

The plethora of endocannabinoid receptors in the basal ganglia, especially the globus pallidus interna, pars reticulata, and cerebellum indicate they must be playing a role in regulating

tone and motor function through the effect of the endogenous cannabinoid ligand, arachidonylethanolamide (anadamide), on modulation of GABA transmission [12]. Many studies have been done with primate or rat models to determine if cannabinoid agonists or antagonists could act to suppress dyskinesias without exacerbating hypokinesia; however, translation to patients has proved difficult.

Since the initial observation in 1991 of no improvement of resting tremor in 5 patients who smoked one marijuana cigarette [13], surveys have been done asking patients with PD to say if they had tried marijuana on their own (presumably the smoked botanical form) and if so with what effect. Venderova sent surveys to 630 patients attending a movement disorders clinic in Prague, and of the 339 respondents, 25 % had used marijuana. Of these 85 patients, 39 benefitted in rest tremor (31 %), bradykinesia (45 %), and dyskinesias (14 %), and continued its daily use [14]. A recent survey of Colorado residents with Parkinson using all types of complementary therapies found 9 using medical marijuana (4 %), reporting improvement of mood and sleep, but only 2 with improvement of motor symptoms, not specifically dyskinesias [15].

A small but class III randomized double-blind study using nabilone (synthetic Δ^9 -THC) showed a significant reduction in Rush score on levodopa-induced dyskinesias in 7 patients, observed and measured with the Rush dyskinesia scale [16], and 2 reported improvement in dystonia occurring in the off period for dopa. In a study of 17 patients using the oral preparation Cannador (2.5 mg Δ^9 -THC/1.25 mg CBD) no improvement was noted in dyskinesias as measured in Q32–34 of the Unified Parkinson's disease rating scale (the primary outcome), or other scales including Parkinson Disease Questionnaire-39 scale, nor was there a dose response [17]. The study by Carrol et al. [17] was the only one considered class I for the purposes of evidence-based recommendations. Various doses of cannabidiol were given to 21 patients over 6 weeks; no change was found in the total motor score, despite improvement in the quality of life section of the Unified Parkinson's disease rating scale if the target dose of 300 mg daily was reached, which was possible in only 35 % of the patients [18]. Finally, an open-“label” study of smoked marijuana in 22 Israeli patients showed improvement in the number of dyskinesias observed after dopa challenge, 30 min after smoking the cigarette [19]. In an interesting twist, a single dose of the CB₁R antagonist rimonabant (SR141716) was found to have no effect on motor symptoms, or induced dyskinesias in 8 patients [20].

Side effects mentioned in the studies included hypotension, vertigo, hyperacusis, and disorientation and visual hallucinations [15], somnolence, dizziness and bad taste, with hypoglycemia in 1 patient [19], and, rarely, bradykinesia, but in the few studies where it was measured [17], there was no effect on cognitive function as measured by Mini Mental State Examination; in fact, an improvement in Mini Mental State

Examination was noted, which was attributed to a practice effect but may have been precognitive (the 4-week trial was too short to call cannabis neuroprotective).

In summary in PD, the symptom that responded best to cannabis, levodopa-induced dyskinesias, is a fairly rare complication of dopamine replacement in advanced cases. The role of cannabis in other symptoms of PD is unclear, and these symptoms vary according to the stage of neurodegeneration and also to the state of treatment with dopamine transmitter replacement. As there is the potential of cannabis worsening some symptoms, especially hypokinesia, very careful research must be done with PD.

Dyskinesias in HD

Abnormalities of motor function, along with psychiatric and cognitive dysfunction, are a main feature of HD, a dominantly inherited neurodegenerative disease. Cannabis products have been most often used to ameliorate agitation and other psychiatric symptoms, but the presence of endocannabinoid receptors in the striatum, where they modulate GABA transmission and affect glutamate release, suggests a role for management of the excessive involuntary movements (choreoathetosis or dystonia) of HD. As in other degenerative processes, these receptors can decrease as the disease progresses, leaving less response to cannabinoid agonists as the brain's substrate changes. Obviously, current or prior use of dopamine-blocking medication (neuroleptics), which can superimpose tardive dyskinesias on the direct movements of HD, will also change the therapeutic effects of cannabis.

Consroe et al. [21] first reported the clinical use of CBD in HD in 1991. This class III study of 15 patients receiving cannabis extract in capsule form (10 mg/kg), crossing to placebo over a 15-week period, off neuroleptics for at least 2 weeks, found no difference in the chorea severity score of Marsden and Quinn, or on videotape and live assessment of chorea severity, nor on secondary end points of Shoulson and Fahn disability scores, finger tapping, or manipulation. Side effects, as checked off a symptom inventory, did not vary between placebo and treated patients. After a case report in a patient who had improved mood and movements after smoking marijuana and then taking prescribed nabilone, 1 mg daily [22], the authors gave 1 or 2 mg of nabilone to 37 patients in a class II study [23]. Despite improvement in the secondary measures of neuropsychiatric index and chorea score, the primary outcome, total motor score of the Unified Huntington Disease Rating Scale, showed only a modest response, with no dose response (i.e., 2 mg was not better than 1 mg).

Drowsiness and forgetfulness were the main reported adverse events in both groups, with no increase in psychosis or euphoria in the treated group. In 1 case nabilone actually caused increased chorea [24].

Tourette Syndrome Tics

As in any condition influenced by anxiety, a nonspecific beneficial effect of cannabis might be expected, but given the presence of endocannabinoid receptors in the striatum, it is possible that a direct effect of cannabis is reducing the number of tics.

Success in treating symptoms of Tourette syndrome, including involuntary movements (tics) and compulsive behaviors, was first mentioned in an observation of 3 patients who, in 1988, noted improvement in tics and urges while smoking marijuana cigarettes [25], followed by another case of a patient remaining symptom free for a year while smoking marijuana daily [26]. In 1998 a survey of a larger population confirmed a reduction in tic or complete remission in 82 % of patients [27]. The same authors used Δ^9 -THC capsules of varying strengths in a single dose in 12 patients (class II study) and reported improvement in scores of the Tourette Syndrome Symptom List and obsessive-compulsive behavior scores, with a decreased number of complex motor tics observed by the examiner [28]. The following year, in a study of 24 patients using the maximum-strength Δ^9 -THC capsule from the pilot study (10 mg) for 6 weeks, a significant response in self-rated Tourette score and observer-rated scores, including the Tourette Syndrome Clinical Global Impression Scale, the Shapiro Tourette Syndrome Severity Scale, and the Yal Global Tic Severity Scale, as well as the review of video, was noted [29]. These were then summarized in a Cochrane review [30]. Little additional work was summarized in a more recent review [31]. Of note, improvements occurred without exacerbating performance on neuropsychologic testing [32].

Side effects were minimized by a simple technique of providing dronabinol after breakfast in order to slow its absorption and provide a steady level acting in the brain [29].

Conclusions

Although clinical studies in this area are difficult to do, even in countries where the use of cannabis has been allowed for years, there is a clear role for cannabis products in symptom management for these difficult conditions. The movement disorders are well-known to be worsened in patients who are anxious, but the careful observations reviewed above lead to the conclusion that there is a direct effect of cannabis in various formulations in some conditions, especially hyperkinetic symptoms. Caution in using a potential central nervous system depressant is always required in patients whose neurologic function is already compromised by disease, but

larger studies will prove there is a promising role for this class of drug in the therapy of dyskinesias, tics, and possibly dystonia.

An Analysis of Applicants Presenting to a Medical Marijuana Specialty Practice in California

Helen Nunberg, MD, MPH, Beau Kilmer, PhD, Rosalie Liccardo Pacula, PhD, and James Burgdorf

Abstract

For more than a decade, medical marijuana has been at the forefront of the marijuana policy debate in the United States. Fourteen states allow physicians to recommend marijuana or provide a legal defense for patients and physicians if prosecuted in state courts; however, little is known about those individuals using marijuana for medicinal purposes and the symptoms they use it for. This study provides descriptive information from 1,655 patients seeking a physician's recommendation for medical marijuana, the conditions for which they seek treatment, and the diagnoses made by the physicians. It conducts a systematic analysis of physician records and patient questionnaires obtained from consecutive patients being seen during a three month period at nine medical marijuana evaluation clinics belonging to a select medical group operating throughout the State of California. While this study is not representative of all medical marijuana users in California, it provides novel insights about an important population being affected by this policy.

I. INTRODUCTION

As of December 2010, 15 states and the District of Columbia provide allowances for medical marijuana (National Conference of State Legislatures, 2010).¹ There is a small literature about whether these laws influence the overall demand for marijuana (Gorman and Charles, 2007; Pacula et al., 2010), and a tremendous amount of discussion about how medicinal marijuana is distributed, especially in California (see e.g., Hoeffel, 2010a; 2010b). What remains largely missing from the literature and policy discussions is a good understanding of the individuals who seek a medical allowance for marijuana.

This paper helps fill this gap by systematically evaluating the characteristics, ailments, and medical histories of a large group of applicants seeking a medicinal marijuana recommendation. Data are collected from medical charts and doctor interviews with 1,655 individuals seen in June, July and August of 2006 from nine medical marijuana specialty practices dispersed throughout California. The results provide some interesting insights as to the characteristics of those seeking medicinal allowances nearly a decade after the policy was introduced in California.

The remainder of this paper is organized as follows. In Section 2 we briefly review the literature on the therapeutic value of cannabinoids, provide details of the specific allowances provided for within California state law, and review previously published surveys of populations of medical marijuana users. In Section 3 we discuss the methods that were used in the current study, including our data collection procedures, and in Section 4 we present

¹This excludes Maryland. While Maryland does allow those arrested for marijuana possession to use a medical necessity defense, those found to be using for medical purposes are still convicted and can be fined up to \$100.

our results. A general discussion of these findings and the limitations of our study are presented in Section 5.

II. BACKGROUND AND LITERATURE REVIEW

Research on the therapeutic value of cannabinoids

Cannabinoids are compounds related to tetrahydrocannabinol (THC) found in the cannabis plant (phytocannabinoids), in animals (endocannabinoids), and synthesized in laboratories (e.g., THC analogues, cannabinoid receptor agonists and antagonists) (Pertwee, 2006). Cannabinoid receptors are found in all animals; in humans, cannabinoid receptors are concentrated in the brain but are also found in other parts of the body.

The use of cannabis as a medicine originated thousands of years ago. After being introduced to the West in the mid-nineteenth century, cannabis-based medicines were popular through the early decades of the twentieth century (Grinspoon, 2005; Zuardi, 2006). The virtual disappearance of cannabis-based medicines by the mid-1900s was due to the introduction of new pharmaceuticals (e.g., aspirin, chloral hydrate, barbiturates) for the same conditions, such as pain, migraines, menstrual cramps, and sedation, as well as the legal restrictions associated with the 1937 Marijuana Tax Act (Fankhauser, 2002; Grinspoon).

The Institute of Medicine's (IOM) 1999 report *Marijuana and Medicine: Assessing the Science Base*, concluded that "Scientific data indicate the potential therapeutic value of cannabinoid drugs, primarily THC, for pain relief, control of nausea and vomiting, and appetite stimulation; smoked marijuana, however, is a crude THC delivery system that also delivers harmful substances" (4). The report further noted that, "For the most part, the logical categories for the medical use of marijuana are not based on particular diseases but on symptoms...[that] can be caused by various diseases or even by treatments for diseases" (IOM, 1999; pp. 137–138). Based on these findings, the panel recommended that "clinical trials of cannabinoid drugs for symptom management should be conducted with the goal of developing rapid-onset, reliable, and safe delivery systems" (4). In addition to focusing on pain relief, control of nausea and vomiting, and appetite stimulation, the IOM report also called recommended that clinical trials focus on the suitability of cannabinoid drugs to address anxiety reduction and sedation.

Reviews published since the IOM report also highlight the potential therapeutic value of cannabinoid drugs; however, few of the studies focus on inhaled marijuana. A review of 72 randomized, double-blind, placebo-controlled studies from 1975 to 2004 evaluating the therapeutic effects of cannabinoids concludes that "Cannabinoids present an interesting therapeutic potential as antiemetics, appetite stimulants in debilitating diseases (cancer and AIDS), analgesics, and in the treatment of multiple sclerosis, spinal cord injuries, Tourette's syndrome, epilepsy and glaucoma" (Ben Amar, 2006). A more recent review focusing on clinical studies published from 2005 to 2009 (Hazekamp and Grotenhermen, 2010) concluded that cannabinoids have "therapeutic potential mainly as analgesics in chronic neuropathic pain, appetite stimulants in debilitating diseases (cancer and AIDS), as well as in the treatment of multiple sclerosis." For both reviews, a minority of the trials evaluated inhaled marijuana (six and eight studies, respectively). The others used a synthetic THC isomer or analog for oral administration, or plant extract in oral or sublingual preparations.²

²Hazekamp and Grotenhermen included recent studies of nabilone, a prescription drug that is a THC analog. Skrabek et al. (2008) performed a randomized, controlled trial to assess the benefit of nabilone on pain reduction and quality of life improvement in patients with fibromyalgia. They found significant decreases in pain and anxiety. Similarly, Ware et al. (2010) concluded that nabilone "is effective in improving sleep in patients with fibromyalgia and is well tolerated." Finally, in a more recent observational study (Bestard and Toth, 2010), nabilone was found to be as effective as gabapentin, a first line medication for peripheral neuropathy, in measures of pain, sleep, depression and anxiety.

In February 2010, the Center for Medicinal Cannabis Research (CMCR) at the University of California San Diego submitted a report to the Legislature and Governor of California describing five completed clinical trials with inhaled marijuana (Grant et al., 2010). Four demonstrated pain relief effects in conditions secondary to injury or disease of the nervous system (Abrams et al., 2007; Wallace et al., 2007; Wilsey et al., 2008; Ellis et al., 2009), and one suggested a reduction of spasticity in multiple sclerosis (Corey-Bloom et al., 2008).

Medicinal Marijuana in California

In California, patients with a physician's recommendation, along with their designated caregivers and recommending physicians, are exempted from state criminal laws against marijuana. Although provision and use remain illegal under federal law, U.S. Attorney General Eric Holder made a statement in March 2009 suggesting that the federal government would not target those who complied with state medical marijuana laws. This was made more official in an October 2009 memo to U.S. Attorneys which noted that: "As a general matter, pursuit of these priorities should not focus federal resources in your States on individuals whose actions are in clear and unambiguous compliance with existing state laws providing for the medical use of marijuana."

The California medical marijuana law, passed through voter referendum (Proposition 215) in 1996, permits the use of marijuana for "cancer, anorexia, AIDS, chronic pain, spasticity, glaucoma, arthritis, migraine, *or any other illness for which marijuana provides relief*" [emphasis added]. California Senate Bill 420, signed into law on October 12, 2003, named additional ailments such as severe nausea, cachexia, seizures, and persistent muscle spasms (regardless of whether they are associated with multiple sclerosis). In an effort to provide better guidance to law enforcement agencies, SB 420 allowed patients and primary caregivers to possess up to six mature plants (or 12 immature plants) and eight ounces of marijuana; however, it granted local governments the authority to establish larger maximum quantities.

Many of the early studies about medicinal marijuana users in California focused on individuals with HIV or AIDS (e.g., Harris et al., 2000; Sidney, 2001; de Jong et al., 2005; Prentiss et al., 2004). Based on analyses of several unpublished surveys of clients entering cannabis buyer clubs in the San Francisco Bay Area, Gieringer (2002) found that the share of clients that were AIDS and cancer patients declined after the passage of Proposition 215. More recent research in California shows that medicinal marijuana patients are largely men who present with pain and/or emotional/mental health concerns (O'Connell and Bou-Matar, 2007; Reiman, 2007; Reiman, 2009). An informal survey of several California medical marijuana specialty physicians revealed that more than 95% of the patients of each physician were already "self-medicating" prior to the receipt of their recommendation, leading Mikuriya et al. (2007) to conclude that the physicians were really "approving" the medical use of marijuana as opposed to "recommending" it.

III. DATA AND METHODS

The data used in this study come from medical records of 1,745 applicants consecutively presenting to one of nine MediCann clinics located in large and small cities throughout California.³ The sample is based on visits in June, July, and August 2006, roughly ten years after the original law was enacted. Medical charts were reviewed and data entered within a few weeks of the visit. Our final sample excludes 90 individuals who are either missing diagnosis information (N=35) or did not report using marijuana before seeking a

³Since 2006, MediCann has expanded to 21 locations throughout California.

recommendation (N=55).⁴ There are no statistically significant differences in terms of age, race/ethnicity, and gender between those included and excluded in the analysis sample.

We drew on consecutive visits from all nine clinics in hopes of approximating a representative sample of applicants seeking recommendations at these medical marijuana specialty practices. The sample is not generalizable to all individuals applying for a medical marijuana recommendation as it only represents those individuals selecting this particular network of physicians.

In general, the MediCann policy was to provide a 12-month recommendation to those with an acceptable medical condition who had supporting medical record documentation.⁵ Those without medical record documentation received a provisional three-month recommendation conditional upon them providing the MediCann physician with a copy of the relevant supporting medical record, or, if not currently under the care of a medical professional, seeking care and providing those records. Applicants were only denied if they did not report having an eligible medical condition or if they refused to be under the care of a medical professional. For our sample the denial rate was less than 2%.

MediCann's medical records include two standard forms specifically created for MediCann. One form is filled out by the applicant and includes demographic information, medical history, and marijuana use history. The second form is filled out by the evaluating physician and contains clinical information related to the health problem and symptoms for which the applicant is seeking help. Clinic physicians relied on medical histories, physical exams, and the supporting medical documents when they assigned diagnoses. The supporting medical documents included laboratory and radiological evaluations to validate applicant claims of use of marijuana for relief of symptoms due to a medical condition. Over two-thirds of applicants (67.8%) brought medical record documentation with them at the time of the visits analyzed in our study.

In light of the limited information on this population of interest, we examine simple means or sample proportions for several variables of interest, including patient characteristics and stated therapeutic needs, physician diagnoses, and medical history. Results are provided for the entire sample and then broken down by gender.

IV. RESULTS

Applicant Characteristics

Applicant demographic information is shown in Table 1 both for the full sample and by gender, since almost 73% of the applicants seeking a recommendation were male. This is not much different than the share of those in the 2006 National Household Survey on Drug Use and Health who reported purchasing marijuana in the previous month (70%). Female applicants seeking recommendations were, on average, older and more likely than men to be African American, have some college education, have Medicaid (MediCal) health insurance, or to be unemployed and disabled (19.5% of women reported being unemployed due to disability). In general, those seeking recommendations were insured (73.0% currently insured, of whom 24.2% were covered through Medicare or Medicaid), have at least a high school degree (only 8.8% have less than a high school degree), and are generally employed (68.7%).

⁴While in many ways the applicants who report not using marijuana prior to seeking this recommendation are perhaps the most interesting, there are an insufficient number of these individuals in our sample for robust comparisons.

⁵Qualifying patients would be given a recommendation and would be reassessed periodically to review the course of treatment and any new information about their health, as well as to monitor response to treatment as indicated by a decrease in symptoms, an increase in level of function, or an improvement in quality of life.

As for the age distribution, at least half of the population seeking medical recommendations through this physician group was over the age of 35. For comparison, the median age for those 18 and older in the 2006 NSDUH who reported purchasing marijuana in the previous month was in the 26–29 year old category (those over 21 are placed into age categories).

Applicants' Self Reports of the Therapeutic Benefits of Marijuana

In light of the IOM's argument that the "logical categories for the medical use of marijuana are not based on particular diseases but on symptoms (IOM; pp. 137–138), we examined the self-reported therapeutic benefit received from marijuana and the symptoms it helped relieve. Applicants were asked "Which of the following best describe the therapeutic benefit you receive from medicinal cannabis? (Check the most important reasons you use cannabis.)" The results are presented in Table 2.

Applicants most frequently reported using medical marijuana for pain relief (82.6%), improved sleep (70.6%), and relaxation (55.6%). The next most frequently reported benefits included relief of muscle spasms (41.3%), headache (40.8%), relief of anxiety (38.1%), improved appetite (38.0%), relief of nausea and vomiting (27.7%), and relief of depression (26.1%). Half the applicants (50.8%) reported using marijuana as a substitute for prescription medication and 13.2% reported using marijuana as a substitute for alcohol.

Interestingly, women were statistically more likely than men to report that they used marijuana to relieve most of the indications listed, including headaches, anxiety, nausea, depression, panic, and medication side-effects. The only indication for which men were more likely than women to report use of marijuana was to help with focus. One in four men reported that marijuana improved focus.

Physician Diagnosis

Table 3 presents the highest frequency diagnoses and the diagnoses specifically listed in the Compassionate Use Act. Recall that treating physicians make their diagnoses based on a review of applicant's history, the medical records from treating physicians (in two-thirds of the cases), and on their own physical examination. Evaluating physicians were then asked to "circle only diagnoses related to patient's medicinal marijuana use" from a list of 162 diagnoses.

In general, chronic pain disorders were the most common diagnoses made by physicians, with nearly 60 percent (58.2%) of applicants being diagnosed with some sort of musculoskeletal or neuropathic chronic pain condition. Low back pain was diagnosed for over one quarter (26.2%) of patients seen during this three month period, with lumbar and cervical degenerative disc disease (together 21.8%) and arthritis (18%) the next most common diagnoses in the chronic pain group. Mental health disorders were the next largest group of diagnoses made (22.9%), followed closely by sleep disorders (21.3%). Diagnoses in the grouping "neurological disorders," including migraine and other headache, were made in 16.6% of applicants. Only 3% of the applicants were diagnosed with either cancer or HIV/AIDS.

Previous Treatments and Physician's Recommendations for Additional Treatment

Because self-reported information was collected from applicants and most provided medical documentation from their treating physician that could be reviewed by the evaluating physician, it was possible to consider the extent to which previous therapies had been used to cope with or treat the primary symptoms for which they were seeking a medical allowance. In Table 4 we provide a list of therapies or approaches that were previously tried or currently being used. Almost half of the applicants (47.6%) reported taking prescription

medication at the time of their evaluation, and nearly 4 out of 5 (79.5%) reported having taken prescription medication in the past for their problems. As chronic pain was the leading diagnosis for which marijuana was being recommended, we were curious to see what percent of applicants had used opioids or opiate medication to deal with their problem. On the physician evaluation form, evaluating physicians were asked to check yes or no if the applicant was currently using or had used in the past opioids or opiate medication prescribed by another physician for their chronic pain. Evaluating physicians determined that almost half of all applicants (48.0%) experiencing chronic pain either currently or in the past had been prescribed opioids or opiate medication.

Non-prescription therapies tried by applicants seeking medicinal marijuana allowances included physical therapy (48.6%), chiropractic services (37.2%), surgery (21.9%), psychological counseling (20.7%), and acupuncture (19.6%). Thus, these data do not suggest that applicants immediately seek marijuana recommendations as the first strategy to deal with their symptoms. In many cases, these individuals tried more traditional forms of medicine.

V. DISCUSSION

This study provides descriptive information from 1,655 applicants seeking a physician's recommendation for medical marijuana in California, the conditions for which they sought treatment, and the diagnoses made by the physicians. The most common diagnoses reported were for chronic pain, mental health conditions (primarily anxiety and depression), and sleep disorders (insomnia). For physicians who make medical marijuana recommendations, the risk of being deceived is not dissimilar to the risk of deception faced by those who prescribe oxycodone and other painkillers; however, those prescribing the latter can limit the number of pills and refills.⁶ For medical marijuana, existing laws and policies only allow physicians to distribute recommendations, they cannot control the number of purchases, what is purchased (e.g., % THC or other cannabinoid content), where it is purchased, or the route of administration (e.g., inhale smoke or vapor, ingest an edible, apply topically).

The majority of applicants reported that they tried other therapies, including prescription drugs, to manage their symptoms prior to seeking the medicinal allowance. Fifty percent of the sample reported that they used marijuana as a substitute for prescription medicine. This is consistent with other studies (e.g., Reiman, 2007; 2009) and raises important questions about the specific drugs they are replacing. Future research with this population should focus on previous and concurrent prescription medication use to examine claims that marijuana enables people to reduce or eliminate their use of prescription medications. These data could also be useful for understanding whether there could be cost-savings associated with substituting certain prescription medicines with marijuana.

This also raises the issue about whether the legalization of marijuana for non-medicinal purposes would influence the consumption of prescription drugs. Not only would legalization increase availability and reduce the price of marijuana (Kilmer et al., 2010), but the reduced stigma may increase the likelihood that some individuals try it for medicinal purposes. It could also be the case that doctors may be more willing to discuss marijuana use with patients if it was not prohibited.

Less than 5% of the applicants in our sample were diagnosed with HIV/AIDS, cancer, or glaucoma. While these were not the only diseases/conditions discussed when Proposition

⁶However, doctors prescribing oxycodone cannot prevent patients from crushing the pill to deactivate the time-release functionality and then snorting or injecting it.

215 was on the ballot, they did receive a lot of attention. This is not surprising; we would expect the number of applicants presenting with HIV/AIDS, cancer, or glaucoma to be relatively low compared to the number presenting with pain, anxiety, and insomnia, due to the relative prevalence of these conditions in the general population. However, it is also important to note that many of those receiving recommendations did so for conditions other than those listed by the IOM (pain relief, control of nausea and vomiting, and appetite stimulation).

Finally, the age profile observed in the sample of applicants is intriguing, especially when compared with those who report purchasing marijuana in the previous month in the 2006 NSDUH. One should not assume the larger median age for these applicants is statistically meaningful in light of the potential non-representativeness of our sample and the fact that it is drawn exclusively from California. However, if these age differences appear in future studies, it could offer important insights about age-related risk aversion and/or age-specific access to distribution networks—each with different policy implications. Thus, future work should explore the robustness of these differences and consider their implications for policy.

We conclude by reminding readers that we did not examine randomly-selected representative sample of all individuals in California seeking a medical recommendation for the use of marijuana. We were merely able to collect data from a sample of individuals who presented themselves within a three month window to a group of doctors that they most likely expected would be willing to provide them with a recommendation. The applicants receiving recommendations from these doctors may differ from those in the general population in important ways that we are unable to know. As applicants receiving physician recommendations are not required by law to register with county or state health officials, we have no way of knowing the extent to which the population served by this particular physician group might differ from that served by other medical marijuana specialists or by primary care physicians. Knowledge about the number and type of individuals that receive recommendations from other specialists or from primary care physicians would improve our understanding medical marijuana users in California.

Since California law allows for medical marijuana use for any “illness for which marijuana provides relief,” we have an enormous opportunity to further our understanding of the risks and benefits of marijuana with careful questioning of some of the thousands of patients willing to discuss their use of marijuana. Detailed information about the doses, frequency, methods, and forms of marijuana consumed, as well as information about past and present alcohol, illicit drug, and prescription drug consumption would be of great interest.

Improvement in Refractory Obsessive Compulsive Disorder With Dronabinol

TO THE EDITOR: It has been reported that 40%–60% of patients with obsessive-compulsive disorder (OCD) do not respond to first-line treatment. Treatment options for these patients include switching to another agent or augmentation (1). We report on two patients with treatment-resistant OCD and comorbid axis I disorders who responded to an augmentation with the cannabinoid dronabinol.

“Mrs. L” was a 38-year-old woman who was admitted with recurrent major depression and OCD (Yale-Brown Obsessive Compulsive Scale score: 20) after outpatient treatment with paroxetine (60 mg) for 8 months and cognitive behavioral therapy (CBT) were not efficacious. Switching to clomipramine (300 mg) resulted in partial response after 12 weeks of treatment. Based on the patient’s report that smoking marijuana usually relieved her symptoms, an augmentation with dronabinol (2.5%; 10 mg t.i.d.) was started. The prior medication was continued. While undergoing treatment with dronabinol (2.5%), the patient’s OCD symptoms decreased significantly within 10 days (Yale-Brown Obsessive Compulsive Scale score: 10).

“Mr. K” was a 36-year-old man with schizophrenia and OCD who was admitted for deterioration of psychotic and obsessive symptoms (Yale-Brown Obsessive Compulsive Scale score: 23). During his course of illness, Mr. K had been treated with antipsychotics (including haloperidol, olanzapine, risperidone, quetiapine, and aripiprazole), both in monotherapy and in combination with selective serotonin reuptake inhibitors. His OCD symptoms in particular remained predominately treatment resistant. Treatment with clozapine (400 mg), which he had already received for more than 1 year (in combination with paroxetine [60 mg] for 13 weeks) resulted only in partial response of his psychotic and OCD symptoms. Switching paroxetine to clomipramine (for another 10 weeks), followed by an additional course of 18 electroconvulsive therapy treatments (right unilateral high dose), did not improve the patient’s psychotic or OCD symptoms significantly. After the addition of dronabinol to ongoing treatment with clomipramine (150 mg) and clozapine (400 mg), a significant reduction of OCD symptoms was observed within 2 weeks (Yale-Brown Obsessive Compulsive Scale score: 15). In order to prevent psychotic deterioration, dronabinol (2.5%) was carefully increased to 10 mg b.i.d.

Apart from anticholinergic symptoms that preceded the addition of dronabinol (patient 1: dry mouth, constipation; patient 2: constipation, hypotension), both patients reported no side effects. In particular, there was no deterioration of psychotic or mood disorder symptoms.

Based on data from case reports and small clinical trials suggesting that cannabinoids can reduce symptoms of tic disorder (2) and on findings from genetic studies linking tic disorder with OCD (3), we hypothesized that cannabinoids

might also reduce OCD symptoms. Moreover, there is evidence suggesting that besides serotonergic and dopaminergic systems, glutamatergic hyperactivity is involved in the pathophysiology of OCD (4, 5). This view is supported by data suggesting the efficacy of glutamate modulating drugs, such as topiramate, memantine, riluzole, or N-acetylcysteine, in the treatment of OCD (6). It has been reported that cannabinoids inhibit glutamate release in the CNS (7, 8). Additionally, cannabinoid type 1 (CB₁) receptors are distributed abundantly in the striatum (8), a brain region frequently associated with OCD. Hence, it can be speculated that the anti-obsessive effect observed in our patients may have been a consequence of the glutamate modulation of the cannabinoid dronabinol. Since it is well known that cannabinoids may trigger psychotic symptoms in patients with schizophrenia (8), caution is warranted when prescribing for patients with a history of the disorder.

Maintenance Treatment With Transcranial Magnetic Stimulation in a Patient With Late-Onset Schizophrenia

TO THE EDITOR: A recent meta-analysis (1) concluded that repetitive transcranial magnetic stimulation (rTMS) efficiently reduces resistant auditory hallucinations in patients with schizophrenia (effect size=0.76). Nevertheless, treatment is

presently only provided over short periods of time, and little is known about longer-term impact. Maintenance treatment protocols have been developed, and we previously described a case report involving a maintenance protocol with a weekly, once-a-day stimulation (2); however, we failed to demonstrate long-term benefits. To our knowledge, the case presented below is the first report of a twice-daily transcranial magnetic stimulation as efficacious for auditory hallucinations, both in acute and maintenance treatment.

“Ms. A,” a 55-year-old right-handed, postmenopausal woman who had DSM-IV late-onset schizophrenia with an illness duration of 2 years, was referred for transcranial magnetic stimulation treatment. She was noted to have benzodiazepine addiction involving the use of lorazepam (9 mg/day). She had been suffering from resistant auditory hallucinations for 2 years (very frequent and loud, with >5 critical and command voices). She was unresponsive to four antipsychotic medication trials lasting >4 months each, including haloperidol (5 mg/day), amisulpride (1200 mg/day), olanzapine (15 mg/day), and risperidone (8 mg/day). A detailed assessment did not reveal any other pathology or transcranial magnetic stimulation contraindications. Auditory hallucinations were assessed using the Auditory Hallucination Rating Scale (3), and positive symptoms were assessed using the Scale for the Assessment of Positive Symptoms (SAPS). Lorazepam withdrawal was completed without exacerbation of the psychotic symptoms (Auditory Hallucination Rating Scale score: 34). Four months after her initial presentation, the patient gave informed consent and was included in a transcranial magnetic stimulation protocol. Twice-a-day, 1000 low-frequency repetitive stimulations (1 Hz) were administered to the temporoparietal cortex at 100% of motor threshold over a 5-day period. The patient's current dose of risperidone was maintained during treatment with transcranial magnetic stimulation. After the first course, auditory hallucinations were moderately improved, with a 35% reduction in her Auditory Hallucination Rating Scale score, which did not change over the next several months, as observed in a follow-up assessment. However, the patient's general SAPS score improved, with a 30% reduction in severity.

Six months after the first course of transcranial magnetic stimulation therapy, the patient presented with a relapse of hallucinations. A new transcranial magnetic stimulation course, with the same parameters, was conducted. This second course was followed by a once-per-month, twice-daily maintenance protocol (one session in the morning, the other in the afternoon on the same day). The patient's auditory hallucinations were greatly improved, by 80%, and her SAPS score decreased from 38 to 16. This maintenance course was associated with a remission of auditory hallucination symptoms, with a stabilization of SAPS scores at 10 over the next 6 months. Presently, more than 1 year later, Ms. A is not receiving any antipsychotic medication, and her Auditory Hallucination Rating Scale and SAPS scores remain at 0.

Our case raises the question as to whether twice-daily transcranial magnetic stimulation may be useful in some patients as a possible maintenance intervention. Certainly, further research will help us to understand whether the benefits observed in this single case might also be evident in larger studies.

Abstract

Objectives

Although cannabis use is common in bipolar disorder and may contribute to worse clinical outcomes, little is understood about the relationship between this drug and bipolar disorder over the course of daily life. The aim of study was to examine the effect of cannabis on affect and bipolar symptoms in a group of individuals with bipolar disorder.

Methods

Twenty-four participants with bipolar disorder type I or type II completed diaries for 6 days using Experience Sampling Methodology to investigate the temporal associations between cannabis, affect and bipolar disorder symptoms.

Results

The results indicated that higher levels of positive affect increase the odds of using cannabis (OR:1.25 ,CI:1.06–1.47, P=0.008). However, neither negative affect, manic nor depressive symptoms predicted the use of cannabis. Cannabis use was associated with subsequent increases in positive affect ($\beta=0.35$, CI:0.20-0.51, P=0.000), manic symptoms ($\beta=0.20$, CI:0.05-0.34, P=0.009) and depressive symptoms ($\beta=0.17$,CI:0.04-0.29, P=0.008).

Conclusion

The findings indicate that cannabis use is associated with a number of subsequent psychological effects. However there was no evidence that individuals with BD were using cannabis to self-medicate minor fluctuations in negative affect or bipolar disorder symptoms over the course of daily life. The findings in relation to existing literature and clinical implications are discussed.

Clinical Psychology training course. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Introduction

Cannabis is the street drug most frequently used by individuals with bipolar disorder (BD) [1, 2, 3]. Estimates of current use range from 8% to 22% and lifetime use from 30% to 64% [4]. Cannabis use in BD is associated with poorer outcomes, including increased symptom severity [5] and poorer treatment compliance [5, 6]. A recent study found that individuals who were diagnosed with BD and a co-occurring cannabis disorder had a younger age of BD onset and an increased number of manic, hypomanic and depressive episodes per year [7].

Specific reasons for the high levels of cannabis use in BD remain equivocal and are not yet fully understood. Whilst there have been a number of reviews reporting on the co-occurrence of substance use and BD [8] few studies have focused specifically on the relationship between cannabis use and BD [7].

Prospective cohort studies [9, 10, 11] have found evidence to suggest that cannabis use begins prior to bipolar onset, which might suggest a causal role in the development of BD. However there is also evidence to suggest that for some, cannabis use commences following the onset of manic symptoms [12]. Self-report literature including case histories [13, 14] and qualitative interviews [15] suggests that individuals with BD use cannabis as a form of self-medication to alleviate manic symptoms [13, 15] and to relieve depression [14]. These findings [13, 14, 15] are consistent with the proposal of Ashton et al [16] that the key constituents of cannabis, Δ^9 -tetrahydrocannabinol (THC) and cannabidiol (CBD), can have both sedative and antidepressant effects. Therefore whilst manic, individuals may use cannabis for the sedative effects and when depressed for the anti-depressive effects.

As with BD, rates of cannabis use in individuals with psychosis are high [17, 18] and there is no single model available which fully explains this co morbidity [19]. A recent study [20] used the experience sampling method (ESM) to provide further insight into the complicated dynamics of cannabis use and its effect on individuals with psychosis, in the context of daily life. Henquet et al [20] found that cannabis use predicted an increase in positive affect in both individuals with psychosis and a non-clinical control group. Cannabis use also predicted a decrease in negative affect and an increase in the number of hallucinatory experiences in the psychosis group alone. They found no evidence to support the self-medication hypothesis as neither psychotic experiences or mood was found to predict cannabis use. The current study was similarly designed using ESM to allow a close investigation into BD and cannabis use over the course of daily life and to aid further understanding of this seemingly complex relationship.

ESM is a structured diary method where individuals are asked to report their thoughts, feelings and symptoms over the course of daily life. ESM was pioneered in mental health research by researchers at the University of Maastricht [21, 22]. The methodology offers a number of advantages in comparison to traditional assessments of mental health experiences [23, 24], which rely on using retrospective data, and may be open to recall bias. With ESM, the short space between an event occurring and reporting of the details reduces the possibility of memory bias [25]. ESM examines phenomena in the real world as they occur and therefore has a high level of ecological validity. It provides a rich and descriptive data set, detailing a participant's daily experience and has the capacity to assess the temporal relationship between numerous variables [24].

ESM has previously been used to investigate the perception of daily 'hassles' and 'uplifts' in individuals with BD [26]. The study found that individuals who had more previous depressive episodes and current depressive symptoms experienced negative events as more stressful [30]. Furthermore, Knowles et al [27] used a diary method, where individuals with remitted BD or remitted unipolar depression plus a non-clinical sample reported on self-esteem and positive and negative affect twice a day, over the course of a week. The study reported instability of self-esteem and affect in the remitted BD individuals compared to both other groups.

To the authors knowledge there are no published studies that have used ESM to examine the relationship between BD and cannabis use. Therefore the current study aimed to provide an investigation into the associations between cannabis use, positive affect, negative affect and BD symptoms (mania and depression) in individuals with BD in daily life over a six day period, and to test two key predictions suggested in the literature outlined above:

- 1]. frequency of cannabis use will increase as a function of affect and BD symptom change (i.e. self medication effects)
- 2]. cannabis use will be associated with subsequent changes in affect and BD symptoms

Materials and Methods

Ethics statement

Full ethical approval for the study was obtained from Liverpool National Research Ethics Service (NRES) Committee and the University of Manchester research ethics committee. Written, informed consent was obtained from all participants in the study.

Participants

Twenty-nine participants were recruited for the study from a number of sources. These included four mental health trusts in the North-West of England, self-help organisations (Bipolar UK and Mood Swings Network) and self-referral from the online University of Manchester research volunteering website (<http://www.studentnet.manchester.ac.uk/volunteer/>).

All individuals met criteria for BD-I or BD-II, as determined by the Structured Clinical Interview for Axis I Disorders (SCID) based on the DSM-IV diagnostic criteria [28]. Current symptomatology was assessed using the Hamilton Rating Scale for Depression [29] and the Bech Rafaelson Mania Rating Scale [30]. Substance use disorders were assessed using the substance use module of the SCID [28]. To be included, participants were required to report using cannabis on at least two occasions per week (in at least half the weeks in the 3 months prior to assessment). Exclusion criteria for the study included meeting criteria for a current episode of mania or depression (if currently met criteria they were kept on a waiting list until out of episode, except for those who remained unwell throughout the recruitment period), aged below 18, evidence of an organic brain disease or moderate/severe learning disability.

Experience sampling method and procedure

At the beginning of this study, participants were given a paper diary and a digital wristwatch. In accordance with previous research [31, 32], the ESM period lasted for six consecutive days and the watch emitted a signal on ten occasions throughout the day at unpredictable times, between the hours of 8am and 10pm.

Each time participants heard the beep they were required to fill out a page of the diary. The diary consisted of questions on thoughts, affect, BD symptomatology, contextual information regarding their current situation and substance use. Participants were required to fill out the diary within 15 minutes of hearing the beep and to record the time of completion. Any entries completed outside this time frame were excluded from analyses. Previous research has demonstrated that entries completed after the 15 minutes are less reliable and valid [22]. A minimum of 20 valid diary reports were required by each participant, to ensure the data was representative [24].

During the initial visit informed consent was gained from the participant and the SCID [28], Hamilton Rating Scale for Depression [29] and the Beck Rafaelson Mania Rating Scale

[30] were completed. Where all inclusion criteria were met, a second visit was arranged, one day prior to the ESM period. During the second visit, the participant was introduced to the watch and paper diary and briefed about the study. The general procedure described above was explained in detail. On the seventh day a final meeting was arranged to collect the watches and diaries and debrief the participant.

Measures

The ESM diary—affect items

Current affect was assessed using ten items, rated on a 7-point Likert scale (where 1 = 'not at all' and 7 = 'very much so'). In previous ESM studies [20,31,33], with individuals with psychosis and healthy controls, a positive and negative affect scale was identified using a factor analysis on the raw-within participant scores for the affect items ($N = 10$). A principal components analysis for this study was conducted and like the similar studies [20,31,33] revealed two separate scales. The items 'cheerful', 'excited', 'relaxed', 'satisfied', 'happy' formed the positive affect scale ($\alpha = 0.85$) and the items 'lonely', 'anxious', 'irritated', 'sad', 'guilty', formed the negative affect scale ($\alpha = 0.82$). This analysis yielded similar results to other ESM studies. Henquet et al [20] reported a positive affect scale ($\alpha = 0.89$) and a negative affect scale ($\alpha = 0.80$). The mean scores for each scale were used in the analyses.

The ESM diary—BD Symptoms

Current BD symptomatology (mania and depression) was assessed using 7 items rated on a 7-point Likert scale. The items were formulated by the authors (SJ, CB, ET), all of whom had significant experience of working with people with BD. They were chosen in accordance with guidelines for selection of ESM items [24] and to assess momentary experiences of BD symptoms that might reasonably occur and fluctuate during the flow of daily life. A service-user group of 4 people with a BD diagnosis took part in a consultation exercise and checked the appropriateness of the potential questions. Members reported that the language reflected how they would describe their own behaviour and experiences. A principal components analysis revealed two distinct subscales with high internal consistency. The mania scale ($\alpha = 0.76$) consisting of the items: I am 'full of energy', 'high', 'full of good ideas' and the depression scale ($\alpha = 0.83$), consisting of items: I feel 'slowed down', 'low', 'bad about myself', 'fearful'. The mean scores for each scale were used in the analyses.

The ESM diary—substance use

Cannabis use, referred to as a 'cannabis moment' was reported in the diary after each beep (the period between the current beep and previous beep). Information was derived from the question (since the last beep I've used cannabis 'Yes' or 'No?') Cannabis use **previous** was defined as cannabis use during the period between previous beep and the beep before that. The type of cannabis used was also recorded (skunk, resin or grass).

Alcohol and drug use other than cannabis were reported in the diary after each beep, termed 'alcohol moment' and 'other drug moment' respectively.

Statistical analysis strategy

STATA 11 [34] was used for the analyses. ESM data has a hierarchical structure with the repeated participant observations (level one), nested within days (level two), nested within participants (level three). Responses for one individual or for one day are more likely to be similar than those for a different individual or for a different day. Multilevel random regression

analysis was used as it takes the whole data set into account and can estimate the amount of variation that is associated with the three different levels. The multilevel regression XTMELOGIT routine was used for the dichotomous variables and the XT MIXED routine for the continuous variables. Therefore the odds ratios (dichotomous variables) and the betas (continuous variables) are the associations between the independent and dependent variables in the multilevel model.

Preliminary analyses

Multi-level regression analyses were conducted to identify whether age, gender, alcohol use at the same beep, other drug use at the same beep, type of cannabis used and total cannabis use for the ESM period were associated with changes in affect, BD symptoms and cannabis use. The results were used to identify which variables would be adjusted for in the main analyses.

Self medication effects

To investigate whether affect or BD symptoms predicted cannabis use; multilevel analyses were conducted using the XTMELOGIT routine. Positive affect **previous**, negative affect **previous**, mania **previous** and depression **previous** were entered as the independent variables and cannabis use as the dependent variable. Overall cannabis use during the ESM week was adjusted for in these analyses.

Cannabis effects on affect and BD symptoms

The main effects of cannabis use on affect / symptoms were investigated with cannabis use as the independent variable and positive affect, negative affect, mania and depression as the dependent variables. Alcohol use at the same beep and overall cannabis use during the ESM week were adjusted for in these analyses.

Temporal analyses of cannabis use

Post hoc analyses were conducted to further investigate the duration of cannabis effects on affect and symptoms. To investigate these, cannabis use at the current beep and cannabis use **previous** were entered simultaneously into the model, predicting positive affect, negative affect, mania and depression.

Results

Participants

Twenty-nine participants initially participated in the study. However three participants were subsequently excluded as they had fewer than 20 valid reports and a further two dropped out due to personal circumstances. The final study sample consisted of 24 participants. See [table 1](#) for socio-demographics of the participant sample.

Participant exclusion /drop outs

Five participants were excluded / dropped out of the study. There were no significant differences between individuals who completed the study and those who did not in relation to gender, ethnicity, bipolar diagnosis, marital status, occupational status or living arrangements. However significant differences were revealed between the two groups in terms of age. Individuals who were excluded/ dropped out had a higher mean age and scores on the HAM and the MAS were elevated for the group that was excluded/ dropped out (see [table 2](#) for actual values).

** Personality disorders included Borderline personality disorder and anti-social personality disorder

doi:10.1371/journal.pone.0118916.t001

Substance use

Three participants met current criteria for cannabis abuse disorder and 12 met criteria for current cannabis dependence disorder. Over the course of the six-day ESM period, the mean number of cannabis moments for the sample was 15.0 (SD: 8.6, range: 2–30). During this period all participants reported only using one type of cannabis, with the majority using ‘skunk’ (54%). The mean number of alcohol moments for the sample was 3.1 (SD: 5.5, range 0–21) and for ‘other’ drug use 0.8 (S.D: 2.5, 0–12). See [table 3](#) for other drug and alcohol use.

Preliminary analyses

Age, gender, other drug use (at the same beep) and type of cannabis used were not associated with any of the outcome variables, therefore were not adjusted for in the main analyses. Total cannabis use for the ESM period (number of cannabis moments) was positively associated with cannabis use at the current beep ($\beta = 0.12$, 95% CI: 0.10–0.15, $P = 0.000$), therefore this was adjusted for in all the main analyses. Alcohol use (at the same beep) was positively associated with subsequent increases in positive affect ($\beta = 0.48$, 95% CI: 0.21–0.74, $P = 0.000$) and manic

Table 4. Effect of mood/ BD symptomatology on cannabis use (Self-medication effects).

Positive affect	OR: 1.25, 95% CI: 1.06–1.47, P = 0.008
Negative affect	OR: 0.88, 95% CI: 0.74–1.05, P = 0.147
Mania scale	OR: 1.08, 95% CI: 0.93–1.26, P = 0.291
Depression scale	OR: 0.92, 95% CI: 0.78–1.08, P = 0.303

doi:10.1371/journal.pone.0118916.t004

symptoms ($\beta = 0.40$, 95% CI: 0.15–0.65, $P = 0.002$), therefore it was adjusted for in the analyses which investigated the effects of cannabis.

Self—medication effects

There was a significant positive relationship between positive affect **previous** and cannabis use at the current beep (OR: 1.25, 95% CI: 1.06–1.47, $P = 0.008$). The odds of cannabis use at the current beep were increased for those with higher scores of positive affect at the previous beep. Negative affect **previous** did not significantly predict cannabis use at the following beep (OR: 0.88, 95% CI: 0.74–1.05, $P = 0.147$). Similarly no association was found between manic symptoms **previous** (OR: 1.08, 95% CI: 0.93–1.26, $P = 0.291$) or depressive symptoms **previous** (OR: 0.92, 95% CI: 0.78–1.08, $P = 0.303$) and cannabis use. See [table 4](#).

Cannabis effects on affect and BD symptoms

Cannabis use was associated with subsequent increases in positive affect ($\beta = 0.35$, 95% CI: 0.20–0.51, $P = 0.000$). Cannabis use was also associated with subsequent increases in manic symptoms ($\beta = 0.20$, 95% CI: 0.05–0.34, $P = 0.009$) and depressive symptoms ($\beta = 0.17$, 95% CI: 0.04–0.29, $P = 0.008$). Overall, cannabis use had no effect on negative affect ($\beta = -0.01$, 95% CI: -0.13–0.10, $P = 0.806$). (See [table 5](#)).

Temporal dynamics of cannabis effects

Follow up post-hoc analyses were conducted to investigate the duration of cannabis effects on affect and BD symptoms. This was achieved by entering cannabis use and cannabis use **previous** simultaneously into the model. The results suggested that increases in positive affect were observed in the short term ($\beta = 0.29$, 95% CI: 0.10–0.48, $P = 0.003$ for cannabis use) but not the longer term (over one beep but not two) ($\beta = 0.01$, 95% CI: -0.18–0.20, $P = 0.943$ for cannabis use **previous**). Similarly increases in depressive symptoms were observed in the short term ($\beta = 0.18$, 95% CI: 0.03–0.33, $P = 0.019$ for cannabis use) but not the long term ($\beta = 0.11$, 95% CI: -0.04–0.27, $P = 0.138$ for cannabis use **previous**). For mania, when both cannabis use and cannabis use **previous** were entered simultaneously in the same model, increases in manic symptoms were not observed in the short term ($\beta = 0.07$, 95% CI: -0.10–0.24, $P = 0.393$) or long term ($\beta = -0.08$, 95% CI: -0.25–0.09, $P = 0.359$). See [table 6](#).

doi:10.1371/journal.pone.0118916.t006

Discussion

Higher levels of positive affect increase the odds of using cannabis, however neither negative affect, manic symptoms nor depressive symptoms predicted the use of cannabis at the subsequent beep. The data from the current study indicates that individuals with BD are not using cannabis to self-medicate minor fluctuations in negative affect and bipolar symptoms (previous beep to current beep). It remains to be seen how this data relates to the broader self-medication hypothesis in BD. In line with the second prediction, the findings from the study indicate that the use of cannabis in daily life was associated with subsequent increases in positive affect, manic symptoms and depressive symptoms. In addition, the data suggests that increases in positive affect and depressive symptoms were only experienced in the short-term, as cannabis use at the previous beep did not predict a significant increase in affect or symptoms at subsequent time points.

Cannabis effects

The findings that cannabis use was associated with an increase in positive affect, manic and depressive symptoms is consistent with current literature that suggests cannabis can produce a range of psychological effects [35, 36, 37]. It has been suggested that the psychological and physiological effects of cannabis are primarily due to its main chemical compounds, THC and CBD. The effects of cannabis have previously been found to be bidirectional [35, 38], causing effects such as euphoria and dysphoria; this may partially explain why cannabis use was associated with both manic and depressive symptoms in the current study. The bidirectional effects of cannabis have been found to depend on a range of factors such as dose, route of administration and personality differences [35, 38].

The effect of cannabis use on individuals with psychosis has received rather more investigation than the effects of the drug on those with BD. Research suggests that compared to ‘healthy’ control participants, individuals with at high risk for psychosis may be more sensitive to THC [39, 40]. Barkus and Lewis [41] found that individuals scoring higher on Schizotypal traits were more likely to experience both psychosis-like experiences and more pleasurable experiences after smoking cannabis. Individual differences in sensitivity to the effects of THC may explain the range of experiences, as noted by Henquet et al [20]. In a similar way, individuals with BD may also differ in their sensitivity to the effects of THC, which may explain why there was a range of effects in the current study.

Effects of affect / BD symptoms on cannabis use (Self-medication effects)

The results indicated that higher levels of positive affect increase the odds of using cannabis, and it appears that individuals were using cannabis when they were feeling good. Alternatively, higher positive affect prior to cannabis use may have been experienced due to the expected enjoyment of the effects of substance use.

Data from the current study does not support the idea that cannabis is used by individuals with BD for the self-medication of minor fluctuations in negative affect and BD symptoms in the context of daily life. An increase in negative affect and BD symptoms did not predict cannabis use at the following beep. This finding is consistent with Henquet et al [20] who similarly did not find evidence to support the self-medication hypothesis for psychosis over the course of daily life, as changes in hallucinations, delusions and negative affect did not predict cannabis use.

The interpretation of the findings of this study is limited to the associations between the current beep and the previous beep. It is possibly the case that self-medication effects appear further down the chain of events, following a longer period of negative affect / symptom changes. Alternatively, failure to find self-medicating effects from cannabis may have been due to the nature of the participant sample. BD is characterised by shifts in affect regulation and therefore over time individuals may have become accustomed to subtle changes in mood. Therefore, within the context of daily life, cannabis may not be used as a way to cope with these slight fluctuations. Participants in the study were currently well and out of episode and therefore it may be that cannabis is used to self-medicate more pronounced symptoms or the onset of manic / depressive episodes. This would be consistent with the self-report literature where individuals have found cannabis useful in the management of their BD [13, 14, 15].

Limitations

Several limitations need to be taken into account in interpreting the results of the study. First, details of cannabis use were based on self-report. Cannabis use remains illegal in the United Kingdom, and this may have led to underestimations in reported use. Hair sample analysis may have offered a way to confirm usage [42], however this was beyond the resources of the current study. Additionally, whilst type of cannabis was reported and adjusted for in analyses, the individual potency of the drugs consumed was not controlled for. There are in excess of 100 different strengths of cannabis and research has revealed that on average, cannabis resin and herbal (grass) contains around 2–4% THC, however Sinsemilla (Skunk) contains around 12–18% THC [43, 44]. Data for cannabis use at each beep was dichotomized into 'yes' or 'no'; future studies might attempt to collect and report information regarding the amount of cannabis ingested and route of consumption at each beep.

The items used on the scales for mania and depression were formulated specifically for use in the ESM diary in this study. They were chosen in accordance with guidelines for the selection of ESM questions [24] which highlights the need for items to be 'momentary experiences which occur in the flow of daily life'. Whilst we have limited evidence for their validity, items were reviewed by a service user panel with BD who felt they accurately described their experience when manic and depressed. A correlation matrix was computed to investigate the relationship between the positive affect, negative affect, mania and depressive scales. There was a strong correlation between the negative affect and depressive scales ($r = 0.82$). This indicates that there may have been a high degree of overlap between the scales. The correlation between the positive affect scale and mania scale was ($r = 0.58$). However during the main analyses the scales produced different results (e.g. cannabis use was significantly associated with depressive

symptoms but not with negative affect and higher levels of positive affect increase the odds of using cannabis, however higher levels of manic symptoms did not). This provided some predictive validity to support the use of separate scales: and it suggests that they were measuring different emotional states. Items from the positive and negative affect scales were considered to reflect everyday mood fluctuations as expected within the 'normal' range. The items formulated for the mania and depression scales were deemed to reflect symptoms specific to BD that would fluctuate over the course of daily life.

Cannabis is known to have an impact on cognition [45, 46] and as suggested by Henquet et al [20] this may therefore have impacted on the ability to report information accurately in the diaries. However one of the main advantages of using ESM is the short space of time between an event occurring and the recall, which reduces memory bias [25]. Additionally, a recent study [47] found cannabis use was associated with better neuro-cognitive functioning in participants with BD, particularly executive functioning.

Cannabis is rapidly metabolized in the body and the pharmacological effects can often begin within minutes after smoking [48]. Blood plasma levels of THC peak approximately 20 minutes after ingestion [49]. However traces of THC can exist in the body for several days following use. There may have been a background level of cannabis in the system for some of the regular users taking part in the study and this must be taken into account when interpreting the results. However, the consequences produced from 're-dosing' during the cannabis moments are still valid due to the almost immediate effects of cannabis use.

ESM can be a demanding methodology and requires sustained attention and motivation to fill out diary entries. This may deter some individuals, and thereby result in a selection bias. In addition, like other ESM studies [50, 51] the participant sample size was relatively small and therefore may not generalize to all individuals with co-occurring cannabis use and BD. However a large number of data points were generated as ESM data has a hierarchical structure with the repeated participant observations (level one), nested within days (level two), nested within participants (level three).

Additionally, the majority of the sample was from a white British background and had a diagnosis of BD-I. It is therefore questionable how much the findings of this study may generalise to people from different ethnic minorities or other BD groups.

Finally, Henquet et al [20] used a study sample with individuals with a clinical diagnosis of a psychotic disorder and healthy controls. Both groups were frequent cannabis users (current use of at least 3 times per week). The results from the study were different for both groups, with cannabis use associated with a decrease in negative affect and an increase in hallucinatory experiences in the clinical group alone. The inclusion of a control group (individuals without a mental health diagnosis who regularly used cannabis) in this study may have provided insight into whether the findings of the study relate exclusively to those with a diagnosis of BD, compared to a non-clinical sample.

Clinical Implications

Overall results from the present study indicate that cannabis use can cause a range of psychological effects for individuals with BD, including an exacerbation of both manic and depressive symptoms. Co-occurring BD and substance abuse is highly prevalent [6, 52] and it is associated with worsened outcomes [5, 6, 7]. However intervention research for BD and substance abuse is in its infancy [53, 54, 55, 56] and demonstrates a limited evidence base [53]. The results from this study may help to inform future interventions.

Clients often find it difficult to reduce their substance intake and the literature suggests that some individuals perceive cannabis as a useful coping strategy in the management of their BD

symptoms. However results from this study may help to counter these positive expectations of their substance use. The findings suggest that cannabis is not being used to self-medicate changes in symptoms, within the context of daily life, and in fact it may be further complicating affective states. Services and clinicians need to be aware of the potential impact of using cannabis and able to inform clients of the risks. Alongside this it may be helpful for clinicians to offer alternative strategies to help clients cope with changes in BD symptoms, which may in turn increase an individual's confidence to reduce their substance intake.

Similar to Henquet et al's findings [20], the majority of participants in this study reported that they found the ESM diary a useful and reflective tool to monitor their mood and cannabis use. Anecdotally, a number of participants reported that tracking patterns of mood and cannabis use led them to question their substance use and in some cases reduce intake. ESM could provide an invaluable therapeutic tool, particularly with clients who are ambivalent about changing their drug use habits, providing insight into unhelpful patterns of behaviour, which may contribute towards the maintenance of their difficulties.

Conclusion

The findings from the study indicate that cannabis use is associated with a subsequent change in positive affect, depressive symptoms and manic symptoms over the course of daily life. No evidence for the use of cannabis to self-medicate minor fluctuations in negative affect or BD symptoms was revealed. Participants in the study were currently well and out of episode. Future research should explore whether the self-medication hypothesis is more relevant to individuals that are in the acute stages of depression or mania. This would be consistent with the broader self-medication hypothesis in BD where individuals have reported finding cannabis useful in the management of their symptoms [13, 14, 15].

The Use of Cannabis as a Mood Stabilizer in Bipolar Disorder: Anecdotal Evidence and the Need for Clinical Research

Lester Grinspoon, M.D.* & James B. Bakalar**

Abstract—The authors present case histories indicating that a number of patients find cannabis (marihuana) useful in the treatment of their bipolar disorder. Some used it to treat mania, depression, or both. They stated that it was more effective than conventional drugs, or helped relieve the side effects of those drugs. One woman found that cannabis curbed her manic rages; she and her husband have worked to make it legally available as a medicine. Others described the use of cannabis as a supplement to lithium (allowing reduced consumption) or for relief of lithium's side effects. Another case illustrates the fact that medical cannabis users are in danger of arrest, especially when children are encouraged to inform on parents by some drug prevention programs. An analogy is drawn between the status of cannabis today and that of lithium in the early 1950s, when its effect on mania had been discovered but there were no controlled studies. In the case of cannabis, the law has made such studies almost impossible, and the only available evidence is anecdotal. The potential for cannabis as a treatment for bipolar disorder unfortunately can not be fully explored in the present social circumstances.

Keywords—bipolar, cannabis, depression, lithium, mania, marijuana

[EDITOR'S NOTE: The following article is based in part on materials that appear in the revised and expanded edition of the authors' book, *Marijuana, The Forbidden Medicine*, republished in 1997 by Yale University Press, New Haven and London. While the interviews have previously appeared in print, they provide a reference point for the authors' discussion of cannabis' potential role in the treatment of bipolar disorder as it appears in this theme issue. In their revised and expanded book, Grinspoon and Bakalar discuss a wide range of what they refer to as "Common Medical Uses" and "Less Common Medical Uses" for cannabis. The

former include treatment for the nausea and vomiting of cancer chemotherapy, glaucoma, epilepsy, the muscle spasms of multiple sclerosis, paraplegia and quadriplegia, the weight loss syndrome of AIDS, chronic pain, migraine, rheumatic diseases, pruritus, PMS, menstrual cramps and labor pains, depression and other mood disorders. The latter include treatment for asthma, insomnia, antimicrobial effects, topical anesthetic effects, antitumoral effects, dystonias, adult ADD, schizophrenia, systemic sclerosis, Chron's disease, diabetic gastroparesis, pseudotumor cerebri, tinnitus, violence, PTSD, phantom limb pain, alcoholism and other addictions, terminal illness and aging.]

In bipolar or manic-depressive disorder, major depression alternates with uncontrollable elation, or mania. Symptoms of depression include loss of interest and pleasure in life, sadness, irrational guilt, inability to concentrate,

appetite loss, lethargy, and chronic fatigue. Manic symptoms include sleeplessness, tirelessness (until exhaustion leads to a breakdown), and recklessly gregarious and expansive behavior, which sometimes turns to irritability, rage and paranoid delusions. Bipolar disorder is treated mainly with lithium salts and anticonvulsant drugs, which can have serious side effects. Thirty percent to 40% of patients with bipolar disorder are not consistently helped by or cannot tolerate standard medications. In the course of the authors' studies of the medical uses of cannabis (Grinspoon & Bakalar 1997), a number of sufferers were discovered who believed marijuana to be more effective than conventional anti-manic drugs, or who used it to relieve the side effects of lithium.

Our first account was written by a 47-year-old woman:

I was born on Friday, October 13, 1950, a few months before my father had his first serious bout with manic depression. My mother said he was taking valuable art objects they owned and throwing them down the trash chute in their New York apartment building.

I enjoyed my youth with a great deal of abandon. How much of this would be mood disorder I could not tell you. As a single person I didn't notice; I just rode the waves of emotional highs and lows and didn't think much about it. I was an old pro at this by the time I was 19 and met my husband. It was only through my association with him that I came to terms with my mood problems, although right before I met him I had checked myself in at a mental health clinic complaining that I sometimes felt unable to concentrate on one thing at a time.

I think I was 22 years old when my troubles cropped up again. At one point my husband and I went to see a psychologist. We talked about my mood swings and spells of nervousness, anger, and depression. The tiniest negative thing happening would cause long-lasting rage, very hard to quell. We told the psychologist of my father's history, even longer and grislier by then. He must have been in every state mental institution along the east coast. My grandmother, his mother, was wasting away by this time, losing her lifelong battle with chronic depression. I don't know much about her case except that she was chronically sad and starved herself to death after her husband passed away.

This man said my husband and I needed to lose weight; that was the extent of his advice. We did not see him much longer. By this time I was experiencing most of the symptoms I have today, although they have strengthened year by year. Sometimes I feel elated, exhilarated, with a great deal of energy. It sounds great, but you can get to be feeling so good that you scare the people around you, believe me! This is accompanied by light sleeping and nocturnal habits. I tend to become angry or aggressive when it is not appropriate, or just talk too loud. I often have a low self-image or feel sad. I sometimes have a hard time getting up to work, a heaviness that keeps me from moving. I get racing thoughts that make concentration hard. I have strong emotions that change rapidly. I tend to be physically clumsy. I develop unexplained skin rashes, and sometimes feel like I'm generating electricity and shooting it out my fingers and toes. My judgment is often poor.

It was in my early twenties that I first used cannabis for my condition. I had been exposed to it several times, the first

when I was quite young. My mother had taken me to a mental health center after my initial signs of trouble as a child. After a group therapy session there, some of the other kids took me riding and gave me a joint. Nothing at all happened, and I concluded it must be a mild drug.

When I was exposed to it later, I would actually choose it over alcohol because it didn't have such strong and negative effects on me. This is how I discovered that it was effective against most of my symptoms. Suppose I am in a fit of manic rage—the most destructive behavior of all. A few puffs of this herb and I can be calm. My husband and I have both noticed this; it is quite dramatic. One minute out of control in a mad rage over a meaningless detail, seemingly in need of a strait jacket, and somewhere, deep in my mind, asking myself why this is happening and why I can't get a handle on my own emotions. Then, within a few minutes, the time it takes to smoke a few pinches—why, I could even, after a round of apologies, laugh at myself!

But this herb is illegal and I have a strong desire to abide by the law. My father was having great success with a new drug, lithium carbonate. I saw my father's physician and he recommended that I try it. I took lithium for six months and experienced several adverse side effects: shaking, skin rashes, and loss of control over my speech. But I would still be taking it if it had worked for me as it did for my father. It literally restored his life. I had gotten worse, if anything.

The combination of lithium side effects and increased manic depressive symptoms drove me back to the use of cannabis. Some years later I tried to go without it again, this time because of increased social pressure against illegal drug use. It was a very difficult time for my family. Whenever I started to become manic, my husband and son would get scared and cower, triggering rage and making matters worse. When depression struck it was a black funk on our household. And I can tell you from the experience with my father that this can really destroy a family. After a while the knowledge that a little bit of marijuana would help me so much became irresistible. At first I tried eating cannabis, but soon returned to smoking because I could control the dose better.

I don't at all consider myself a drug abuser. I am doing what any rational person in my position would do. Cannabis does not cure my condition and over the years it has probably continued to worsen. But with judicious use of this medicine my life is fine. I can control things with this drug that seems so harmless compared to the others I've tried, including tranquilizers as well as lithium. I am constantly concerned that I will be cut off from my supply of marijuana or caught with it in my possession. I feel my sanity may depend on it. Cannabis lessens what is troubling me and returns me to a more normal state. Often I do not experience a "high" at all, just a return to normal.

This patient's husband bears witness to the usefulness of cannabis:

I've been mates with my full-blown manic-depressive (M-D) wife for 26 years. Her father was the classic, well-studied and well-written-about manic-depressive, and she's the one who inherited it. She's lovely, and as I've always truthfully told her, she has the perfect personality, blemished only by M-D.

I've always been smooth-sailing. Smoking marijuana only makes me sleepy. I never use it. She requires it, or, I

swear she'd be institutionalized just like her father. There wouldn't be any other way.

We've tried Marinol (dronabinol). It works for her too, but to get the same effect as marihuana she must take 10 mg about six times a day, which costs about \$65 a day. What's worse is that it takes forty-five minutes to engage and tapers off within two hours maximum. Timing of capsule ingestion must be exact or the symptoms can print through. Marihuana [smoked] lasts a little longer and is smoother, and, most importantly takes effect quickly.

What does marihuana do for my wife? It "recenters" her personality and her interaction with the immediate family moves back into a normal range—no highs, no lows, at least not the highs and lows that are abnormally extreme and that you can tell are from a crazy person with active M-D. Narcoleptic drugs really "zone" her out, like a temporary lobotomy in a medicine bottle. Marihuana never does that! It normalizes, that's all. If there's an overdose, which is rare, it's not dangerous and is very short.

Yesterday we went downtown (one and a half hour's drive one way). However, going several hours without the medicine can be quite calamitous. The worst kind of getting along badly ensued. That's the exact nature of M-D. You tear at your mate with unfounded suspicions, accusations, insane bitterness—enough to make you hate each other. It makes no sense. That's why it's crazy behavior. If you're lucky, like my wife, your mate understands and gets you home right away to have a smoke. It used to be that you could take trips, but the police have cracked down so hard that you don't dare smoke a joint in the car.

I can bear witness to the probability of a near normal life situation for a manic-depressive if they've got good marihuana, a lifestyle that allows one to be home nearly always, and an understanding partner.

Here is the account of another woman with bipolar disorder who finds cannabis more useful than conventional medications:

I am a 35-year-old woman with severe manic depression. When I was growing up I was hypersensitive, cried all the time, and fought with my brothers and sister. My parents always said they had to handle me with kid gloves. I had more energy than most and used it to the hilt. I was an agile gymnast and one of the fastest swimmers in my school. I was also at the top of my class in algebra and good at art and creative writing. I used to stay awake at night and dream up stories.

Around age 14 my mood swings began to get more intense. I was agitated, restless, and constantly fighting at home. I lay awake at night and lost a lot of weight. Eventually I snapped and was sent to a mental hospital, where I was diagnosed as having manic-depressive disorder. They put me on lithium and told me I would have to take it the rest of my life. But lithium made me lethargic. I had trouble communicating and lost all my animation and creativity. Eventually I quit taking it. Recently I have also tried Tegretol [carbamazepine] and Depakote [valproic acid], neither of which helped. Tegretol started a manic episode, and Depakote had some very bad side effects. I'd like to find something else, but I don't have health insurance or the money to spend trying out new medications.

Since the age of 14 I have had manic episodes regularly about once every six months. It would always start with

not being able to sleep or eat. After two weeks I would just break down and seem to trip out into another world. Usually I ended up in a mental hospital.

I smoked marihuana for the first time in high school and couldn't believe how good it made me feel. My normally chaotic emotions subsided and I had a sudden sense of calm, peace, and well-being. My perceptions of others and life changed dramatically. The world no longer seemed hostile but more within my control. I could sleep easily and actually had cravings for food. There were practically no side effects. When I had enough marihuana I would just naturally stop, because once you've gotten a certain effect you really don't want any more.

Only another manic-depressive using marihuana could possibly know how much this has changed the quality of my life. Although they don't know it, my family actually likes me better when I'm stoned than when I'm taking lithium or not taking anything. When I'm stoned they can predict my moods and actually get close to me. But I can't tell my family or the doctors because it's illegal. I have to live a double life to get along.

I've often tried to quit marihuana, but I have a manic episode every time. Last year I decided I could control my emotional ups and downs without marihuana, but it led to one of the worst episodes I've ever experienced. I had been having trouble sleeping as usual. I began to get super clear vision that a disastrous earthquake was going to hit Los Angeles. I was feeling so good I was sure I was right. Soon I had my roommate convinced that we didn't have much time and would have to buy as many supplies as possible and then leave. We thought that after the quake the New World Order would be implemented and everyone would have to take the number that Revelations talks about in the Bible. We planned to go to El Salvador, where her family lives, and hide out for the next three and a half years. Crazy! But I really believed it. I maxed out all my credit cards, quit my job, and packed up all my things, including disguises I thought we were going to need. Eventually I had to return home with no job and major bills.

I knew then and there that I would have to go back on marihuana. It's been seven months now since I resumed smoking marihuana, and I don't know what else to do. I have to choose between obeying the law and staying sick or breaking the law and being well.

J.P. is a 45-year-old health professional and the mother of a 20-year-old son:

In late 1994 and early 1995 my son Michael, age 18, began to go out of control. He was unable to sleep, attend school, or function in a normal fashion. He was running around non-stop, acting on impulse without any sense of normal judgment. He was in serious danger of accidentally harming himself or others. There was no way to reason with him, because he was unable to think or listen long enough to understand what you were trying to say. He had become a human time-bomb.

Then, on February 14, 1995, he had a full-blown psychotic manic episode and refused treatment. I had to petition a court to commit him to a psychiatric hospital in Portland, Maine, where he was given a diagnosis of manic-depressive disorder. Both Michael's father and my grandmother suffered from the same disorder, which is now called bipolar disorder.

During his nine days in the hospital (the time allotted by my insurance company) Michael was given lithium and Trilafon [perphenazine]. We were told that he would need lithium for the rest of his life. They explained that it worked very well in 60% of people with this disorder.

We returned home, and for the first month or two, the mania seemed to have ended. At the end of the second month the Trilafon was discontinued, but Michael was still taking a high dose of lithium. At that point he developed a rash on his neck and chest; he also had dark circles under his eyes, and he was incoherent most of the time. The lithium level in his blood was exactly where the doctor wanted it, but now he was acting like an Alzheimer's patient. He couldn't read or comprehend a paragraph, let alone finish school. He was detached from his surroundings and himself. There was no emotional content left in him. He was becoming unrecognizable. He had always been very much like [comedian] Robin Williams in personality and extremely athletic—a skier, football player, and weight lifter. It was heartbreaking to watch him lose himself in a medicated stupor. I became convinced that lithium did not eliminate the disease but instead was drowning his brain so the symptoms could not be activated. I could still see tiny mood swings and moments of complete restlessness, but in a body that was unable to become hypomanic.

Michael decided to cut his lithium in half. I knew this would be dangerous but I agreed that something had to be done. Soon he was more himself, laughing and talking and almost back among the living. Then he started to become more hypomanic, and I knew we were headed for trouble. He was back to the energy level of someone on high doses of speed, and this lasted for months. He was running through life like a high-bred stallion, while I was gathering everything ever written on manic-depressive disorder.

Then one day he came home and was perfectly normal in every respect. I thought that maybe he was in remission because the disease is known to do that, and I was thrilled at the possibility. Later that night he was back to full speed ahead, and all hope sank within me. This continued as the weeks passed. There would be times when he was perfectly normal, but only for short intervals. I could not figure it out. I started to chart his sleep pattern, his food intake, the kinds of foods, what chemicals he was subjecting himself to, and so on. Finally one day I discovered that he was smoking pot. Of course I freaked out. We talked about it at length and he told me point blank, "I only feel normal when I smoke a joint." By this time I was ready to blame the disease on his pot smoking. I was totally irrational about this. Michael and I fought constantly for a month about it. Finally he asked me to research cannabis and let him know what I found. I figured I would be able to find enough damaging information to put the subject to rest. The next week was my week of discovery. Not only could I not find what I was looking for, but I became convinced that there was no permanent damage, and that cannabis was actually helpful for people with mood disorders.

I went on-line on the computer to talk to other people suffering from bipolar disorder, and I was overwhelmed by first-person stories of the benefits that others had found.

The hardest part of this entire thing was rearranging my value system. I was raised to be a law-abiding citizen. Although I grew up in the sixties and had tried pot and inhaled, I was never a regular user because it was illegal. I raised Mike right. He was taught to respect elders, do what you are supposed to do, and above all follow the law.

It is hard enough to live with an 18 year old during a naturally rebellious time, but to be forced to participate in an illegal activity is the absolute worst scenario. But that is exactly what I'm doing. Mike has been smoking pot for two months now. He does not smoke daily, but when the mania begins he smokes and within five minutes he is fine. He never appears to be "high," just happy and relaxed. We don't have to deal with mood swings anymore. He can work on his home-schooling program, and I don't doubt that he will finish by the end of summer. He has been repairing lobster traps with a friend and will be lobstering six days a week by the end of April.

At this point I expect to be arrested some day, because if Mike gets arrested, they will have to take me right along with him. I plan to grow a plant this summer for his use. I know I could end up in jail, but I also know that without some kind of medication that works, my son could end up in jail, institutionalized, or dead. What choice do I have?

Another account of cannabis use by a person with bipolar disorder emphasizes the reduction of lithium side effects:

I am 29 years old, born and raised in North Carolina. My academic background is in English literature, computer science, and law; I now work as a technology consultant and writer, although I am contemplating returning to graduate school. I am divorced. I am reasonably active in my community, though work takes much of my time these days.

I was first diagnosed with bipolar disorder about five years ago, when I was in law school (a psychiatrist also tentatively ventured this diagnosis during my undergraduate years), but I suspect that I have had a mood disorder for most of my life. I was certainly clinically depressed as early as age nine, and my first hypomanic episode occurred at 17. There is also a family history of mood disorders, especially on my mother's side. All three of her brothers had "mercurial" personalities, and they all experienced tremendous successes and notable failures in business. Their extravagance and outgoing personalities resemble my behavior while manic or hypomanic. Although none of them was formally diagnosed with a mood disorder, both my parents have been treated for clinical depression.

Before I was diagnosed and found the right treatment, I had the typical symptoms of bipolar disorder. During depressive phases I became withdrawn, uncommunicative, and preoccupied with suicide. I found it nearly impossible to function in school or at work. During hypomanic or manic phases I spent freely, traveled all over the country (and world), made poor personal and business decisions, engaged in risky sexual behavior, and so forth. The illness has caused me a great deal of personal pain as well as financial woes. I separated from my wife (who eventually divorced me) the summer before I was diagnosed. I've lost jobs, ruined friendships, and alienated members of my family. Fortunately, much of this damage has been repaired with time and understanding. I thank God that my ruined credit rating is the only apparent lasting harm.

Thanks to lithium and sensible therapy, including the judicious use of cannabis, I have been relatively stable and sane for the past three years, although my sleep is often disturbed and I still have (very much milder) hypomania and depression in much the same cyclic pattern as before.

I first used cannabis in my freshman year of college (1984). I preferred it to alcohol as an intoxicant, and used it a few times a week, almost always by smoking (I still prefer to take it that way). In retrospect, it seems clear to me that I was medicating myself for bipolar disorder even then. When depressed and anxious, I found that cannabis was soothing and enhanced my ability to enjoy life. When I was in a manic phase, it relaxed me and helped me get to sleep. I often felt as though I had so much energy inside me that I would jump out of my skin; the cannabis helped tremendously with that. But there was a downside. Manics have a big problem with impulse control, and cannabis seemed to exacerbate it. ("Drive to Canada? Great idea. Let's go!") It also ratcheted up my already overactive libido a notch or two, which wasn't the healthiest thing in the world.

When I was diagnosed and began treatment with lithium, I got almost immediate relief, but I also suffered from nausea, pounding headaches, hand tremors, and excess production of saliva. A friend suggested that I try getting high, reasoning that if cannabis helped chemotherapy patients deal with their nausea and discomfort, it might help me too. My doctor thought the idea was absurd but admitted that it would be safe to take cannabis together with lithium. So I tried it, and the results were remarkable. The hand tremors subsided, the headaches vanished, and the saliva factory resumed normal production levels. All I needed was one or two puffs on a marihuana cigarette. When lithium side effects get bad, the availability of cannabis has been an absolute godsend. It is also nice to be able to use cannabis as an intoxicant, knowing that, unlike the combination of lithium and alcohol, it cannot damage my kidneys.

Every one of the many thousands of Americans who use marihuana as a medicine runs a risk of being arrested. They have to worry about financial ruin, the loss of their careers, and forfeiture of their automobiles and homes. Some have an additional burden because mandatory school drug programs and Parents for a Drug-Free America advertisements have given their children an exaggerated idea of the dangers of using marihuana. Many of these children become concerned about the health and well-being of their marihuana-using parents. A few of those parents have been arrested because their worried children informed on them to the police officers who serve as instructors in the popular school drug program known as Drug Abuse Resistance Education (DARE).

The following accounts are by a 40-year-old software engineer and his 37-year-old wife, who suffers from bipolar disorder. He speaks first:

My wife and I and our two boys live in Tyngsboro, Massachusetts. My wife was given a diagnosis of bipolar disorder in 1982 and has been taking lithium since 1992. She also uses marihuana for her symptoms. She has had six psychiatrists in the past 14 years and has been interviewed by many more. I have always told them that she uses marihuana regularly, and not one of them has told her to stop. They do not even seem to care or pay attention.

I posted a question about this to the alt.support.depression.manic newsgroup on the Internet. I asked whether doctors knew something about marihuana but could

not recommend it because of its illegality. The responses were varied, but most people who were manic-depressive said marihuana helped them, and one said that some doctors considered it effective in controlling mood disorders.

My wife functions much better when she uses marihuana. When she is hypomanic, it relaxes her, helps her sleep, and slows her speech down. When she is depressed and would otherwise lie in bed all day, the marihuana makes her more active. When she runs out of marihuana and can't get more, she becomes more irritable and hard to live with. Lithium is also effective, but it doesn't always keep her in control.

Our dilemma is that our 13 year old has been through the DARE program and has learned about the evils of drugs and alcohol. He opposes all substance use, legal or illegal—and I want it that way. But he knows that my wife uses marihuana and it "eats" at him, although he also knows about her illness and how marihuana helps. Understandably, all this confuses him.

I believe that marihuana could help some people if it were made available as a prescription medicine. Certainly there are other health and social issues involved, and I can't decide what would be right for the country as a whole. All I know is that in this family it has relieved us all of much suffering.

Now his wife:

I am 37, and I have been using marihuana for 20 years. I was diagnosed bipolar in 1982. I take lithium and Wellbutrin [bupropion], although I dislike these drugs. I've gained about 40 pounds since I started taking lithium, but otherwise there are no side effects.

My 13-year-old son knows about my illness. He has also known about my marihuana smoking for about five years. He realized what I was doing after he participated in the DARE program in school. It bothers me when he comes home and says they talked about drugs and he was thinking that his mother is "one of them." He doesn't want anyone to know his mother is a "druggie," and until now we've kept it as our secret. I don't think he would tell anyone, but I'm still afraid something might get out. Sometimes these programs use tricks to get kids to inform on their friends and relatives. They say, "If you really care about this person, the only way you can help them is to report them." My husband has talked to him about it. He has explained that lithium and the other medications I'm taking are drugs. He also explained that many legal drugs are far more dangerous than marihuana and that no one has ever died from using marihuana. But my son insists that if it is illegal, then it is wrong. This bothers me so much that I have considered stopping.

The trouble is that at times when I feel tired and run-down, just a couple puffs of marihuana bring me back to life. Sometimes I think it brings me to a level of normalcy that everyone else achieves naturally. At other times, when everything seems to be going like a whirlwind around me and I can't keep track of what I'm thinking about or saying or feeling, the marihuana just seems to slow the world down a bit. When I have trouble sleeping, it helps zonk me out, but if I have trouble waking up it brings me to life. I don't like being thought of as a "drug-abusing mother," but I actually think I'm a better mom when I'm feeling in control because of marihuana.

In some ways cannabis today is in a position analogous to that of lithium in 1949, when J. F. J. Cade, after observing its sedative effect on guinea pigs, administered it to patients suffering from "chronic and recurrent mania." His seminal paper, "Lithium Salts in the Treatment of Psychotic Excitement," presented ten one-paragraph case histories, and this compelling anecdotal evidence attracted the attention of psychiatrists around the world because there was no adequate treatment for bipolar disorder. In his paper Cade (1949) mentioned the need for "controlled observation[s] of a sufficient number of treated and untreated patients." In 1951, Noack and Trautner followed up by reporting on the treatment of another 30 patients with "mania alone." But they pointed out that not all patients improved, that many discontinued the treatment, and that "it does not appear to be justified to accept the lithium treatment of mania as invariably safe." (Noack & Trautner 1951).

In 1954, Schou and colleagues published a controlled study in which they alternated lithium and a placebo at two-week intervals. Lithium was clearly beneficial for 12 patients; 15 showed improvement that was "not as clear-cut," and three did not improve at all. Schou and his colleagues found it "rather astonishing that [lithium's success] has failed to arouse greater general interest among psychiatrists." One explanation they offered was its low therapeutic ratio. Another explanation was "the difficulties encountered in attempts to convey to others in a quantitative manner . . . the effect of a new psychiatric therapy," i.e. to move beyond anecdotal data to controlled studies (Schou et al. 1954). But there was an even more compelling reason for the delay in lithium's acceptance in the United States. In this country, drugs are introduced by pharmaceutical companies which invest in the studies necessary for official acceptance. They do this because they receive a patent (in the 1950s, for 17 years) on the new drug which allows them to recoup their investment. Lithium salts, of course, could not be patented.

Similar obstacles face the medical use of cannabis today. Lithium had a reputation for toxicity that grew out of its use as a salt substitute for cardiac patients in the 1940s. There were a number of deaths before its dangers were fully appreciated, and today blood levels are carefully monitored. Because of its nonmedical use, cannabis also has a reputation for toxicity, in this case undeserved. Lithium was unpatentable, and so is cannabis. Finally, like the evidence for lithium in 1949, the evidence for the therapeutic value of cannabis in bipolar disorder today is anecdotal. Although it has been repeatedly considered as a treatment for affective disorders in the Western medical literature since 1845, when Jacques-Joseph Moreau de Tours (1857) recommended it for melancholia, there is little in the medical literature on the use of cannabis as a mood stabilizer (see Parker & Wrigley 1950; Pond 1948; Stockings 1947).

Today drugs must undergo rigorous, expensive, and time-consuming tests to win approval by the Food and Drug

Administration (FDA) for marketing as medicines. The purpose of the testing is to protect the consumer by establishing both safety and efficacy. First the drug's safety (or rather limited toxicity) is established through animal and then human experiments. Next, double-blind controlled studies are conducted to determine whether the drug has more than a placebo effect and is at least as useful as an available drug. As the difference between drug and placebo may be small, large numbers of patients are often needed in these studies for a statistically significant effect. Because no drug is completely safe (nontoxic) or always efficacious, a drug approved by the FDA has presumably satisfied a risk-benefit analysis. When physicians prescribe for individual patients they conduct an informal analysis of a similar kind, taking into account not just the drug's overall safety and efficacy but its risks and benefits for a given patient and a given condition. The formal drug approval procedures help to provide physicians with the information they need to make this analysis.

But devotion to formal procedures may have caused us to undervalue anecdotal evidence. Regulators today are willing to accept the experience of physicians and patients as evidence of adverse effects but not as evidence of therapeutic effects (Lasagna 1985). Yet case histories and clinical experience are the source of much of our knowledge of synthetic medicines as well as plant derivatives. Controlled experiments were not needed to recognize the therapeutic potential of chloral hydrate, barbiturates, aspirin, curare, insulin, or penicillin. More recently, the uses of propranolol for angina and hypertension, diazepam for status epilepticus, and imipramine for childhood enuresis were discovered in the same way, although these drugs were originally approved by regulators for other purposes.

A related source of evidence is the experimental method known as the "N of 1" clinical trial or single-patient randomized trial. This is the kind of experiment used by Schou and his colleagues (1954), in which active and placebo treatments are administered in alternation or succession to a patient. The method is often used when large-scale controlled studies are impossible or inappropriate because the disorder is rare, the patient is atypical, or the response to treatment is idiosyncratic. Several patients the authors have encountered carried out somewhat similar experiments on themselves. They alternated periods of cannabis use with periods of no use and discovered that cannabis was effective.

The familiar deficiency of anecdotal evidence is the risk of counting successes and ignoring failures. If many people suffering from clinical depression take, say, St. John's Wort after unsuccessful treatment with conventional antidepressants and a few recover, those few stand out and come to attention. Bipolar disorder is a cyclical condition, so it is essential to avoid confusing natural remission with drug-induced improvement. At present we do not know how many patients with bipolar disorder would benefit

from cannabis. The promising anecdotal evidence points to the need for more systematic clinical investigation, just as it did 50 years ago in the case of lithium.

Thousands of years of widespread use as well as recent research designed to discover toxic effects have made it clear that cannabis is an unusually safe drug. In fact, its long-term safety is better established than that of St. John's Wort. Yet unlike St. John's Wort, cannabis would be subject to government regulations that demand further time-consuming and unnecessary safety tests. The classi-

fication of cannabis as a Schedule I drug creates further obstacles to clinical research. But given the disinterest of pharmaceutical companies, there is no immediate prospect of such studies being funded even if the political obstacles are removed. We are left with the tantalizing possibility that cannabis (or one or more of its constituent cannabinoids) is useful in the treatment of bipolar disorder and the sad knowledge that in the present circumstances little can be done to explore that potential.

Abstract

Marijuana is the most widely used illicit substance in those diagnosed with bipolar I disorder. However, there is conflicting evidence as to whether marijuana may alleviate or exacerbate mood symptomatology. **As bipolar disorder and marijuana use are individually associated with cognitive impairment, it also remains unclear whether there is an additive effect on cognition when bipolar patients use marijuana.** The current study aimed to determine the impact of marijuana on mood in bipolar patients and to examine whether marijuana confers an additional negative impact on cognitive function. Twelve patients with bipolar disorder who smoke marijuana (MJBP), 18 bipolar patients who do not smoke (BP), 23 marijuana smokers without other Axis 1 pathology (MJ), and 21 healthy controls (HC) completed a neuropsychological battery. Further, using ecological momentary assessment, participants rated their mood three times daily as well as after each instance of marijuana use over a four-week period. Results revealed that although the MJ, BP, and MJBP groups each exhibited some degree of cognitive impairment relative to HCs, no significant differences between the BP and MJBP groups were apparent, providing no evidence of an additive negative impact of BPD and MJ use on cognition. Additionally, ecological momentary assessment analyses indicated alleviation of mood symptoms in the MJBP group after marijuana use; MJBP participants experienced a substantial decrease in a composite measure of mood symptoms. Findings suggest that for some bipolar patients, marijuana may result in partial alleviation of clinical symptoms. Moreover, this improvement is not at the expense of additional cognitive impairment.

Competing Interests: The authors have declared that no competing interests exist.

Introduction

Bipolar disorder (BPD), considered one of the most debilitating mood disorders, is the sixth leading cause of disability in the world according to the World Health Organization. In those affected, BPD is often a significant source of distress and burden on relatives and caregivers [1]. Further, among Axis I pathologies, BPD carries the highest risk of substance use comorbidity, which can complicate the course of illness and impact treatment outcomes. In fact, patients with co-occurring BPD and substance use often experience poor treatment response, relapse of mood symptoms, psychosocial difficulties, and reduced treatment compliance [2–4]. Despite evidence that suggests substance use is linked to poorer outcomes, some studies have also shown that BPD patients engage in substance use to improve clinical symptoms. Bolton and colleagues [5] found that almost a quarter of those with mood disorders used alcohol or drugs to relieve symptoms, with the highest rates of self-medication seen in bipolar I disorder. In another study, the authors found that specifically amongst BPD patients who use substances, 79% engaged in drug use *specifically* to improve mood symptoms [6].

Marijuana (MJ) is the most commonly used illicit substance in the US; this statistic also holds true among those diagnosed with BPD [7]. Moreover, rates of MJ use disorders in BPD patients have been found to equal or exceed those of alcohol abuse or dependence, particularly in younger patients [8]. Research has also shown that 20–50% of patients report some form of MJ-related problems [9]. In those who endorse MJ-related problems, 63.7% reported disability, as compared to only 44.5% of those not meeting criteria for MJ use disorders, supporting previous findings that patients with BPD who engage in MJ use exhibit reduced compliance, higher levels of illness severity, and increased likelihood to attempt suicide [4, 7–8, 10–12].

While these studies appear to suggest that MJ use *results* in negative outcomes, a specific cause-and-effect relationship has yet to be determined. Although many studies have reported that MJ use precedes the onset of BPD [13–16], it remains unclear whether MJ use contributes to the pathogenesis of the disorder, or if it is used to address symptomatology, perhaps as a form of premorbid self-medication [17–19], especially if traditional pharmacotherapeutic regimens are ineffective at symptom alleviation. Others have also reported that individuals with higher levels of illness severity may be at risk for MJ use *after* the onset of the disorder [20]. Further research is needed to clarify the relationship between MJ use and the manifestation of BPD symptoms. Despite claims of negative outcomes associated with MJ use, whether patients' view MJ use as successful in symptom improvement is rarely assessed. In a single study of BPD patients, Weiss et al. [21] reported that nearly all patients initiated substance use as the *result* of one bipolar symptom, and the majority of patients reported improvement that was attributable to substance use for at least one symptom. Further, in a review of anecdotal reports of MJ use among BPD patients, the authors concluded that MJ was not utilized for the “high” sought out by recreational users, which may suggest that the effects of MJ are unique in sub-euphoric doses [22]. Regardless of the motive for use, the fact remains that MJ use is common in patients with BPD. As noted above, patients with BPD who use MJ have been shown to have higher illness severity and poorer outcome, yet report subjective improvement in symptoms after using MJ, suggestive of a complex relationship between MJ and mood [23]. Taken together, these data provide evidence that some patients with BPD may derive a clinical benefit from using MJ and highlight the importance of understanding the effects of MJ on mood symptomatology in those diagnosed with affective disorders.

Ecological Momentary Assessment (EMA), utilized in the current study, allows for the investigation of real-time assessment of mood and related symptoms as well as repeated collection of real-time data in participants' natural environment [24–25]. While most symptom assessments and diagnostic tools in both research and clinical settings rely on retrospective

recall of emotions and symptomatology using interviews and self-report questionnaires, EMA data is collected in naturalistic, real-world contexts and therefore offers improved ecological validity over traditional, retrospective methods. In fact, retrospective reports of mood have been shown to have a bias towards negative mood states such as anxiety, depression, and helplessness [26]. Collecting data in real-time with EMA reduces error bias from retrospective assessment and limits the effects of recall bias and generalization of symptoms over a period of time (Shiffman et al., 2008). Additionally, in a review article assessing the contribution of EMA on psychopathology research, Myin-Germeys and colleagues [27] suggest that symptoms in psychiatric disorders are dynamic and can meaningfully fluctuate through the course of the day. Thus, the increased ecological validity of EMA tools can provide better insight into the phenomenology and etiology of psychopathology than retrospective techniques. Better understanding of the development, maintenance, and progression of symptoms may lead to improved models of these disorders and help inform future treatment strategies [27].

Given a growing body of research indicating cognitive deficits associated with MJ use, it is also important to explore the impact of MJ across various cognitive domains. Interestingly, MJ users (without Axis I pathology) and BPD patients (who do not necessarily smoke MJ) have been shown to exhibit similar cognitive deficits. MJ use has been linked to impairments across a wide range of areas, including attention [28], memory [29–31], IQ [32–34], and executive function [35–37]. Similarly, BPD patients often evidence cognitive deficits across multiple overlapping domains; in two meta-analyses of euthymic BPD patients [38–39], the authors note marked impairment relative to healthy controls on measures of executive function, verbal memory, and attention. Despite the fact that MJ use and a diagnosis of BPD are both individually related to cognitive deficits, two studies examining neurocognitive function in MJ-smoking patients with BPD report surprising outcomes. Both Ringen et al. [40] and Braga, Burdick, DeRosse, and Malhotra [41] reported a *positive* association between neuropsychological functioning and MJ use in BPD patients, perhaps suggestive of a unique relationship between BPD and MJ use. Specifically, Ringen and colleagues [40] examined a variety of cognitive domains, including psychomotor speed, attention, working memory, executive functioning, and verbal learning. Overall, BPD patients who used MJ demonstrated better performance than patients who did *not* use MJ, although statistically significant results were only observed on tests of executive function. Similarly, Braga et al. [41] reported neurocognitive advantages in MJ-smoking BPD patients, relative to a non-smoking BPD group, spanning several domains, including executive function (Trails B) as well as attention and working memory. These results suggest that despite a more severe clinical course, BPD patients who use MJ may demonstrate a cognitive advantage relative to patients without a history of MJ use, underscoring the need for additional investigation.

Through EMA and a comprehensive neuropsychological battery, the current study aimed to clarify the relationship between acute MJ use and mood symptoms as well as cognitive function in patients with BPD. In order to accurately assess the impact of MJ use, BPD diagnosis, and the additive effects of both MJ use and BPD, we utilized a four-group study design enrolling healthy control subjects without MJ use or Axis I disorders (HC), MJ smokers without other Axis I disorders (MJ), individuals diagnosed with BPD without a history of MJ use (BP), and those diagnosed with BPD who currently used MJ (MJBP). We expected, in line with previous research, that the BP and MJBP groups would have more severely affected mood overall relative to the HC group. However, we further hypothesized that the MJBP group would experience significant mood improvement secondary to MJ use. In addition, although previous studies have shown that MJ use is related to cognitive deficits, there is a relative paucity of literature focused on the association between MJ use and cognitive function in patients with BPD. Therefore, the current study also aimed to determine whether MJ use has a differential effect

on cognitive performance in pure MJ smokers, BPD patients who smoke MJ (MJBP), and BPD patients who do not use MJ (BP).

Materials and Methods

Prior to participation, study procedures were thoroughly explained. All participants were also required to read and sign an informed consent form, a document that describes the procedures, risks, benefits, and voluntary nature of the study. This study and all study procedures were approved by the McLean Hospital Institutional Review Board.

Participants

As part of a larger study conducted between 2008 and 2014, 21 healthy control subjects (HC), 23 MJ smokers without other Axis 1 pathology (MJ), 18 individuals with bipolar I disorder who do not smoke MJ (BP), and 12 individuals diagnosed with bipolar I disorder who smoke MJ (MJBP), were enrolled and completed neuropsychological assessments. A subset of these participants also completed daily EMA assessments over the course of four weeks to assess mood.

Participants were not enrolled in the current study if they met criteria for any *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) Axis I pathology (with the exception of bipolar I disorder in the BPD groups, and MJ abuse/dependence in the MJ-smoking groups), as assessed by the Structured Clinical Interview for DSM-IV, Patient Edition (SCID-P) [42]. Individuals were also excluded if they reported a neurological disorder or significant medical problems, significant head injury with loss of consciousness, or were non-native English speakers (as necessitated by the cognitive assessment battery). Further, no participant was enrolled if they reported more than 15 lifetime uses of any illicit drugs (except MJ for the smoking groups) or recreational use of prescription or over-the-counter (OTC) medications, or had received electroconvulsive therapy.

Subjects enrolled in the MJ and MJBP groups were all well-characterized as chronic MJ smokers who reported smoking a minimum of 2,500 times in their lives, used MJ at least four out of the last seven days and tested positive for urinary cannabinoids. In order to ensure that cognitive test results were not affected by acute intoxication, all participants were also required to abstain from MJ use for at least twelve hours prior to study visits. Upon arrival, all individuals were required to provide a urine sample and, to ensure adherence to the twelve-hour abstinence requirement, were led to believe that this sample could be used to detect use within this time frame. This method has previously been used by our laboratory with success [36, 43–44]. Subjects were assessed for most recent use and any who violated the abstinence schedule or who appeared even vaguely intoxicated were rescheduled for a later date. An aliquot of the urine sample was sent to an outside laboratory for quantification of urinary cannabinoid concentration via gas chromatography–mass spectrometry during the initial and final study visit. Urinary THC levels were averaged across the two study visits.

Study Design and Measures

After completing diagnostic assessments, subjects who met inclusion criteria were enrolled in the four-week study, which contained a baseline visit and four weekly check-in visits. This study employed a combination Time-Based EMA design and Event-Based Monitoring [24–25]. The Time-Based EMA employed an alarm schedule, which alerted participants to complete three rating sessions per day. Each subject pre-selected three times throughout the day (at least five hours apart), which were tailored to his/her typical daily schedules, to rate their mood. In Event-Based Monitoring, EMA measures are triggered by the occurrence of a specific

event. For this study, participants were instructed to complete rating scales as soon as possible after MJ use in order to assess the acute impact of MJ on mood.

At the end of their initial screening study visit, all enrolled participants were issued a Palm Pilot (Palm Tungsten T5 PalmOne PDA) and instructed to use the device to rate their mood three times daily over the course of the four-week study. All individuals rated their mood using a custom-designed application, which contained electronic versions of several clinical rating scales: the Profile of Mood States (POMS) [45], which yields subscores for vigor, anger, confusion, tension, fatigue, depression, and a composite score for total mood disturbance (TMD); the Hamilton Anxiety Rating Scale (HAM-A) [46]; Montgomery-Asberg Depression Rating Scale (MADRS) [47]; and the Young Mania Rating Scale (YMRS) [48]. Participants who smoked MJ were also asked to use the device to record episodes of MJ use to allow for the calculation of pre- and post-MJ use mood changes. More specifically, for each episode of MJ use, participants recorded the amount (in grams), frequency, and mode of MJ use (bong, bowl, joint, etc.). Date and time were automatically recorded at the completion of each scale in order to assist with accurate pre- and post-smoking determinations. However, participants were also given the option to adjust the time of last MJ use when completing post-use ratings. Only ratings identified as being completed within four hours of MJ use were categorized as post-MJ use and used for analysis. To ensure that participants were not arbitrarily answering clinical rating questions, “quality control” questions were interspersed throughout the scales, with such questions such as “who is the current US president?” and “how thoughtfully are you answering these questions?”

In order to establish an estimate of overall intellectual functioning, participants completed the Wechsler Abbreviated Scale of Intelligence (WASI) [49]. In addition, all individuals enrolled also completed a neuropsychological battery designed to assay a variety of cognitive domains. Neuropsychological assessments were typically completed by the end of the first check-in visit, and consisted of a number of measures including the Wisconsin Card Sorting Test (WCST), Trail Making Test, Stroop Color Word Test, the Controlled Oral Word Association Test (COWAT), and Digit Span, which served as direct measures of executive function. The WCST assesses the ability to form abstract concepts, shift and maintain set, and utilize feedback, and is considered a gold-standard measure of executive function [50–51]. The Trail Making Test is comprised of two parts; while Trails A measures visual scanning and psychomotor speed, Trails B serves as a measure of cognitive set-shifting and attention [51]. The Stroop measures the ability to establish competing response tendencies, inhibit inappropriate responses, and resist interference [52]. The COWAT consists of two parts and serves as a measure of phonemic verbal fluency and executive function (participants must generate words starting with the specific letters F, A, and S) as well as verbal memory function (participants are required to generate words from a specific semantic category, in this case “Animals”) [53–54]. The Digit Span subtest from the Wechsler Adult Intelligence Scale—Revised (WAIS-R), requires subjects to recall increasingly longer strings of numbers in forward and then backward order, and reflects attention, working memory and executive functioning [55–56].

Study participants also completed additional cognitive measures, including the California Verbal Learning Test (CVLT), Rey-Osterrieth Complex Figure Test (ROCF), and Hooper Visual Organization Test (HVOT). The CVLT-II requires subjects to learn an orally presented list of words across five trials to assess verbal learning [57]. Errors and clustering strategies (i.e., grouping list items by category) are also documented to assess efficiency of learning. Further, the CVLT incorporates a delay trial, in which individuals are required to remember the list of words after a 20-minute delay in order to assess verbal memory. The ROCF assesses visual-spatial organization as well as visual memory and requires individuals to copy a complex figure and then draw it from memory both immediately and after a twenty-minute delay [51]. Finally,

the HVOT, a measure of visuoperception, requires participants to name objects in drawings that have been “cut” into pieces [58].

In addition, study participants completed the Fagerström Test for Nicotine Dependence (FTND) [59] in order to assess current level of nicotine use and level of dependence. The Addiction Severity Index (ASI) [60] was administered to calculate days of alcohol use within the past month. In order to assess average frequency and magnitude of MJ use, a modified timeline follow-back procedure [61] was utilized at weekly study visits, with a specific focus on the past week of use. Participants were asked to report the number of times they smoked MJ, the amount of MJ used (in grams) and the mode of use each time (i.e., joint, blunt, bong, etc.). Lifetime use was also assessed using the SCID-P and guided substance use interviews.

Statistical Analyses

In order to ensure that groups were well-matched, one-way analyses of variance (ANOVAs) with Scheffé all pairwise post hoc comparisons (two-tailed) were used to compare the four groups on all continuous demographic variables: age, IQ, ASI alcohol use (days/month), and FTND. As analyses identified age as a potential confounding variable, analyses of covariance (ANCOVAs) controlling for age were performed for all comparisons in which age was significantly different between the groups. In addition, chi-squared analyses were used to compare the sex frequencies between the four groups and to compare medication in the BP and MJBP groups. One-way ANOVAs (two-tailed) were conducted to compare age of BP onset in the BP and MJ BP groups, as well as MJ use variables in the MJ and MJBP groups, including age of MJ onset (defined as first *regular* use: a measurable, consistent pattern of use that occurred at least monthly); frequency of MJ use (average number of smoking episodes per week); magnitude of MJ use (average amount, in grams, used each week); duration of use (number of years since onset of regular MJ use); and urinary THC concentration (ng/mL).

EMA analyses

Average mood scores over the entire four-week EMA data collection period were calculated for all clinical rating scales for each individual. Additionally, for MJ-smoking participants (MJ & MJBP groups), clinical rating scales were coded to indicate whether each rating was collected before (pre) or after (post) MJ use and, with this information, “average pre-MJ use” and “average post-MJ use” ratings scales were calculated for each individual. As previously mentioned, a four-hour threshold was utilized, such that all scales completed within four hours of MJ use were coded as post-MJ use ratings. Ratings completed before MJ use each day, as well as those completed in excess of four hours after MJ use were labeled as pre-MJ use ratings. In an effort to obtain at least one daily baseline rating per day, participants were asked to complete their first set of clinical rating scales prior to smoking MJ. Obtaining overall mood rating averages for each individual, as well as pre- and post-MJ use ratings in the MJ and MJBP participants, provided the opportunity to conduct several levels of analyses in order to assess the unique effects of MJ and BPD on mood, as described below.

One-way ANCOVAs controlling for age were used to analyze differences between the four groups. In order to reduce the number of unnecessary pairwise comparisons, one-tailed Dunnett *t* post hoc comparisons were employed to compare each group to the HC control group. More specifically, to assess the effects of MJ use on both mood and cognition, the HC and MJ groups were directly compared. Similarly, the effect of BPD was examined by comparing the HC group to the “pure” BP group. The additive effect of MJ use and BPD was assessed by comparing the HC group to the MJBP group, and additional one-way ANCOVAs (one-tailed) were also conducted in order to compare the BP group to the MJBP group. These analyses were

performed on the overall average mood ratings from the EMA data and, to determine whether significant between-groups differences in overall mood were affected by MJ use, ANCOVAs were repeated using the pre-MJ use average mood ratings, and again using the post-MJ use average mood ratings from the MJ-using groups (MJ and MJBP). In addition, in order to investigate the acute effects of MJ on mood *within* both the MJ and MJBP groups, pre-MJ use average mood scores were compared to post-MJ use average mood scores using paired *t* tests (one-tailed) in each of these two groups separately.

EMA compliance analyses and controlling for missing data. Compliance checks were completed during weekly visits and involved saving the EMA data from the PDA to ensure that subjects were completing the majority of their scales. Subjects were informed of their level of compliance at each check-in visit and were encouraged to complete as many scales as possible during the following week. Overall compliance percentages were calculated for each subject. One-way ANOVAs with two-tailed Scheffé all pairwise post hoc comparisons were used to assess compliance percentage differences between the four groups. Additionally, two-tailed Pearson correlations between compliance percentage and EMA average rating scales were used to ensure that missing data did not significantly impact or skew the study findings.

Neuropsychological assessment statistical analyses. To examine the effect of BPD on cognition, regardless of MJ use status, one-way two-group ANCOVAs (2-tailed) controlling for age were performed to compare HC participants to participants with BPD (BP and MJBP groups combined). One-way, three-group ANCOVAs with Scheffé all-pairwise post hoc comparisons (2-tailed) were also conducted to compare the HC, BP, and MJBP participants. These three-group analyses assessed the impact of BPD on cognition *exclusive* of MJ use (HC vs BP), and addressed any potential additive effects of MJ use in BP patients (HC vs MJBP and BP vs MJBP).

Results

Demographics

Demographics are reported in [Table 1](#). ANOVAs of demographic variables between the four groups revealed that the groups were well matched for IQ and alcohol use (days/month). Between-group differences were noted for age ($F(3,70) = 5.819, p = .001$); Scheffé post hoc comparisons indicated that the BP subjects were significantly older than both HC ($p = .029$), and MJ ($p = .002$) participants. Accordingly, age differences were controlled for by utilizing ANCOVAs in all analyses of mood and cognitive performance. Chi-squared analyses indicated that the groups were not well matched for sex ($X^2(3, N = 74) = 11.628, p = .009$) with the MJBP group having a significantly lower percentage of females than the HC ($X^2(1, N = 33) = 8.972, p = .003$) and BP groups ($X^2(1, N = 30) = 6.914, p = .009$). Average scores on the FTND reflected very low nicotine use across the groups. However, between-group differences were noted ($F(3,70) = 6.335, p = .001$); the MJBP group reported significantly more nicotine use relative to the HC ($p = .002$), MJ ($p = .019$) and BP ($p = .004$) groups. All of the other groups reported similar FTND scores to one another, and given such low use indicated by the total scores, even for the MJBP group ($M = 1.92, SD = 3.00$), it is unlikely that nicotine use was a confound for subsequent analyses.

Analyses of medication use revealed that the BP and MJBP groups reported similar medication regimens ([Table 2](#)). No significant differences were noted for the frequency of use of different classes of medications: mood stabilizers, antidepressants, antipsychotics, and benzodiazepines. There were also no significant differences between the BP and MJBP groups for the number of medicated vs unmedicated patients within each group. In addition, the BP and MJBP groups were well-matched for age of BPD onset. With regard to MJ use characteristics,

Table 1. ANOVAs for 4-group comparison of demographic data (2-tailed).

Variable	HC	MJ	BP	MJBP	ANOVA		Scheffé All Pairwise Post Hoc Comparisons

doi:10.1371/journal.pone.0157060.t001

the MJ and MJBP groups were also well-matched for age of MJ onset (Table 1), as well as current levels of MJ use. In fact, no significant differences emerged between groups for frequency (smokes/week) and magnitude of MJ use (grams/week), duration of MJ use (years since onset of regular use), or urinary THC levels (ng/mL).

EMA Results

EMA compliance results and controlling for missing data. Across all groups, high levels of compliance were noted for rating scale completion, with the average overall number of completed rating scales at 88% of all possible rating opportunities. Within the HC group, EMA rating compliance indicated that they completed 94% of scales, while the BP completed 90%, and the MJ and MJBP groups each completed 84% of scales. Notably, the MJ and MJBP groups both were required to complete more rating scales than the non-smoking groups, as they rated their mood three times daily *in addition* to completing ratings after MJ use. Therefore, it is not

Table 2. Chi Squared Analyses of Medication Use in the BP and MJBP Groups.

Variable	BP	MJBP	Chi Squared	
			χ^2	p

doi:10.1371/journal.pone.0157060.t002

surprising that ANOVA results indicated that despite very high levels of compliance across all groups, some differences in compliance levels were evident ($F(3,57) = 3.238, p = .029$). Two-tailed Scheffé all pairwise post hoc comparisons revealed that these differences were driven by a trend in which the MJ group exhibited lower percentages for completion of EMA ratings ($M = 83.71, SD = 9.81$) than the HC group ($M = 93.78, SD = 5.91, p = .055$). Compliance percentages for the BP ($M = 90.08, SD = 9.90$) and MJBP groups ($M = 84.20, SD = 19.29$) were not significantly different from the other groups. However, due to the significant between-group differences, EMA analyses were re-run with compliance percentage as a covariate, and results remained unchanged. Further, in order to determine the nature of missing EMA data, correlation analyses were also conducted to assess the association between compliance percentage and EMA clinical ratings. Compliance percentage did not significantly correlate with any clinical rating scale ($r(59) \leq .203, p \geq .12$), suggesting that ratings were missing at random, and therefore missing EMA data did not unduly influence clinical mood ratings results.

Between-group analyses. Overall average mood ratings from across the 4-week data collection period are presented in [Table 3](#). As expected, compared to the HC group, BP and MJBP participants reported higher levels of anger, confusion, tension, fatigue, depression, and total mood disturbance (TMD) as measured by the POMS, as well as increased anxiety (HAM-A), depression (MADRS), and mania (YMRS). Among patients, those in the BP group reported similar overall mood to MJBP participants, with no significant differences observed on any rating scale, with the exception of higher MADRS scores in the MJBP group. Despite this difference, depression ratings on the POMS were similar between groups, and actually were slightly (albeit not significantly) lower in the MJBP group relative to the BP group. With regard to the MJ group, no significant differences were noted between MJ smokers and HCs for average mood ratings.

Analyses of average *pre*-MJ use mood data in the MJ and MJBP group compared to overall average mood in the HC and BP group are presented in [Table 4](#) (top portion of table); analyses of average *post*-MJ mood data in the MJ and MJBP group compared to overall average mood in the HC and BP group are presented in [Table 4](#) (bottom half of table). *Prior to* smoking MJ, the MJBP participants reported higher levels of anger, confusion, tension, depression, and TMD on the POMS, as well as greater anxiety, depression, and mania as measured by the HAM-A, MADRS, and YMRS, relative to the average mood ratings of the HC participants. *After* smoking MJ, while some significant differences remained between the MJBP and HC groups, the MJBP group no longer endorsed significantly higher anger, tension, or TMD on the POMS relative to the HCs. Notably, the MJ participants did not report significantly different mood ratings compared to the HC participants either *pre*- or *post*-MJ use.

Two-group ANCOVAs directly comparing the BPD patient groups (BP vs MJBP; [Table 4](#)) revealed that *prior to MJ* use, MJBP participants exhibited higher depression (MADRS) scores and a trend for higher mania (YMRS) ratings relative to the BP group. Interestingly, *after smoking MJ*, the MJBP group reported decreased levels of depression and mania; MADRS scores fell to a level no longer significantly different from ratings in the BP group, and the trend for higher mania ratings on the YMRS was no longer observed in MJBP participants relative to BP participants. In addition, the MJBP group reported a trend for lower levels of tension on the POMS after MJ use compared to BP patients. Together, these decreases in clinical symptoms led to far lower TMD scores in the MJBP group *after MJ* use, relative to the BP group's average TMD score (MJBP: 11.15 vs BP: 22.53); however, this difference was not statistically significant.

Within-group analyses. Paired *t* tests investigating within-group mood changes *pre*- and *post MJ* use suggest that *after* smoking MJ, the MJ smokers experienced slightly worse mood overall. As a group, they reported significantly increased confusion and fatigue, and decreased

Table 3. ANCOVAs (controlling for age differences) of the 4-group (HC, MJ, BP, MJBP with Dunnett *t* post hoc comparisons) and 2-group (BP v MJBP) comparisons of overall 4-week average mood EMA ratings (1-tailed).

doi:10.1371/journal.pone.0157060.t003

vigor on the POMS, resulting in higher TMD scores relative to pre-smoking levels. It is of note, however, that their average TMD scores still fell below zero, reflecting very low levels of mood-related symptomatology overall. MJ smokers also reported higher levels of anxiety (HAM-A) after MJ use (Fig 1A). In contrast, the MJBP participants reported positive changes in mood after MJ use. Paired *t* tests comparing pre- and post-MJ use mood ratings within the MJBP group indicated significantly decreased ratings of anger, tension, depression, and TMD scores on the POMS as well as lower levels of depression on the MADRS. In addition, MJBP participants reported increased vigor on the POMS after MJ use (Fig 1B).

Neuropsychological Assessment

HC vs All BP: Effects of BPD on cognition (regardless of MJ use status). When all BPD patients (BP and MJBP combined) were compared to the HC group, they generally demonstrated poorer performance on tasks of executive function. Specifically, as noted in Table 5, 2-way ANCOVAs revealed that patients with BPD achieved fewer categories, made more perseveration errors and had more losses of set on the WCST. Patients with BPD had significantly longer completion times and made more errors on the Stroop during the Color Naming and Word Reading condition. They also demonstrated slightly slower completion times on the Stroop Interference condition relative to the HCs, although this did not reach statistical significance. Similarly, BPD patients also performed Trails B significantly more slowly and exhibited

a trend for more errors on Trails A relative to HCs. BPD patients achieved lower total scores across the three trials of the COWAT in which they had to generate words starting with a given letter (F, A, S); during the semantic category trial (animals) a trend was also observed for fewer words generated among BPD patients. In addition, BPD patients recalled fewer digits on Digit Span overall, including recollection of digits in forward order (Forward) and in reverse order (Backward), which led to lower Total Digit Span scores.

On the remaining measures, BPD patients also tended to demonstrate reduced performance. Despite similar scores on the copy condition of the ROCF, they exhibited slightly lower scores on the immediate recall condition, and achieved significantly lower scores on delayed recall relative to the HCs. On the CVLT, BPD patients recalled fewer words during the initial learning trial (Trial 1), as well as across all five trials (Trial 1–5 Total Correct), and after the Long Delay. They also used less semantic clustering on the CVLT across the five trials (Trial 1–5 Total Semantic Clusters). No significant differences in performance were apparent on the HVOT.

HC vs BP: Effects of BPD on cognition (exclusive of MJ use). Post hoc analyses from a three-way ANCOVA comparing HC, BP and MJBP patients revealed that, relative to HCs, the non-MJ smoking BP participants (BP group only) demonstrated similar deficits when examined separate from the MJBP group as when grouped with MJBP participants (see Table 5). The BP group exhibited poorer performance across the majority of assessment measures. Non-MJ smoking BP patients achieved significantly fewer categories on the WCST; they also made more perseverative errors, and had more losses of set, although this did not reach the threshold for significance. Participants in the BP group also made more errors on the Stroop Color Naming and Word Reading subtests. They took significantly longer to complete Trails B, and exhibited a trend for more Trails B errors. Further, they recalled slightly fewer digits across on Digit Span Backwards, which contributed to significantly lower scores on the Total Digit Span scores among BPD patients relative to HCs. On the CVLT, the BP group recalled fewer words than

HCs on the CVLT across all five trials and after a delay. On the COWAT and ROCF, although results were not significant, the BP group demonstrated several trends for worse performance, as noted in Table 5. No deficits were noted the HVOT between HCs and the BP group.

HC vs MJ: Effects of MJ use on cognition (exclusive of BPD diagnosis). Similar to our previous report of MJ smokers [43], two-way ANCOVAs directly comparing MJ smokers to HCs demonstrated that pure MJ smokers exhibited impairment on a number of tasks relative to HCs, including the WCST, Trail Making Test, COWAT, and CVLT (See Table 6). Specifically, as noted in the BPD patients, MJ smokers demonstrated poorer executive functioning relative to controls. They achieved fewer categories and made more perseverative errors on the WCST, and took longer to complete Trails B of the Trail Making Test. MJ smokers generated fewer words than HCs on the COWAT when asked to provide words in a given semantic category. On the CVLT, although MJ smokers recalled a similar number of correct words, they had more Intrusions (incorrect responses) and utilized less semantic clustering across trials (Total Semantic Clusters). HC and MJ participants did not differ significantly with regard to their performance of the Stroop Color Word Test, Digit Span, ROCF, or HVOT.

HC vs MJB and BP vs MJB: Potential additive effects of BPD and MJ use. Post hoc analyses from three-way ANCOVAs (HC vs BP vs MJB) designed to detect potential additive effects of BPD and MJ use revealed that MJB patients demonstrated some areas of poorer cognitive performance relative to HCs (see Table 5, HC vs MJB). They achieved fewer categories on the WCST and their performance suggests a trend for making more perseverative errors on this task. On the Stroop, significantly slower times were noted relative to HCs on the Color Naming subtest, while on the CVLT, MJB participants recalled significantly fewer words

during Trial 1, throughout all five learning trials, and after a 20-minute delay. MJBP participants also had fewer semantic clusters on the CVLT. On the ROCF, like the pure BP group, MJBP participants exhibited a trend for lower scores on the Delayed Recall; however, they did not exhibit impairment on the remaining conditions of the task, nor did they demonstrate impaired performance on the Trail making Test, Digit Span, or HVOT relative to HCs.

Although BPD patients and MJ smokers each demonstrated impairment on several measures of cognitive performance relative to HCs, *no differences emerged* when directly comparing the BP and MJBP groups (see [Table 5](#), BP vs MJBP). In fact, Scheffé all pairwise post hoc comparisons revealed no significant between-group differences for BP vs MJBP participants for any task: WCST, Stroop, Trail Making Test, COWAT, CVLT, ROCF, Digit Span, or HVOT.

Discussion

The current investigation, to our knowledge, marks the first study to examine the effects of MJ on both mood and neuropsychological performance in BPD patients. As the nation explores indications for medical MJ (MMJ), it is imperative to determine how MJ use might affect clinical symptoms in those diagnosed with mood disorders, such as BPD. In addition, given the fact that cognitive decrements are well-documented in both MJ smokers [[43](#), [62–64](#)] and those with BPD [[39](#), [65](#)], it is critical to examine whether these impairments may be exacerbated or possibly ameliorated by the combination of a BPD diagnosis and regular MJ use. Through the utilization of proper control groups (achieved by including four discrete groups: healthy controls, MJ smokers with no Axis I pathology, non-MJ smoking BP patients, and MJ-smoking BP patients), the current study was able to begin to clarify both the individual effects and potential for additive effects of MJ use and BPD on mood and cognition.

As hypothesized, our findings suggest that after smoking MJ, BPD patients experienced improvement in several aspects of clinical state secondary to MJ use. In fact, direct analyses of the MJ-smoking BPD patients (MJBP) *before* and *after* MJ use revealed notable symptom alleviation within four hours of smoking. After smoking MJ, the MJBP group reported significantly lower scores of anger, tension, depression (POMS and MADRS), as well as higher levels of vigor, which led to a marked decrease in TMD scores (22.39 to 11.15), a composite measure of overall mood on the POMS. Further, prior to smoking MJ, the MJBP participants reported slightly worse levels of symptomatology relative to the pure BP group, with higher levels of depressive and manic symptoms. In contrast, after MJ use, the MJBP group demonstrated considerably *lower* levels of tension and lower TMD scores relative to the BP group. In addition, although depression (MADRS) and mania scores were still slightly higher in the MJBP group after MJ use relative to the BP group, scores dropped to levels that were no longer significant or approaching significance between the two groups, highlighting positive changes in mood-related symptoms. In addition, average mood ratings across the course of the study showed that overall mood was comparable between MJBP and BP subjects. Although MADRS scores were generally elevated in MJBP patients, POMS scores for depression were similar between groups (and were actually marginally lower within MJBP participants). As the MADRS reflects specific depressive symptoms, as compared to the POMS which measures self-perceived mood, results may indicate that while certain depressive symptoms were more evident in MJBP participants relative to BP participants, a *self-perceived* mood of depression (i.e., feeling sad, lonely, blue) was not more prevalent in MJBP participants.

To some extent, these findings support recent work, which found that MJ use was correlated with increased positive affect in BPD patients [[66](#)]. However, the authors also observed a relationship between MJ use and increased manic and depressive symptoms. Although the authors of this study report both positive and negative fluctuations in clinical symptoms, they posit that bidirectional effects of MJ use, outlined by Ashton and colleagues [[22](#)], are likely impacted by a range of factors, including dose, mode of use, and personality differences. In addition, as we learn more about the differential effects of individual constituents of MJ, (i.e., THC vs cannabidiol [CBD]), it is possible that strains higher in certain constituents are at least partially

responsible for the moderation of specific dimensions of clinical symptoms. Some research suggests that CBD may be beneficial in alleviating, anxiety, psychosis, and other psychological symptoms [67–70] and may have a pharmacological profile similar to that of antipsychotic medications [69], which are often prescribed to patients with bipolar I disorder. Further, CBD has been shown to be an effective anticonvulsant treatment for those with pediatric seizure disorders [70], another class of drugs frequently prescribed for mood stabilization in patients with BPD.

Interestingly, among pure MJ smokers (those not diagnosed with BPD), beneficial effects on mood were *not* observed in the current study. MJ smokers reported decreases in vigor, as well as higher levels of confusion, fatigue and TMD after smoking, consistent with effects commonly reported in the general population after MJ use. It is of note, however, that MJ smokers continued to exhibit very low levels of mood-related symptoms even after MJ use, suggesting that while their mood did appear to worsen slightly after using MJ, these changes remained far below clinical thresholds. Overall, results may indicate that MJ use may have unique effects in BPD patients, effects which are not necessarily observed in those without Axis I pathology.

With regard to cognitive performance, MJ smokers and BPD patients performed more poorly than HCs overall. However, within the BPD patients, impairment was observed *regardless* of MJ use status; deficits were apparent when the non-smoking BP patients were analyzed as a whole group (BP and MJBP) as well as separately (BP vs MJBP). Overall, patients in both BPD groups demonstrated poorer performance on tasks of executive function. They also exhibited less efficient learning and recall strategies during a serial list-learning task, reduced verbal fluency, inferior attention and working memory, and poorer visuospatial organization. Interestingly, when the non-smoking BP group was compared to the MJBP group, no significant differences across any measure were noted. Taken together, study findings suggest that MJ use may result in at least short-term mood term stabilization for a subset of BPD patients, and further, that MJ use does not have an additive, negative impact on cognitive performance in BPD patients.

These findings provide a valuable contribution to the field, which has only begun to clarify the effects of MJ on mood and cognition in psychiatric populations. While many would posit that the individual relationships between cognitive impairment and both MJ use and BPD would collectively result in a *more severe impact* on cognitive function, some studies have actually reported a cognitive advantage in BPD patients who use MJ regularly [40–41]. In addition, a recent study of MJ-smoking patients diagnosed with schizophrenia found no evidence for an additive effect of MJ use and schizophrenia diagnosis on cognitive dysfunction [71]. In combination, these studies provide evidence that cognitive deficits associated with certain Axis I pathologies may not be worsened by MJ use. In fact, improved cognitive performance may be related to the potential anxiolytic effects of MJ. Anxiety, common in BPD patients [72], often interferes with attention and the ability to encode information, suggesting that if MJ acts as an anxiolytic in at least a subset of patients, this may result in better concentration and enhanced cognitive performance.

Despite these positive changes, one previous study also observed that patients tended to experience improved cognitive performance at the expense of a more severe clinical course [41]. While the current study did not examine long-term treatment outcomes, our preliminary findings provide evidence that BPD patients who smoke MJ may derive at least a short-term clinical benefit. MJBP participants reported improvements in mood within four hours of smoking MJ, did not have elevated average mood ratings (with the exception of the MADRS) relative to the BPD group across the four-week study, and did not experience additional cognitive deficits when compared to the non-smoking BP group. Future studies will need to be conducted in order to investigate the effect of MJ use on clinical course over longer durations of time.

Limitations

Data from the current study provide critical information about MJ use in psychiatric populations, as guidelines regarding indications for medical MJ are considered; however, these findings must be interpreted in light of several limitations. First, although this study served as a pilot investigation, it is important to acknowledge that the overall sample is moderate in size, with a modest number of patients completing EMA ratings, which may limit the generalizability of findings. For example, only participants who were well characterized as chronic, heavy MJ smokers were enrolled in the current study; participants with less frequent use (i.e., casual MJ smokers) may not experience the same effects of MJ on mood and cognition as observed in this sample of participants. Further, rather stringent enrollment criteria were employed, which excluded participants who reported comorbid diagnoses (via phone interview or through the clinical interview). In addition, participants were required to be predominantly euthymic throughout the course of the study. Although these criteria limited the effects of extraneous variables, the impact of MJ on mood and cognition may differ in those who have been diagnosed with comorbid disorders (i.e., ADHD, PTSD, polysubstance use, etc.) or who may be experiencing more acute clinical symptomatology. Finally, likely related to the geographic region from which patients were recruited (the Greater Boston area is home to many universities, hospitals, and research institutions), participants generally demonstrated higher than average IQs. This may limit generalizability to populations with average to below average cognitive abilities. It will be important for future studies to recruit larger numbers of research participants to further investigate the impact of MJ on mood and cognition in BPD, as well as to examine additional factors that were not explored in the current pilot investigation.

Additionally, although the four groups were not statistically matched for sex (more males were enrolled than females in the MJ and MJBP groups), it is likely that the sex distribution of this sample is actually representative of the larger population. In fact, national surveys of substance-using populations have revealed that males engage in the use of illicit substances, including MJ, more frequently than females [73–74].

Regarding the EMA study design, overall compliance was very high among all study groups with an overall completion rate of 88% of all possible scheduled ratings. Several measures were also put in place to encourage completion of ratings after MJ use, including comparing reported frequency of MJ use during interim visits to the frequency of EMA ratings. However, given the nature of EMA data, it is not possible to guarantee that all participants completed mood ratings immediately after MJ use. In an attempt to address this issue, all participants were asked to adjust the time of last use if necessary, and any ratings reported more than four hours after MJ use were not coded as post-use data. While this four-hour window was selected to capture the acute effects of MJ use on mood, the duration of MJ effects are likely related to a range of factors including, but not limited to the specific product used (i.e. high THC/low THC), amount and frequency of use, mode of use, and metabolism. It may therefore be an important consideration for future studies to explore whether the duration of MJ intoxication is related to the duration of reported symptom improvement by BPD participants.

Further, although this investigation examined the *acute* effects of MJ use in BPD patients, additional investigations should explore the potential long-term impact of MJ use on clinical state. It is of note that over the duration of the study, the overall average mood ratings for the MJBP and BP were not significantly different across any measure (except for the MADRS), which provides preliminary evidence that MJ use may not *directly* result in poorer clinical course. Higher levels of clinical severity previously reported in MJ-smoking BPD patients [4, 8, 11] may be a result of several factors, including a failure to inform clinicians of MJ use. As MJ may partially address mood-related symptoms, the pharmacotherapeutic regimen prescribed

by physicians may, as a result, be different from what would normally be prescribed. Additionally, any short-term improvement following MJ use may result in non-adherence with patients' prescribed medications, which could ultimately result in poorer long-term outcomes.

Due to the preliminary nature of the current study, the relationship between specific patterns or levels of MJ use and symptom improvement were not thoroughly investigated. In addition, all MJ using participants in the current study were chronic MJ users and results may therefore not be generalizable to more casual MJ users. Future investigations should consider the impact of frequency and amount of MJ smoked, as well as mode of use, and strain of MJ used on both cognition and symptomatology. In fact, several studies have shown promise for the alleviation of anxiety using MJ products that contain high levels of CBD [67–68]. Given that CBD is a non-psychoactive phytocannabinoid that has shown promise as an anxiolytic and anticonvulsant (often used to stabilize mood in patients with BPD), high CBD-containing products may afford more viable options than other cannabinoid-based treatments. Therefore, future studies should also aim to explore whether high-CBD relative to low-CBD strains have differential effects in BPD patients as well as other clinical populations.

Finally, it should be noted the current study design does not imply cause and effect, but rather shows a *relationship* between MJ use and mood improvement. Clinical trials will be needed in order to further investigate the potential for MJ and cannabinoid-containing products as a potential treatment for patients with BPD.

Conclusions

New legislation across the nation has increased the overall accessibility of MJ to the general public for both recreational and medical use. To date, 24 states and the District of Columbia have fully legalized medical marijuana and another 18 states have allowed the use of CBD-based products for medical use. Each state individually regulates the use of MMJ, and perhaps not surprisingly, a wide range of acceptable conditions are often listed as eligible for MMJ certification. While some states include a “catchall” category, allowing physicians to certify conditions at their discretion, other states employ a restrictive list of indications suitable for MMJ. Additional studies are needed to help shape public policy regarding conditions that may be amenable to MMJ treatment, especially with regard to psychiatric illnesses. The current study highlights preliminary evidence that patients with BPD who regularly smoked MJ reported at least short-term clinical symptom alleviation following MJ use, indicating potential mood-stabilizing properties of MJ in at least a subset of patients with BPD. Furthermore, despite previous research showing that MJ use and BPD individually can have a negative impact on cognition, MJ use in BPD patients may *not* result in additional impairment. Further research is warranted to explore the impact of MJ on mood in clinical and non-clinical populations.

Supporting Information

S1 File. Manuscript Database. Demographic, cognitive, and EMA raw data, which were analyzed for the current manuscript, are available and arranged by group (HC, MJ, BP, and MJBP).

THE EFFECT OF EXTREME MARIJUANA USE ON THE LONG-TERM COURSE OF BIPOLAR I ILLNESS: A SINGLE CASE STUDY

Rif S. El-Mallakh, M.D.*
Carl Brown, J.D.**

Abstract—The effect of marijuana on bipolar disorder has never been systematically evaluated. Subjective reports by patients suggest an overall positive effect, but these may be unreliable. We herein report a case in which mood data was prospectively collected over two years of total substance abstinence and two years of extreme marijuana use. Marijuana use did not alter the total number of days of abnormal mood, however, marijuana was associated with an increase in the number of hypomanic days and a decrease in the number of depressed days. While not conclusive, the data suggest that marijuana may indeed have an effect on mood in bipolar patients that needs to be systematically examined.

Keywords—bipolar disorder, manic-depression, marijuana, prospective mood ratings

Marijuana use is quite common in patients with bipolar illness (Goldberg et al. 1999) but its effect on the course of bipolar illness is not clear (Tondo et al. 1999; Grinspoon & Bakalar 1998). There have not been any systematic evaluations of objective or subjective consequences of marijuana in bipolar disorder. Recently, the authors had the opportunity to examine the effect of chronic marijuana use in a Type I bipolar individual keeping meticulous daily mood charts.

CASE REPORT

Mr. B is a 53-year-old man, a former practicing attorney with a history of bipolar illness since age 26. He

*Director, Mood Disorders Research Program, Department of Psychiatry and Behavioral Sciences, University of Louisville School of Medicine, Louisville, KY.

**Columnist, Louisville Eccentric Observer, Louisville, KY.

has maintained a daily mood chart for over 15 years. Mr. B utilized marijuana on a daily basis (maintaining a constant state of intoxication with 10 joints or equivalent daily). In 2000, Mr. B was imprisoned for a crime committed during a manic period. His sentence mandated 12 months in federal prison and a one-year probationary period during which he did not use any marijuana. However, immediately after the end of the probation, Mr. B reinstated his daily marijuana use. Mood charts for the four years (two years off marijuana and two years on marijuana) were prospectively recorded using the National Institute of Mental Health self-rating chart (a -4 to +4 scale). During most of these four years, pharmacologic management was kept constant, consisting of carbamazepine (1400 mg daily), lamotrigine (550 mg daily), and clonazepam (1 mg daily).

During the two years on marijuana use, Mr. B experienced 299 depressed days (41.0%, modal score -4), and 171 hypomanic days (23.4%, modal score +1). Depression was significantly less while using marijuana than the two years off marijuana (391 depressed days, 53.5%, modal score -4, $z = 5.0$, $P < 0.01$). Similarly, the hypomania occupied significantly greater time while using marijuana than off (111 hypomanic days, 15.2%, modal score +1, $z = 3.9$, $P < 0.01$). If the year in jail is excluded, and the year on probation is compared to the subsequent year, the results are not significantly different. Total number of depressed days while using marijuana was nonsignificantly less than the total number off marijuana (139 [38.1%] vs. 160 days [43.8%], respectively, $z = 1.58$, ns), while the total number of hypomanic days was significantly greater while using marijuana (104 [28.5%] vs. 67 [18.4%] days, $z = 3.26$, $P < 0.01$). The total number of ill days was not different (243 days while using marijuana vs. 227 days off marijuana, $z = 1.19$, ns). There were no full manic episodes in the entire four-year period.

DISCUSSION

This anecdotal prospective evaluation of the comparative effect of marijuana on the long-term course of bipolar illness suggests that heavy use is associated with a statistically significant reduction in depressed time and a significant increase in hypomanic days compared to abstinence. It is of interest that when marijuana is associated with psychosis, it frequently presents with manic or hypomanic features (Chaudry et al. 1991; Rottanburg et al. 1982). Anecdotally, patients report that marijuana use provides subjective mood

stabilization (Grinspoon & Bakalar 1998) or antidepressant effect (Gruber, Pope & Brown 1996).

In this case marijuana was not mood stabilizing since the total number of ill days did not change. However, the relative decline in depressed days and increase in hypomanic days was felt subjectively as an antidepressant effect by the patient. The apparent hypomanic promoting effect is consistent with previous clinical reports (Chaudry et al. 1991; Rottanburg et al. 1982).

There are clearly problems with this case. The two years in which the subject abstained from marijuana were marked by imprisonment and probation—both of which

could have an adverse effect on mood. However, the pattern of depression and hypomania revealed the same cycling that had gone on before imprisonment and after the end of probation, suggesting that this did not play an overt role.

Despite these considerations, this report suggests that preconceived notions that marijuana is depressogenic may need to be reexamined regarding its effect in bipolar patients. Similarly, the patient-promoted view that marijuana is mood stabilizing also needs to be reexamined. Clearly, larger studies would be important and potentially enlightening.

Pros and Cons of Medical Cannabis use by People with Chronic Brain Disorders

Uma Suryadevara¹, Dawn M. Bruijnzeel¹, Meena Nuthi¹, Darin A. Jagnarine¹, Rajiv Tandon¹ and Adriaan W. Bruijnzeel^{1,2,3,*}

¹Department of Psychiatry, University of Florida, Gainesville, FL, USA; ²Department of Neuroscience, University of Florida, Gainesville, Florida, USA; ³Center for Addiction Research and Education, University of Florida, Gainesville, FL, USA

Abstract: Background: Cannabis is the most widely used illicit drug in the world and there is growing concern about the mental health effects of cannabis use. These concerns are at least partly due to the strong increase in recreational and medical cannabis use and the rise in tetrahydrocannabinol (THC) levels. Cannabis is widely used to self-medicate by older people and people with brain disorders such as amyotrophic lateral sclerosis (ALS), multiple sclerosis (MS), Alzheimer's disease (AD), Parkinson's disease (PD), bipolar disorder, and schizophrenia.

Objective: This review provides an overview of the perceived benefits and adverse mental health effects of cannabis use in people with ALS, MS, AD, PD, bipolar disorder, and schizophrenia.

Results: The reviewed studies indicate that cannabis use diminishes some symptoms associated with these disorders. Cannabis use decreases pain and spasticity in people with MS, decreases tremor, rigidity, and pain in people with PD, and improves the quality of life of ALS patients by improving appetite, and decreasing pain and spasticity. Cannabis use is more common among people with schizophrenia than healthy controls. Cannabis use is a risk factor for schizophrenia which increases positive symptoms in schizophrenia patients and diminishes negative symptoms. Cannabis use worsens bipolar disorder and there is no evidence that bipolar patients derive any benefit from cannabis. In late stage Alzheimer's patients, cannabis products may improve food intake, sleep quality, and diminish agitation.

Conclusion: Cannabis use diminishes some of the adverse effects of neurological and psychiatric disorders. However, chronic cannabis use may lead to cognitive impairments and dependence.

1. INTRODUCTION

Cannabis is one of the most widely used illicit drugs in the world. The United Nations Office on Drugs and Crime estimates that worldwide 3-5% of adults use cannabis [1]. The prevalence of cannabis use is very high in countries such as Ghana (21.5%), Zambia (17.7%), Canada (17.0%), the United States of America (US, 12.3%), and New Zealand (13.3%) [1]. It has been estimated that there are 20 million cannabis users in the US, including 1.2 million medical cannabis users [2, 3]. About 6 percent of Americans above the age of 18 will meet the DSM-5 criteria for cannabis use disorder at some point in their life [4].

In the US, federal law does not allow recreational or medical cannabis use. However, recreational and medical

cannabis use is legal in an increasing number of states. Twenty-three states and the District of Columbia have legalized the medical use of cannabis and 4 states have legalized its recreational use. It is expected that cannabis use will continue to increase as there is growing tolerance towards the use of cannabis and an increase in the number of patients who use cannabis for medical purposes [5]. Most cannabis studies have investigated the effects of cannabis in healthy adolescents and young adults. However, cannabis is also used recreationally by older adults and by patients with neurological and psychiatric disorders to alleviate symptoms associated with their disorder. A large study with participants from 31 countries showed that 24.1% of cannabis users are between the ages of 51 and 60, 5.8% between 61 and 70, and 0.6% are older than 70 [6]. Cannabis use has more than quadrupled among the 55-59 year olds (1.6 to 7.4%) and doubled among 60-64 year olds (2.4 to 4.4%) between 2002 and 2012 [7].

In addition to the increase in cannabis use in the elderly, there has also been an increase in the use of cannabis for the

*Address correspondence to this author at the University of Florida, College of Medicine, Department of Psychiatry, 1149 Newell Dr. Gainesville, FL, USA 32611; Tel: 352-294-4931; E-mail: awbruijn@ufl.edu

treatment of neurological disorders [8, 9]. This is in combination with the dramatic increase in THC levels in cannabis which could lead to an increase in the number of people who experience adverse mental health effects [10]. In addition to cannabis, cannabis-based treatments such as nabiximols (trade name Sativex, cannabis plant extract, 1:1 ratio of CBD:THC), dronabinol (trade name Marinol, synthetic THC), and nabilone (trade name Cesamet, synthetic cannabinoid with chemical structure similar to THC) have also been used by people with brain disorders. Both nabilone and dronabinol have been approved by the US Food and Drug Administration (FDA) for the treatment of nausea and vomiting associated with chemotherapy for cancer and to stimulate appetite in AIDS patients with wasting syndrome. Nabiximols is already being used in 15 countries for the treatment of spasticity associated with multiple sclerosis (MS) and in the US, Sativex is being reviewed by the FDA for the treatment of cancer pain. The goal of this review is to provide insight into the potential beneficial and harmful effects of cannabis use and cannabis-based treatments in people with common neurological or psychiatric disorders and older individuals.

2. CANNABINOIDS

Cannabis has been used in religious ceremonies and for medical purposes for thousands of years [11]. Cannabidiol (CBD), the main non-psychoactive component of cannabis, was isolated in the 1940s and its structure was established in the 1960s [12, 13]. It wasn't until 1964 that tetrahydrocannabinol (THC) was isolated [14]. Cannabidiol does not induce intoxication and diminishes the psychotropic effects of THC [15, 16]. The cannabinoids can be classified into three groups: phytocannabinoids, endocannabinoids, and synthetic cannabinoids [17]. More than one hundred phytocannabinoids have been isolated but in most commercial cannabis strains, only THC is produced in high levels [18]. Another phytocannabinoid that is sometimes expressed at high levels is CBD. Furthermore, two endocannabinoids have been discovered, namely 2-arachidonoyl glycerol (2-AG) and anandamide [19-21]. Some synthetic cannabinoids have a much higher potency than THC and have been associated with severe adverse mental health effects [22]. Cannabinoids mediate their effects *via* the activation of the cannabinoid type 1 (CB₁) and type 2 (CB₂) receptor. The endogenous ligands for these receptors are 2-AG and anandamide. The CB₁ receptor is one of the most common receptors in the central nervous system. High levels of CB₁ receptors have been detected in the hippocampus, basal ganglia, prefrontal cortex and cerebellum [23]. The localization of this receptor in the basal ganglia, hippocampus, and prefrontal cortex underscores the critical role of the cannabinoid system in the regulation of motor function and cognition [24]. The CB₂ receptors are mostly found in the periphery (thymus and spleen), but they have also been detected on cerebellar and brain stem neurons [25]. Cannabinoid type 2 receptor levels are extremely low in the healthy brain but their levels increase after injury and inflammation [26, 27]. The CB₂ receptors are mainly expressed on activated microglia, which play a critical role in the removal of dying cells but also induce the release of cytotoxic molecules that can lead to cell

death [28, 29]. Activation of the CB₂ receptor decreases the release of cytokines and chemokines and diminishes inflammation and cell death [30, 31].

3. ANIMAL STUDIES

Studies with animals have provided evidence for the fact that chronic exposure to cannabis smoke, tetrahydrocannabinol (THC), or CB₁ receptor agonists leads to the development of dependence. Cannabis withdrawal leads to somatic withdrawal signs (*e.g.*, abdominal constriction, wet-dog shakes, head shakes, forepaw fluttering), anxiety-like behavior, and an increased release of the stress peptide corticotropin-releasing factor in the amygdala [32-35]. The negative affective state associated with drug withdrawal provides powerful motivation for the continuation of drug use [36, 37]. There is also extensive evidence that cannabis and THC impair memory and cognition in rodents. The eight-arm radial maze is a well validated test for investigating the neuronal mechanisms that underlie memory [38]. Nakamura *et al.* demonstrated that THC disrupts working memory in the radial maze test [39]. THC inhibits the release of acetylcholine in the hippocampus and this is likely one mechanism by which it impairs memory. This is supported by the observation that drugs that prevent the THC-induced decrease in acetylcholine release in the hippocampus also prevent memory impairments [40]. It has also been suggested that repeated THC administration leads to increased glutamate levels, which induces a downregulation of glutamate receptors and a reduction in the density of dendritic spines on hippocampal neurons. This may reduce synaptic plasticity and thereby cause memory impairments [41]. Memory impairments due to THC exposure may gradually diminish over time. In the above mentioned study by Nakamura *et al.*, memory function returned to baseline levels after 4 weeks of abstinence [39]. Another study reported that memory function in mice was still impaired three weeks after the administration of one low dose of THC [42]. Therefore, this suggests that the memory function might recover after cannabis use, but only after an extended amount of time.

4. ACUTE EFFECTS OF CANNABIS USE

Cannabis has a wide range of subjective effects. The effects may vary between light and heavy users and can include feelings of intoxication, euphoria, altered sensory perception, cognitive and perceptual distortions, anxiety, dizziness, and increased appetite [43]. The most reliable markers of acute cannabis exposure are intoxication and tachycardia [44]. In terms of cognitive processes, there is extensive evidence that acute cannabis exposure impairs attentional tasks, consolidation and retrieval of memory, working memory, verbal memory, learning, and executive functions [44]. Impaired performance has been consistently found in multiple aspects of attention, including sustained attention, divided attention, selective, and focused attention [45]. Additionally, studies have found executive dysfunction related to cannabis exposure, including disinhibition and impaired decision making [46]. Acute cannabis intoxication in healthy young people causes slower reaction times, impaired accuracy, and impaired response inhibition [47, 48]. Other frontal dysfunction that has been observed

includes decreased information processing speed, poor planning, lack of self-monitoring, and inability to alter behaviors to suit changing tasks [49-51]. There can also be alterations in mathematical abilities and time perception, along with changes in the gross and fine motor skills [52, 53]. Taken together, these studies indicate that acute cannabis use affects emotional states and dramatically impairs cognitive processes and motor functions.

5. CHRONIC EFFECTS OF CANNABIS USE

One of the main adverse effects of cannabis use is the development of dependence. In the US, almost 10% of adults use cannabis and one third users meet the criteria for cannabis use disorder [54]. Cannabis use disorder is characterized by a strong desire to use cannabis, using larger amounts than intended, and continued usage despite negative social and physical consequences, craving, tolerance and withdrawal [55]. It has been estimated that 30% of regular cannabis users and 50-95% of heavy users experience a cannabis withdrawal syndrome [56]. Cannabis withdrawal is characterized by anxiety, depression, irritability, decreased sleep quality along with the quantity and stomach pain [57, 58]. This negative affective state plays a critical role in the maintenance of drug addiction [37]. Studies that have evaluated the long term effects of cannabis use on cognition are sparse. In one study in which participants were followed from birth to age 38, persistent cannabis users had a 6 point reduction in IQ compared to non-users [59]. Some longitudinal studies have shown persistent adverse effects of cannabis use on neurocognitive performance. These effects depend on the length of abstinence, age at the onset, or cumulative lifetime exposure [60]. Significant psychomotor dysfunction has also been reported in chronic cannabis users [61]. Some recovery of cognitive function might occur after cessation of cannabis use. Adolescent cannabis users with 3 weeks of sobriety demonstrated resolution of learning and verbal memory deficits, but continued to have difficulty with attentional tasks [62]. In one longitudinal study in young adults, episodic memory improved over an eight year abstinence period [63]. Taken together, this indicates that chronic cannabis use can lead to loss of control over cannabis use and cognitive impairments, which may diminish gradually after a prolonged abstinence period. Chronic cannabis use can also lead to what is called an amotivational syndrome [64, 65]. This amotivational syndrome is characterized by apathy, lack of motivation, and poor educational performance. Animal studies suggest that the amotivational syndrome is due to a THC-induced dysregulation of dopaminergic systems [66]. This is supported by a study with human cannabis users that showed that cannabis users with the highest level of apathy had the lowest dopamine synthesis capacity in the striatum [67].

6. STRUCTURAL CHANGES IN CANNABIS USE

There is extensive evidence for structural and functional abnormalities in young cannabis users. Chronic cannabis use leads to changes in gray (cell bodies, dendrites, and synapses) and white matter (myelinated neuronal tracts) architecture [68, 69]. There is some evidence that cannabis use may increase the volume of subregions of the cerebellum

and amygdala in adolescents [70, 71]. The changes in the volume of these brain sites were associated with poor executive functioning (cerebellum) and internalizing problems (amygdala) [70, 71]. An increase in the volume of a brain site might be due to disrupted pruning of gray matter during a critical period in adolescence or possibly abnormal connectivity patterns that develop to compensate for cognitive deficits [72]. Although some studies reported that cannabis use can increase the size of brain regions, the great majority of the studies found that cannabis use decreases the volume of brain regions. Cannabis use-induced decreases in brain volume have been reported for the orbitofrontal cortex, hippocampus, striatum, and amygdala [69, 73-76]. One of the most consistent findings has been that cannabis use decreases the volume of the hippocampus and this correlates with the amount of cannabis used and the level of dependence [77]. It should be noted that a recent study reported that daily cannabis use does not affect the volume of the nucleus accumbens, amygdala, hippocampus, or cerebellum [78]. It was suggested that there was no effect of cannabis use on brain volumes because the study closely controlled for other factors that may affect the volume of specific brain sites, such as alcohol use. Taken together, conflicting findings about the effect of cannabis use on the volume of brain sites have been reported. Some of these differences might be due to difference in study design, comorbid drug use, and data analysis. Well controlled animal studies with young and old animals are urgently needed to evaluate the effects of cannabis smoke exposure on the volume of specific brain regions.

Cannabis use is most common among adolescents and young adults and this period is also critical for brain myelination. Cannabinoid receptors are found on myelinating glial cells and are thought to play a role in white matter integrity and connectivity [79]. A number of studies that investigated neuronal tracts in the brain using diffusor tensor imaging have found reductions in white matter integrity throughout the frontal and temporal lobes in adolescent cannabis users [68, 80-82]. These abnormalities are associated with psychological symptoms and cognitive impairments. Chronic cannabis use also leads to impairments in cerebrovascular functioning, which has been associated with an increased risk for stroke [83, 84]. There is a lack of data regarding the effects of cannabis use on the brain of the elderly. The vast majority of cannabis studies have been conducted with young adults. Given the rapid increase in the aging population, it is critical to gain a better understanding of the acute and long-term effects of cannabis use in this group.

7. CANNABIS AND AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease that rapidly progresses and primarily affects the motor neurons in the spinal cord and brain stem. One of the first symptoms is muscle weakness in one part of the body, which then spreads to other parts. Furthermore, thirty to fifty percent of ALS patients have signs of cognitive impairments [85, 86]. Amyotrophic lateral sclerosis is very rare in people before the age of 40, and the median age at diagnosis is 65 for males and 67 for females

[87]. The precise cause of ALS is unknown. However, several possible causes for ALS have been identified: 1) oxidative damage, 2) blockade of axonal transport by neurofilaments, 3) toxicity from intracellular aggregates, and 4) glutamate-mediated excitotoxicity [88]. Although it is not known what causes ALS, there is strong evidence that inflammation plays a role in its progression [89]. Amyotrophic lateral sclerosis has been associated with changes in the endogenous cannabinoid system and cannabinoid receptor agonists may slow down the progression of ALS by decreasing inflammation. Animal studies have shown that endogenous cannabinoid levels are elevated in spinal cord of symptomatic ALS mice [90]. Interestingly, CB₂ receptors, but not CB₁ receptors, are upregulated in a mouse model for ALS (G93A-SOD1 mutant mice) [91]. This observation is in line with a recent study in which CB₁ and CB₂ receptor levels were assessed in TAR-DNA binding protein-43 (TDP-43) mice [92]. These mice are considered an animal model for ALS [93]. TDP-43 aggregates have been detected in the brains of ALS patients and it has been suggested that these aggregates induce toxicity and cell death [94, 95]. Interestingly, in both male and female TDP-43 mice there is an upregulation of CB₂, but not CB₁, receptors in the spinal cord [92]. Treatment with THC, the synthetic CB₁ and CB₂ receptor agonist WIN55,212-2, and the selective CB₂ agonist AM-1241 delays ALS progression in animal models [91, 96]. Furthermore, the neuroprotective effects of THC are diminished by CB₁ receptor blockade [97]. Taken together, this suggests that both CB₁ and CB₂ agonists may slow down the progression of ALS.

Cannabinoids target multiple neuronal pathways and exert anti-inflammatory and neuroprotective effects. A post-mortem study showed that ALS patients have elevated CB₂ receptor levels on microglia in the spinal cord [98]. Unfortunately, CB₁ receptor levels were not assessed in the aforementioned study, but studies with animal models for ALS suggest that ALS is not associated with an upregulation of CB₁ receptors [91, 92]. Microglia do not express CB₂ receptors under baseline conditions but neuronal damage leads to microglia activation and the expression of CB₂ receptors [99].

Clinical studies suggest that cannabis may improve ALS symptoms. There is evidence that cannabis helps with pain, spasticity, drooling, appetite loss, and sleep [100, 101]. In patients with respiratory failure due to ALS, cannabis may help by inducing bronchodilation [102, 103]. Overall, these studies suggest that cannabis diminishes ALS symptoms and thereby improve the quality of life of patients. Clinical studies indicate that ALS is associated with high levels of anxiety and depression [104-106]. Small amounts of cannabis may help people to relax, induces euphoria, and decreases anxiety and thereby could also increase the quality of life of ALS patients [107-109]. Overall, the reviewed studies suggest that cannabis use may diminish some of the symptoms associated with ALS and delay disease progression (See Table I for an overview).

8. CANNABIS AND MULTIPLE SCLEROSIS

Multiple Sclerosis is a chronic demyelinating disease of the central and peripheral nervous system [110, 111]. The symptoms (*e.g.*, vision problems, muscle weakness, pain,

balance problems, and paralysis) are due to uncontrolled or inappropriate neural transmission that gradually worsens when the disease progresses. During the early stage of the disease, patients may experience long periods during which they are relatively symptom free and these periods are interrupted by flare ups that lasts days to weeks. It has been suggested that cannabis, THC, nabiximols, and oral cannabis extract (OCE) may diminish spasticity associated with MS [112]. Thus far, one cannabis based drug (nabiximols) has been developed for the treatment of MS. Nabiximols is a mucosal spray that contains THC and CBD in a 1:1 ratio. The US FDA has approved nabiximols for clinical trials and it has been approved in several European countries, Canada, and New Zealand for the treatment of spasticity associated with MS.

Animal studies show that cannabinoid receptor agonists diminish tremors and spasticity in mouse models for MS [113]. Preclinical studies suggest that spasticity associated with MS is diminished by CB₁, but not CB₂, receptor agonists [114]. Cannabinoids have neuroprotective effects due to their action on microglial cells [115, 116]. Medical cannabis has been shown to decrease spasticity and pain in MS patients but it has negative effects on posture and balance [117, 118]. Furthermore, both nabiximols and THC decrease spasticity in MS patients [119, 120]. Oral cannabis extract has proven to be very effective for the treatment of central pain [119]. In addition to this, people with MS often suffer from severe bladder dysfunction due to the disruption of neuronal transmission between the brain and bladder. Some evidence suggests that nabiximols, but not dronabinol or oral cannabis extract, improves bladder function in people with MS [119, 121]. The cannabis based treatments did not reduce tremors in patients with MS [119, 122].

Multiple sclerosis has been associated with cognitive impairments, depression, and anxiety [123, 124]. It has been estimated that about 50% of MS patients have cognitive deficits and suffer from depression [125-127]. Multiple Sclerosis patients who smoke cannabis have more severe cognitive impairments than nonusers [128, 129]. Patients with MS who smoke cannabis perform poorly on tests for information processing speed, working memory, executive functioning, and visuospatial perception compared to ALS patients who do not smoke cannabis [129]. Multiple sclerosis patients who used cannabis were also twice as likely to be considered cognitively impaired [129]. Furthermore, in MS patients who use cannabis there is a correlation between cognitive impairments and reductions in gray and white matter volume in medial and lateral temporal regions, thalamus, basal ganglia, and prefrontal regions [130]. So far there is no evidence that cannabis use affects anxiety and depression in MS patients. Overall, the reviewed studies indicate that cannabis use may diminish spasticity and pain associated with MS, but chronic cannabis use has a detrimental effect on cognition in MS patients.

9. CANNABIS AND PARKINSON'S DISEASE

Parkinson's disease (PD) is a neurodegenerative brain disorder that decreases quality of life as it leads to bradykinesia (slow movements), rigidity, and tremors. Parkinson's has also been associated with non-motor symptoms that may

Table 1. Cannabis based treatments and expression of disease symptoms.

Disorder / Drug	Effect on Symptoms	Type of Study	Refs.
ALS			
Cannabis (smoked)	Appetite (↑), anxiety and depression (↓), Pain (↓), spasticity (↓), muscle relaxation (↑), drooling (↓), sleep (↑).	Survey	[101, 222]
THC (synthetic, dronabinol, drops)	Cramp intensity (=)	Clinical study	[223]
MS			
Cannabis (smoked)	Spasticity (↓), Pain (↓)	Clinical study	[117]
THC/CBD (nabiximols, oral spray)	Spasticity (↓), Pain (↓)	Clinical studies	[120, 224, 225, 226, 227]
THC (plant extract, oral capsule)	Muscle stiffness (↓)	Clinical study	[228]
THC (synthetic, dronabinol, capsule)	Spasticity (↓), Pain (↓)	Clinical study	[119]
THC (synthetic, nabilone, oral capsule, adjunct to gabapentin)	Pain (↓)	Clinical study	[229]
Parkinson's disease			
Cannabis extract (oral capsules)	Levodopa-induced dyskinesia (=), Parkinson's motor symptoms (=).	Clinical study	[142]
Cannabis leaves (oral leaves)	Rigidity (↓), bradykinesia (↓), resting tremor (↓), levodopa-induced dyskinesia (↓)	Survey	[138]
Cannabidiol	Quality of life (↑)	Clinical study	[230]
THC (synthetic, nabilone, oral capsule)	levodopa-induced dyskinesia	Clinical study	[141]
Alzheimer's disease			
THC (dronabinol, synthetic THC, oral capsule)	Agitation (↓), food intake (↑), sleep duration (↑)	Clinical study	[154]
THC (dronabinol, synthetic THC, oral capsule)	Disturbed behavior (↓), body weight gain (↑)	Clinical study	[155]
THC (dronabinol, synthetic THC, oral capsule)	Nocturnal motor activity (↓), agitation (↓), appetite disturbances (↓), irritability (↓)	Clinical study	[156]
THC (nabilone, synthetic)	Agitation (↓), resistance during care (↓)	Case report	[231]

Cannabidiol	All schizophrenia symptoms (Brief Psychiatric Rating Scale) (↓)	Case report	[232]
Cannabidiol	Positive and negative symptoms (↓)	Clinical study	[185]
Bipolar disorder	Not evaluated in clinical studies		

include psychosis, cognitive impairments, anxiety, and depression [131]. Parkinson's symptoms are at least partly due to the loss of dopaminergic neurons in the substantia nigra, which leads to a dysregulation of the extrapyramidal system. There is evidence that the endocannabinoid system is dysregulated in PD patients. It should be noted, however, that at this point it is not known if a dysregulation of the endocannabinoid system contributed to the development of PD or that PD leads to changes in the endocannabinoid system. Patients with PD have elevated levels of anandamide in the cerebrospinal fluid (CSF) and decreased CB₁ receptor levels in the basal ganglia [132, 133]. Animal studies suggest that drugs that target the cannabinoid system might diminish

PD's motor symptoms and slow disease progression. In a Marmoset PD model, THC improved both activity and hand-eye coordination [134]. The phytocannabinoid Δ⁹-tetrahydrocannabinol (THCV; CB₁ receptor antagonist and CB₂ receptor agonist) attenuates motor inhibition in the 6-hydroxydopamine (6-OHDA) model of PD [135]. Furthermore, the cannabinoids THC and CBD diminish the neurotoxic effects of 6-OHDA, and these effects might be mediated by their antioxidant or anti-inflammatory properties [136]. In the same animal model, a drug treatment (AM404) that enhanced anandamide levels also decreased PD symptoms [137]. Therefore, there is strong preclinical evidence that increasing cannabinoid tone diminishes PD symptoms.

Clinical studies suggest that cannabis may diminish the motor symptoms associated with PD [138, 139]. A small study with 22 patients showed that smoking cannabis improves motor symptoms such as resting tremor, rigidity, bradykinesia, and posture. In the same study, cannabis also decreased pain and improved sleep quality [139]. It has also been reported that CBD diminishes REM sleep behavior disorder in people with PD [140]. Furthermore, the synthetic cannabinoid receptor agonist nabilone attenuates levodopa-induced dyskinesia in PD patients [141]. Oral cannabis extract or CB₁ receptor blockade with rimonabant does not improve motor symptoms associated with PD [142, 143]. Overall, clinical studies suggest that cannabis, CBD, and synthetic cannabinoid agonists may diminish motor symptoms and pain associated with PD. At this point, only a few relatively small studies have been conducted and additional studies are needed before firm conclusions can be drawn about the effect of cannabis on PD. Furthermore, before medical cannabis can be recommended to PD patients, clinical studies are needed to investigate the effects of cannabis on non-motor systems (hallucinations, cognitive impairments) associated with PD.

10. CANNABIS AND ALZHEIMER'S DISEASE

Neurocognitive disorders are increasingly prevalent in the aging population. Alzheimer's disease (AD) is the most common age-related neurodegenerative disorder. Alzheimer's is truly a brain disease of the elderly; 4.3% of the 75-80 year olds and 28.5% of the 90 year olds has been diagnosed with AD [144]. The majority of AD patients are between the ages of 80 and 85. One of the first clinical symptoms is memory impairment and this is followed by language and behavioral problems. Alzheimer's is characterized by the loss of synapses and lesions that include plaques composed of an amyloid (A β) core and neurofibrillary tangles that mainly consist of hyperphosphorylated tau [145]. Alzheimer's has significant effects on the expression of CB₂ receptors in the human brain. One study reported a high level of CB₂ receptor expression in microglia associated with β -amyloid-enriched neuritic plaques while CB₂ receptors were not detected beyond the borders of the plaques or in the brains of healthy controls [146]. In contrast, AD does not lead to changes in CB₁ receptor levels [146, 147]. The therapeutic effects of the cannabinoids are hypothesized to be due to their antioxidant, anti-inflammatory, and neuroprotective effects, which may diminish the effects of beta-amyloid toxicity [148, 149]. Animal studies indicate that compounds that elevate endocannabinoid levels decrease the toxic effects of beta-amyloid peptide [150]. Furthermore, studies with an AD mouse model (amyloid-protein precursor/presenilin 1) show that a THC-CBD mixture decreases amyloid beta levels and reverses learning impairments [151]. In the same animal model, a CB₂ receptor agonist improves cognition, decreases tau hyper-phosphorylation, and decreases the expression of pro-inflammatory cytokines [152]. Therefore, cannabinoid based treatments could potentially slow the progression of AD.

Cannabis might also be effective for the treatment of late stage AD symptoms [153]. Several studies have investigated the effects of dronabinol, which is a synthetic version of

THC, in late stage AD patients. These studies showed that dronabinol improves food intake, sleep duration, circadian rhythm, and decreases agitation in late stage AD patients [154-157]. The patients received dronabinol for only a short period of time and it was not investigated if dronabinol affects memory and cognition. Therefore, additional studies are needed to investigate the long-term cognitive effects of THC or THC-like compounds in AD. Overall, these studies suggest that cannabis may slow down the progression of AD and decreases some its symptoms. However, additional insight into the effects of cannabis on cognition in AD patients is needed.

11. CANNABIS AND BIPOLAR DISORDER

Bipolar disorder is characterized by major depressive and manic episodes or episodes with mixed depressive and manic symptoms [55]. Cannabis is the most often used illicit drug in patients with bipolar disorder and people with bipolar are seven times more likely to use cannabis than controls [158, 159]. It was initially believed that cannabis might have some therapeutic effects in bipolar patients, but this is not supported by recent findings [160]. Cannabis use is associated with an early age of onset of bipolar disorder, increased severity, and increased disability [161-163]. Cannabis use in patients with bipolar also further increases the risk for suicide [159]. A prospective study showed that cannabis use is associated with a decrease in long-term remission for bipolar disorder [164]. A large epidemiological study indicated that cannabis use increases the risk for manic symptoms [165]. Cannabis also worsens global functioning in patients with bipolar disorder [166]. There is no indication for CB₁ receptor level changes in people with bipolar disorder [167]. However, a single nucleotide polymorphisms in the CB₂ receptor gene (SNP, rs41311993, 524C>A; Leu133Ile) is more common in people with bipolar disorder than in healthy controls [168]. This gene has been associated with CB₂ receptor stability and therefore changes in the CB₂ receptor could possibly contribute to the development of bipolar disorder. Finally, cannabis may alter the metabolism of medications prescribed for bipolar disorder. Overall, there are no clear indications that bipolar patients derive a benefit from cannabis use.

12. CANNABIS AND SCHIZOPHRENIA

Schizophrenia is a mental disorder that typically presents in late adolescence or early adulthood and is among the top ten leading causes of disability in the world [169]. Schizophrenia is characterized by three core symptom groups: positive symptoms (hallucinations, delusions, grandiosity, paranoia, and suspiciousness), negative symptoms (blunted affect, social avoidance, poor rapport, lack of motivation, lack of spontaneity, and emotional withdrawal), and cognitive dysfunction [170]. Cannabis use is more common among people with schizophrenia than in the general population [171]. In Western countries, 10%20% of the general population use cannabis while 30%50% of people with schizophrenia use cannabis [172, 173]. There are several possible explanations for this. Cannabis might be more rewarding in people with schizophrenia, it might compensate for brain deficits, or people with schizophrenia have less control over drug use.

There is extensive evidence that the endogenous cannabinoid system is dysregulated in people with schizophrenia. Anandamide levels are elevated in the CSF of schizophrenia patients [174]. Furthermore, post mortem studies have shown an increase in CB₁ receptor levels in schizophrenia patients, especially in the dorsolateral prefrontal cortex, pons, cingulate cortex, and nucleus accumbens [175-180].

There is extensive evidence that cannabis use increases the risk for schizophrenia [181]. A large study with 50,087 Swedish men showed that cannabis users are 7 times more likely to develop schizophrenia than people who do not use cannabis [182]. This is in line with another large study that reported an increase in cannabis use in people in the year before they were first diagnosed with schizophrenia [183]. It should be noted that the harmful effects of cannabis depend on the THC:CBD ratio [181]. THC increases the risk for psychosis but CBD diminishes the effects of THC and even has antipsychotic effects in people with schizophrenia [184, 185]. During the last decades there has been an increase in THC levels in cannabis and CBD levels have remained the same. From 1980 to 2008, the THC concentration in cannabis products increased from 3 to 9 % while CBD levels remained stable at 0.4 % [186]. This suggests that cannabis use is more likely to lead to psychiatric illness and in particular in people who are genetically predisposed to develop schizophrenia [187, 188].

It is interesting to note that electroencephalography (EEG) studies have revealed that chronic cannabis use disrupts the brain's ability to generate synchronized neuronal oscillations (beta and gamma band activity) [189, 190]. Neuronal oscillations play a critical role in coordinating the activity between brain sites and a disruption in synchronized neuronal activity can affect a wide range of brain functions. Chronic cannabis use induces similar disruptions in neuronal synchronization as those observed in people with schizophrenia [191]. Therefore it has been suggested that cannabis' effect on neuronal oscillations may contribute to the development of schizophrenia (for an extensive review on this topic see [191, 192]).

Cannabis use has a detrimental effect on some schizophrenia symptoms. Cannabis use worsens positive symptoms (mainly hallucinations), leads to poor treatment outcomes, and increases the risk for relapse after a period of remission [193-196]. It has been suggested that cannabis use disrupts the endogenous cannabinoid system in the prefrontal cortex and thereby induces changes in glutamate and GABA release, which contributes to the development of schizophrenia [197]. The effects of cannabis use on dopaminergic systems might also play a role in the development of schizophrenia. The catechol-O-methyltransferase (COMT) gene plays an important role in the breakdown of dopamine, and a valine to methionine mutation (Val¹⁵⁸Met) in this gene leads to a decrease in dopamine metabolism [198]. It has been suggested that this mutation by itself does not increase the risk for schizophrenia but increases the risk for schizophrenia in people who use cannabis [199]. There is some evidence that cannabis use may diminish the negative symptoms of schizophrenia. Several small studies suggest that a majority of people with schizophrenia use cannabis to diminish negative symptoms [200, 201].

The adverse effects of cannabis use might be more severe for people with schizophrenia than for healthy controls [202]. Cannabis use leads to a larger decrease in gray matter volume in people with schizophrenia than in healthy controls [202]. Interestingly, the decrease in gray matter volume was greatest in brain areas with high levels of CB₁ receptors such as the dorsolateral prefrontal cortex and the anterior cingulate cortex [203]. Despite the negative effect of cannabis use on gray matter volume in people with schizophrenia, several studies suggest that people with schizophrenia who use cannabis have better cognitive function than people with schizophrenia who do not use cannabis [204-208]. However, it has also been reported that people with schizophrenia who use cannabis have worse cognitive function than patients who do not use cannabis [209]. It should be noted that it might be possible that cannabis use does not improve cognition but that patients who use cannabis have less severe cognitive impairments than non-cannabis users. It has been hypothesized that cannabis use in vulnerable young people can lead to a type of schizophrenia that is characterized by psychosis and only mild cognitive impairments [208, 210]. In contrast, people who do not use cannabis and develop schizophrenia have psychotic symptoms and also severe cognitive impairments.

The endogenous cannabinoid system has been identified as a target for the treatment of schizophrenia [169]. Since the 1970's it has been suggested that the cannabinoid CBD has antipsychotic properties [211]. In the prepulse inhibition (PPI) paradigm in healthy humans, a weak pre-pulse inhibits the strong startle response caused by an intense stimulus (e.g., loud noise) [212]. However, this inhibitory response is disrupted in people with schizophrenia (*i.e.*, impaired PPI) [213]. Drugs that induce schizophrenia-like symptoms in humans such as the NMDA receptor antagonists MK-801 and ketamine also disrupt PPI in rats [212]. A wide range of antipsychotic drugs diminish the PPI impairment induced by NMDA receptor antagonists [214]. Interestingly, recent studies suggest that CBD also attenuates the PPI impairment induced by the NMDA receptor antagonist MK-801 or amphetamine [215-217]. This suggests that cannabis might mediate some effects that resemble those of antipsychotic drugs.

Taken together, cannabis has a complex effect on schizophrenia and the effect might depend on the THC and CBD levels in cannabis. Regular use of cannabis with high levels of THC has detrimental effects on gray matter and positive symptoms of schizophrenia. On the other hand, cannabis does not seem to worsen the cognitive symptoms associated with schizophrenia and might diminish some of the negative symptoms. Cannabis with high levels of CBD and low levels of THC could possibly prevent some of the deficits in sensory motor gating in patients with schizophrenia.

CONCLUDING REMARKS

The goal of this article is to provide an overview of the benefits and negative mental health effects of cannabis use by people with a neurological disorder, bipolar disorder, or schizophrenia. The reviewed studies indicate that cannabis use has complex effects and its effects depend on the specific brain disorder for which it is being used. Clinical studies

provide evidence that cannabis might diminish some of the symptoms associated with PD, ALS, and MS. Cannabis use may decrease spasticity and pain in people with MS, decrease tremor, rigidity, and pain in people with PD and improve the quality of life of ALS patients by improving speech and swallowing, and decreasing spasticity. There is also evidence that people with schizophrenia use cannabis to diminish some of the symptoms of their disorders. Cannabis use might temporarily improve the negative symptoms of schizophrenia. There is currently no evidence that people with bipolar disorder derive any benefit from cannabis. The acute and chronic effects of cannabis use in the elderly are poorly understood. Aging is associated with physiological and neurological changes that may affect the response to cannabis. Changes in lean and fat mass may affect the volume of distribution of THC, and impairments in THC clearance may lead to elevated drug levels and increased drug interactions [218, 219]. Cannabis has large effects on neurotransmitter release in the hippocampus and prefrontal cortex and these brain sites also undergo changes during aging [220, 221]. Because cannabis use in the elderly is on the rise, clinical and preclinical studies are urgently needed to investigate the physiological and neurological effects of cannabis use in the elderly.

Taken together, many people with PD, ALS, MS, and schizophrenia smoke cannabis to diminish the symptoms associated with their disorder. It should be noted that while short term use of cannabis could diminish some of the symptoms of these disorders, chronic cannabis use can have adverse long-term effects. It has been firmly established that chronic cannabis use can lead to the development of dependence, cognitive impairments, which increases the risk for depression and anxiety. Cannabis also has adverse physiological effects such as increasing the risk for lung diseases and has negative effects on male and female reproductive systems. Overall, acute cannabis use might provide temporary relief from a wide range of symptoms associated with neurological and psychiatric disorders, but prolonged heavy cannabis use might have adverse effects on mental and physiological health.

CONFLICT OF INTEREST

The authors confirm that this article content has no conflicts of interest. One of the authors (AB) was supported in part by an NIH grant (DA039349) when working on this review.

Continued cannabis use at one year follow up is associated with elevated mood and lower global functioning in bipolar I disorder

Levi Roestad Kvitland^{1*}, Ingrid Melle¹, Sofie Ragnhild Aminoff^{1,2}, Christine Demmo¹, Trine Vik Lagerberg¹, Ole Andreas Andreassen¹ and Petter Andreas Ringen³

Abstract

Background: There is limited knowledge about how environmental factors affect the course of bipolar disorder (BD). Cannabis has been proposed as a potential risk factor for poorer course of illness, but the role of cannabis use has not been studied in a first treatment BD I sample.

Methods: The present study examines the associations between course of illness in first treatment BD I and continued cannabis use, from baseline to one year follow up. Patients (N = 62) with first treatment DSM-IV BD I were included as part of the Thematically Organized Psychosis study (TOP), and completed interviews and self-report questionnaires at both baseline and follow up. Cannabis use within the last six months at baseline and use between baseline and follow up ("continued use") was recorded.

Results: After controlling for confounders, continued cannabis use was significantly associated with elevated mood (YMRS) and inferior global functioning (GAF-F) at follow up. Elevated mood mediated the effect of cannabis use on global functioning.

Conclusions: These results suggest that cannabis use has clinical implications for the early course of BD by increasing mood level. More focus on reducing cannabis use in clinical settings seems to be useful for improving outcome in early phase of the disorder.

Keywords: Cannabis, Bipolar

Background

The prevalence of substance use in bipolar disorder (BD) is high [1-3] with cannabis being the most commonly used drug [3]. This is of interest since cannabis has been indicated as a risk factor for developing BD [4-6]. Cannabis use has also been associated with severity indicators in chronic BD, including earlier age of onset for the first affective episode [7-13], increased risk of manic episodes [4,14], prolonged duration of episodes [4-6], switch to mania in depressed individuals [15] and increased suicidal ideation and suicide risk [16,17], in addition to a more severe general course of the illness

[18-20]. Cannabis abuse has furthermore been shown to predict poorer medication adherence in BD patients [21]. Most of these studies have included patients mainly in the chronic phase of illness after multiple mood episodes, and we cannot rule out the possibility that these findings are biased by a selection of patients with a more severe course, possibly being more prone to self-medication with cannabis.

Longitudinal studies of BD samples recruited at first treatment are very few. Two follow-up studies of first time hospitalized patients with BD I indicate that patients with cannabis use spend more time in affective episodes and exhibit more rapid cycling over the first year of treatment [22], and that periods with cannabis use coincide with periods with manic and hypomanic episodes over a mean follow-up period of 4.5 years [6]. Both studies suggest that continued cannabis use in patients with recently

diagnosed BD has a negative impact on the course of illness. Since these two studies are based on hospitalized patients in two university hospitals with well-acknowledged BD research groups, their patient samples might be biased towards patients with a higher severity of illness.

The current study is based on patients recruited during their first adequate treatment for a manic episode from both inpatient and outpatient services in a catchment area based treatment system, and subsequently followed up after one year. We here aim to ascertain the rate of continued cannabis use over the first year of treatment in patients with recent onset BD and identify clinical outcomes associated with continued use, by exploring the relationship between cannabis use patterns over the follow-up period and clinical status at one year follow-up.

Methods

One hundred and one patients with recent onset DSM-IV [23] BD-I were recruited consecutively from 2003 until 2013 from in- and outpatient units at all major hospitals in the Oslo area as a part of The Thematically Organized Psychosis (TOP) Study at the University of Oslo and Oslo University Hospital. The patients had both psychotic and non-psychotic forms of bipolar disorder. Out of these, 62 patients (63%) participated in a personal follow-up examination after one year. Of the 39 patients that did not attend the follow-up, 20 had decided to withdraw from the study, 18 had moved and were impossible to reach and one patient had died. There were no significant differences in baseline demographic and clinical characteristics between follow-up participants and study drop-outs.

The full inclusion criteria were as follows: meeting DSM-IV diagnostic criteria for BD I, being within the first year of receiving adequate treatment for a manic episode, age between 17 – 65 years. Patients were excluded from the study if they had pronounced cognitive deficits (IQ lower than 70), a neurological disorder, moderate/severe head injury, or were not able to speak a Scandinavian language or to give written informed consent. The patients were given both oral and written descriptions of the study before consenting to participate. The study was approved by the Regional Committee for Medical Research Ethics and the Norwegian Data Inspectorate.

Assessments

Patients referred to the study were interviewed by trained research fellows (psychologists and medical doctors). Diagnosis and episodes of illness were determined at baseline using the Structural Clinical Interview for DSM-IV Axis I disorders (SCID module I, chapters A-E) [24], with the aid of medical charts. For more details, see

[1]. Patients were interviewed in detail, based on a common semi-structural interview form, about substance use in the six months prior to inclusion and in the follow-up period. Forty-seven patients did not use cannabis at any point during this period, 7 patients used cannabis at baseline but not at follow-up, 2 patients started to use cannabis in the follow-up period while 6 patients used cannabis at both time points. Based on these data, the sample was divided into those with continued cannabis use (defined as any cannabis use at both time points, $n = 6$) and those without continued use (the rest of the patient group, i.e. both non-users and those using at one but not both time-points, $n = 56$). The continued use patients reported an average use of cannabis at both baseline and follow up of 2–3 times a week.

Global functioning was measured using the functioning part of the Global Assessment Functioning scale split version (GAF-F) [25,26]. Cut-off for functional recovery was set at a GAF score of 61 [27]. Current depressive symptoms were assessed with the Inventory of Depressive Symptoms – Clinician rated (IDS-C) [28], current manic symptoms were rated with the Young Mania Rating Scale [29], and current psychotic symptoms were assessed with the positive symptoms subscale of the Positive And Negative Syndrome Scale (PANSS) [30] at both time points.

Medication and socio-demographic data were obtained by clinical interviews supported by medical chart information. Premorbid functioning was measured with the Premorbid Adjustment Scale (PAS), divided into academic and social functioning [31]. Childhood premorbid functioning was chosen due to the young age of the sample. Symptomatic recovery was defined as a lack of affective and psychotic symptoms the previous 6 months (PANSS-P less than 4 and no mood episodes as verified by the SCID).

All clinical personnel completed a training program in diagnostics (SCID) and symptom rating (PANSS), based on the training program at the University of California, Los Angeles. They also attended bi-weekly diagnostic consensus meetings led by experienced clinicians in the field of severe mental illness diagnostics. The inter-rater reliability was good with an overall kappa-score of 0.77 (95% LI [0.60, 0.94]) for diagnoses and ICCs of 0.82 [32] for PANSS positive symptoms and 0.86 for the GAF [1].

Statistical analyses

The statistical package for the social sciences (SPSS) version 20.0 (SPSS Inc, Chicago, IL, USA) was used for statistical analyses. Group comparisons for continuous variables were evaluated with independent sample T-tests, and group comparisons for dichotomous data were evaluated with Chi-squared tests or Fischer's exact tests as appropriate. Level of significance was set to $p < 0.05$,

two-sided. The overall effects of continued cannabis use on key baseline measures and on outcome measures at one-year follow-up were first evaluated with a multivariate analysis of variance (MANOVA) with continued cannabis use as the fixed factor. Outcome dimensions indicated to be different between continued cannabis users and the rest of the patients through the MANOVA, were followed up with a series of hierarchical block-wise multiple linear regressions analyses controlling for possible confounders of this association. In addition to sex and age, variables with strong correlations with both continued use of cannabis and the outcome measure were selected as possible confounders, based on a bivariate analysis. Premorbid academic functioning (PAS) was added to the models in order to investigate the role of premorbid traits in the associations. Hence the baseline measures of YMRS and GAF-F were entered in the first step, age and gender in the second, premorbid functioning in the third step and continued cannabis use in the fourth step of the model. There were no associations between the outcome measures and drug treatment adherence on continued cocaine, amphetamine or alcohol use. These factors were thus not added to the model. Information about patient hospitalisations were not collected, and thus not corrected for. Since global functioning (GAF-F) is highly correlated with mood symptoms, a separate analysis was performed with YMRS at one-year follow up in the second-to-last step. To evaluate the possibility of outliers mediating the main effect, a scatterplot of GAF-F by YMRS scores was performed and examined. Finally, in order to investigate if current cannabis use influenced the results, follow-up analyses were done removing patients with cannabis use at one time-point, but not the other,

from the no continued cannabis use group, thus contrasting the continuous cannabis users from the non-users.

Results

The mean age of the sample was 30.9 years (SD: 9.9 years), and 37 patients (60%) were female. Lifetime cannabis use was reported in 52% of the sample. There were more males in the continued use group ($p < .05$) than in the group without continued use. There were no significant differences in key clinical characteristics at baseline, including YMRS and GAF-F levels. There was a negative association between YMRS and GAF-F, indicating that patients with high levels of elevated mood had poorer functioning. The groups did not differ in any other features (Table 1), including the number in symptomatic remission at follow-up (3 (50%) in the continued cannabis use group vs 38 (68%) in the no continued cannabis use group, $p = .601$). Four (67%) of the patients in the continued cannabis use group had not reached a level of functional recovery compared to 19 (29%) patients in the group without continued use; however, this difference was not statistically significant ($p = .390$).

The MANOVA indicated that the continued use group experienced significantly elevated mood, as measured by the YMRS, and significantly lower global functioning as measured by the GAF-F compared to the group without continued use. The effect size for the difference in GAF-F was high. There were however no significant differences in the levels of depression or psychotic symptoms between the groups (Table 2). Repeating the analyses, this time only contrasting continued cannabis users with non-users, gave the same findings.

The bivariate analysis showed a correlation between continued cannabis use and sex ($-.287$ $p < .05$), and a

negative correlation between YMRS at baseline and GAF-F at baseline (-.347 p < .01), and between sex and premorbid academic functioning (.357 p < .01). In the regression analysis of elevated mood (Table 3), the initial level of elevated mood contributed significantly and with an even stronger association between elevated mood at follow-up and continued cannabis use than indicated by the bivariate analysis. After controlling for possible confounders of the relationship between global functioning at follow-up and continued cannabis use (Table 4), we found that baseline global functioning and continued cannabis use both contributed significantly in the final model (4A). When correcting for level of elevated mood (YMRS scores) at the second to last step, the impact of continued cannabis use was reduced to a trend level of significance (4B). Gender, age and premorbid functioning (as represented by the childhood level of academic functioning in the presented final model) did not contribute significantly to any of the models. The scatterplot did not indicate any outliers (Figure 1).

Discussion

The main result of the current study is that continued cannabis use had a statistically significant association with elevated mood but not with depressive or psychotic symptoms, over a one year follow-up period in a sample of first treatment BD-I patients. This relationship was not explained by differences in age, gender, premorbid functioning or symptoms at baseline. Continued cannabis use also had a significant association with poorer global functioning, but this association seemed to be mediated by the elevated mood levels.

The finding of an association between continued cannabis use and elevated mood confirms findings from the two existing first-hospitalization samples in addition to several multi-episode samples [2,6,14,19,20,22,33,34] and supports the hypothesis that cannabis use in these groups is particularly associated with a higher risk for elevated mood [3-6]. The association was not fully explained by baseline levels of mood symptoms. Furthermore, premorbid functioning did not contribute to the explanation, contrary to findings in schizophrenia [35,36].

The finding of worse global functioning in the continued cannabis group is in line with previous studies of multi-episode inpatients with BD [20,33] and negative effects of continued cannabis use in general in BD [37,38]. Our findings indicate that the reduction in global function is partly mediated by elevated mood. The lack of an association between continued cannabis use and depression is in line with a recent systematic review

and meta-analysis of mainly multi-episode samples [39]. The lack of an association with psychotic features is slightly surprising given the extensive amount of studies on the relationship between cannabis and psychosis risk [40-43], but we cannot rule out a type II error due the low number of continued cannabis users, and this finding warrants further research. The YMRS contains items of psychotic manic symptoms [29]. The lack of an association between continued cannabis use and psychotic features could strengthen the notion of a primary association to mood symptoms since this indicates that the higher YMRS scores are not mainly based on psychosis-related items [29], a view supported by the findings of an association between poorer global functioning and elevated mood also at baseline. The effect of continued cannabis use on outcome measures after 12 months did not seem to be explained by premorbid traits, further strengthening a hypothesis of a direct association between cannabis use and outcome.

Strengths and limitations

The main strength of the study is the well characterized and relatively large prospective sample of patients followed during one year after the first treatment for mania in BD-I. The catchment area based consecutive sampling procedure including both in-and outpatient treatments services gives the sample a high degree of representativity.

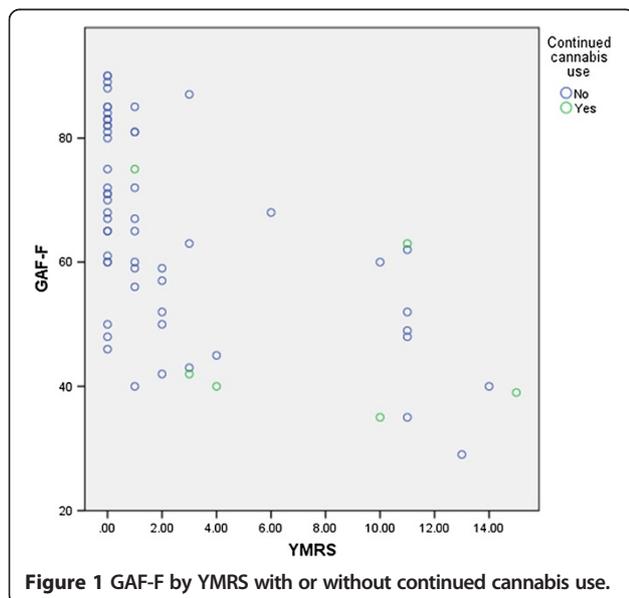

Figure 1 GAF-F by YMRS with or without continued cannabis use.

The low number of continued use patients is our main limitation, but is unlikely to induce type I errors since results did not appear to be driven by outliers. However, type II errors cannot be ruled out. This is a longitudinal study with two cross-sectional points of assessment; we thus lack reliable data of temporal sequencing of cannabis use and mood symptoms in the follow up period. It is thus not possible to conclude with certainty which phenomenon that drives the other. Information about cannabis use was based on self-reports. Self-reports of substance use have however been shown to have considerable validity in earlier studies [44–46].

Conclusion

In conclusion, the current study showed that patients with continued cannabis use throughout the first year of treatment of BD I were at higher risk for elevated mood and worse global functioning compared to the patients without continued cannabis use. The poorer functioning seemed to be, at least in part, mediated by the elevated mood. These findings indicate that continued cannabis use, also below the threshold for a DSM-IV diagnosis of abuse or dependency, may have important clinical implications for patients suffering from BD-I. Future research should aim at replicate these findings in a larger sample to minimize the risk of type II errors.

The medicinal use of cannabis in the UK: results of a nationwide survey

M. A. WARE,¹ H. ADAMS,² G. W. GUY²

Pain Centre,¹ McGill University Health Centre, Montreal, Canada; GW Pharmaceuticals plc,² Salisbury, UK

SUMMARY

The use of cannabis for medical purposes is a controversial but an important topic of public and scientific interest. We report on the results of a self-administered questionnaire study conducted in the United Kingdom between 1998 and 2002. The questionnaire consisted of 34 items and included demographic data, disease and medication use patterns and cannabis use profiles. Subjects were self-selected; 3663 questionnaires were distributed and 2969 were returned [1805 (60.9%) women, mean age 52.7 years (SD 12.7)]. Medicinal cannabis use was

reported by patients with chronic pain (25%), multiple sclerosis and depression (22% each), arthritis (21%) and neuropathy (19%). Medicinal cannabis use was associated with younger age, male gender and previous recreational use ($p < 0.001$). While caution must be exercised in interpreting these data, they point to the need for clinical studies of cannabis and cannabinoids with standardised and quality-controlled products.

Keywords: Cannabis; chronic diseases; epidemiology; pain; therapeutics

INTRODUCTION

The potential use of cannabis and related derivatives (cannabinoids) for medical purposes is currently under intense scientific investigation. Research efforts are predominantly focused on exploring the cellular and neurophysiological effects of agonists and antagonists on endogenous cannabinoid receptors in animal models, and a novel endogenous cannabinoid pathway is being described with roles in movement, pain, appetite and cardiovascular control. This scientific knowledge is emerging at the same time as increasing numbers of patients' reports of the effective use of herbal cannabis. It is therefore plausible that patients using cannabis as a medicine may be exploiting this novel neurophysiological signalling system. Further information on the alleged effects of cannabis may guide the development of cannabis-based medicines for symptoms of chronic diseases.

Few data are available on the patterns and prevalence of the medicinal use of cannabis. A large number of case reports of effective medicinal cannabis use have been published in peer-reviewed journals, including central thalamic pain and dys-

tonia (1), proximal myotonic myopathy (2), familial Mediterranean fever (3) and multiple sclerosis (MS) (4). In a telephone survey of adults in 2508 households in Ontario, Canada, 49 people (1.9%) reported using cannabis for a medical reason in the past year, mainly for pain or nausea (5). Wide-ranging effects of cannabis are noted in large case series: 50 self-selected medicinal cannabis users reported use for a variety of conditions including HIV/AIDS-related problems, chronic pain, depression, anxiety, menstrual cramps, migraine and narcotic addiction, as well as everyday aches, pains, stresses and sleeping difficulties (6). In a survey of 53 UK and 59 US patients with MS, cannabis was reported to affect spasticity, chronic pain of extremities, acute paroxysmal phenomena, tremor, emotional dysfunction, anorexia/weight loss, fatigue states, double vision, sexual dysfunction, bowel and bladder dysfunctions, vision dimness, dysfunctions of walking and balance and memory loss (7). In a survey of 15 chronic pain patients who admitted to using cannabis medicinally, pain, sleep and mood were most frequently improved, while doses used were modest (8).

Several prospective studies among specific patient populations have now been published. In a survey of ambulatory patients with HIV/AIDS in three HIV clinics in eastern Canada, 35% reported current use of cannabis (9). This is higher than an estimated prevalence of 30% in British Columbia (10) and 15–23% in California (11,12). In a survey of 220 patients with chronic non-cancer pain, 10% reported continuing medicinal use (13). The prevalence of medical cannabis use among patients with MS has been estimated at 14% (14). Large population-based surveys are needed to further describe the characteristics of medicinal cannabis users and their reasons for use.

METHODS

A cross-sectional survey was conducted to collect data from self-selected medicinal cannabis users in the UK. Patients were identified by word of mouth and through patients' support groups. A questionnaire instrument was developed for postal distribution and self-administration. A stamped addressed envelope was provided to improve response rates. The questionnaire consisted of 34 items including binary (yes/no) responses, Likert scales and open-ended questions. Information collected included demographics (age and gender), disease and symptom status and patterns of cannabis use both medicinally and non-medicinally. Patients were asked to select their diseases and/or symptoms from a list, and space was provided for additional information. Disease and symptom information was accepted as reported by the patient in the questionnaire responses, and no attempt to validate these diagnoses was made.

Data were single-entered into a relational database (MICROSOFT ACCESS 2000). Missing data and outliers were excluded from the analysis; these accounted for less than 5% of the total responses for the variables of interest. Data were imported and analysed using a standard statistical package (STATA version 8, Houston, TX, USA). Categorical data were compared using Pearson's χ^2 -tests. Ordered categorical data were analysed using Mantel-Haenzel tests. Significance was set at the 95% level, and all tests were two sided. The database was registered with the Data Protection Act 1998.

RESULTS

Over the period 1998–2002, 3663 questionnaires were distributed, and 2969 were returned (81% response rate).

Demographic Information

The mean age of the 2969 subjects was 52.7 years (SD 12.7), of whom 1805 (60.7%) were female. MS was the most common disease, reported by 1753 subjects (59%), while 1280 reported neuropathy (43%), 1125 reported chronic pain (33%) and 777 reported arthritis (26%). There was considerable overlap among these conditions.

Cannabis Use Patterns

Ever Use of Cannabis for Medicinal Purposes. A total of 947 (31.9%) subjects reported ever having used cannabis for medical purposes. The remainder were assumed to be never users. The median duration of medicinal use among 616 subjects for whom the duration of use data were available was 4 years [interquartile range: (2–7)]. The demographic profile of medicinal cannabis users is summarised in Table 1, compared to the never users. Medical cannabis use was associated with male

Table 1 Characteristics of ever-medicinal cannabis users

Variable	Medicinal cannabis use				Total	p-Value
	Ever	%	Never	%		
Age (years)						<0.001
<45	395	55	325	45	720	
45–50	171	39	265	61	436

No	575	28	1454	72	2029	

gender, younger age and non-medical use ($p < 0.001$ for all tests).

Continuing Use of Cannabis for Medicinal Purposes. Of those who had ever used cannabis medicinally, 543 (18.3% of total sample) persons reported continuing to use cannabis for medical purposes, while 403 (13.6%) said they no longer used it. The 30 diseases or symptoms for which continuing medical cannabis use was most common are summarised in Table 2, along with the median duration of use for each condition. As noted above, some subjects reported cannabis use for more than one purpose. Reasons given for no longer using cannabis for medical purposes are also summarised in Table 3.

Patterns of Cannabis Use

Frequency of Use. Patients were asked how many days per week they usually used cannabis for medicinal purposes. Of 946 responses, 333 (35%) used 6–7 days per week, 219 (23%) used 3–5 days per week, 139 (15%) used 1–2 days per week, 73 (8%) used less than 1 day per week and 182 (19%) reported 'other'.

Reasons for Trying Cannabis. When asked why they decided to try cannabis for medical purposes, 585 said it was because a friend, family member or acquaintance had suggested it, 519 said they read a book or article about cannabis, 177 said they had been prior users and found out 'by accident', 152 said their doctor had suggested it and 128 gave other reasons.

Modes of Administration. Smoking was the most common means of administration, reported by 777 (82%) of medical cannabis users. The modes of administration were: eating was reported by 406 (43%) subjects, tea by 267 (28%), sublingual spray by 20 (2%) and 118 (12%) used other means.

Amount of Cannabis Used. Nine hundred and sixteen subjects reported amounts of cannabis used for medical purposes. Of these, 18 used 10 or more grams per day, 60 used 5–9 g

Table 2 Thirty diseases and symptoms for which continuing cannabis use is most commonly reported

<i>Disease/symptom</i>	<i>Number</i>	<i>%</i>	<i>Median years of use (interquartile range)</i>

per day, 107 used 3–4 g per day, 249 used 1–2 g per day, 153 used several grams per week, 107 used several grams per month and 222 used only occasionally when needed.

Change in Amount Used. Seven hundred and seventy-seven subjects reported on whether the amounts of cannabis needed to control symptoms had changed over time since they had started; 54 said they needed much more, 171 needed a little more, 514 said it was about the same, 31 said they needed less and seven said they needed much less.

Table 3 Reasons for stopping medicinal cannabis

<i>Reason</i>	<i>Number of responses</i>	<i>% of number stopping</i>
Unable to find supply	207	7
Could not afford	169	5.7
Did not like side effects	40	1.3
Did not work	25	1
Did not like 'high'	20	0.7
Other	173	5.8

Perceived Effects of Cannabis

Overall Effectiveness. Of 948 reported users, 648 (68%) reported that cannabis made their symptoms overall much better, 256 (27%) said a little better, 36 (4%) said no difference and eight subjects said a little worse (four subjects) or much worse (four subjects).

Effectiveness Compared to Other Medications. When asked how cannabis compared to other medications overall, 412 of 916 subjects (45%) said it worked much better than prescribed medications, 261 (28%) said it was somewhat better and 45 (5%) said it was about the same; only 27 subjects said that prescription medicines worked better than cannabis (18 somewhat better and nine much better). One hundred and seventy-one (19%) subjects said it was impossible to tell.

Side Effects Compared to other Medications. When asked to compare the undesirable effects of cannabis to those of prescribed medicines, 872 subjects responded, of whom six found that cannabis produced much worse side effects, 23 found somewhat worse side effects and 54 said the side effects were about the same. Two hundred and sixty-four (30%) subjects stated that side effects of prescribed medicines were somewhat worse and 294 (34%) said they were much worse. Two hundred and thirty-one (26%) stated that it was impossible to tell.

Effects on Other Medication Use. Of the 909 subjects responding to this question, 374 stated that their use of cannabis had changed their use of other medications, while 521 said it had not. Fourteen were not coded.

Return of Symptoms on Stopping. Of the 876 subjects responding, 673 said their symptoms returned or got worse when they stopped using cannabis, and 203 denied any worsening on stopping cannabis.

Non-medicinal Cannabis Use. Five hundred and thirty-nine (18%) subjects reported ever having used cannabis for reasons not related to disease (assumed to mean non-medical use), while 2029 subjects stated that they had never used cannabis for non-medical purposes. Medicinal cannabis use was significantly associated with recreational use ($p < 0.001$) (Table 1).

DISCUSSION

To our knowledge, this is the most extensive survey of medical cannabis use among chronically ill patients conducted to date. Before any conclusions may be drawn, however, the potential limitations of the study must be addressed.

The sample of patients recruited for this study was not selected through any systematic procedure or by random recruitment. The questionnaire was distributed primarily by word of mouth to patients and patients' support groups, and

the high rate of response (81%) suggests that this was a highly motivated population. Therefore, there is potential for a strong selection bias to inflate the estimated of reported effectiveness of cannabis (assuming the responses reflect mainly 'successful' cannabis users) and to minimise the adverse effects. The subjects were chronically ill patients with a range of comorbid conditions, and the need for additional symptom relief may explain the self-reported on-going medical cannabis use prevalence of 18%. However, this is not out of the range of other prevalence surveys in MS (14%) (14) and chronic pain (10%) (13). However, because of the potential for bias, we caution against drawing any conclusions with respect to the efficacy of cannabis from this study. It is important, however, to recognise these results as contributing to our understanding of what the perceived effects of cannabis are among these subjects.

Most of the awareness of this study was achieved by word of mouth between patients, spread by patients putting notes about the project into their various newsletters/magazines, etc. MS patients have a large active patient support network in the UK and may have raised the awareness of this questionnaire study. This would have the effect of weighting the sample towards this population. There is a noticeable paucity of data from subjects with HIV/AIDS and cancer, populations which are also associated with therapeutic cannabis use. We believe that at the time of analysis, awareness of this questionnaire was not very high among the HIV/AIDS and cancer 'network groups'.

The presence of a significant selection bias may also have the effect of excluding cannabis non-responders, persons who have tried cannabis and for whom it has not been of any use. This is a difficult group to target, and only randomly selected large-scale surveys would be able to identify the extent of this. Such studies usually rely on postal distribution and often have low response rates. Detailed estimates of response to any medication are best captured in formal clinical trials.

In spite of these limitations, we believe that this survey is the best available assessment of current medical cannabis use in the UK. Some key messages emerge from the findings. Our study found that 68% of users had found cannabis to make symptoms overall much better and 27% a little better, suggesting that over 95% of the patients using cannabis had obtained some benefit from cannabis. In spite of this, about half of these subjects had not continued to use cannabis. The reasons for this are illuminating: the lack of supply or cost were more commonly reported as reasons for stopping compared to ineffectiveness or intolerable side effects. This lends support to ongoing efforts to make cannabis-based medicines available for research purposes and lends credence to changes in public policy on compassionate grounds.

The study has found that ever use of medicinal cannabis is significantly associated with young age, male gender and non-medical use. This relationship has been found in other surveys

(13) and may represent a general bias towards medical cannabis use in this population. Alternatively, the association may be explained by factors which make clinical response to cannabis more favourable in this population. It is known that males and females respond differently to cannabis (15), and younger age groups may be better able to find and use cannabis as more socially 'acceptable'. This may particularly be true of the recreational users who would more likely have discovered medical use by 'accident' (19% of ever-medical users).

Finally, recent randomised controlled clinical trials have pointed to potential therapeutic benefits of cannabinoids for patients with MS (16) and chronic neuropathic pain (17). This suggests that patients' reports of the effectiveness of cannabis should not be discounted as purely anecdotal, but rather could serve as a valid indicator of target diseases and symptoms for cannabinoid drug development.

In conclusion, we believe that this survey presents a broad picture of the current state of cannabis use for medical purposes in the UK. The extent of use and the reported effects lend support to the further development of safe and effective medicines based on cannabis.

Conflict of Interest Statements

MAW is conducting research on the safety and efficacy of cannabis for pain management and supported by the fonds de recherche en sante du Quebec and the Canadian Institutes of Health Research. GWG is the Chairman and CEO of GW Pharmaceuticals, a pharmaceutical company which is developing cannabis-based medicinal extracts. HAA is an employee of GW Pharmaceuticals.

Role of the Funding Source. GW Pharmaceuticals was responsible for designing and administering the questionnaire, setting up the database and entering the data. The extraction and analysis of data and the preliminary report were performed by the principal author (MAW) under a service agreement with GW Pharmaceuticals. This paper represents a final report on these data with the collaboration of all the authors.

ACKNOWLEDGEMENTS

The authors acknowledge the contributions of the patients who responded to this questionnaire and of the software team who developed and administered the database.

Executive Summary

A legislative mandate required the Massachusetts Department of Public Health (DPH) to conduct a baseline study to investigate three topics: (1) Patterns of use, methods of consumption, and general perceptions of marijuana; (2) Incidents of impaired driving and hospitalization related to marijuana use; and (3) Economic and fiscal impacts for state and local governments. Pursuant to Section 18 of Chapter 351 of the Acts of 2016, a Report of Findings was submitted to the legislature on June 29, 2018. This document serves as the Final Report.

Summary of Findings

(1) Patterns of Use and Perceptions of Marijuana

- A survey of adults in Massachusetts suggests that approximately 21% of adults have used marijuana in the past 30 days. The proportion of marijuana use was highest among those 18-25 years old. Smoking is the most common method of marijuana consumption, although more than 40% of marijuana users report using multiple methods of use. More than half of adults perceive marijuana to have slight or no risks, and use marijuana for non-medical purposes.
- A survey of patients who use marijuana products for therapeutic use suggests these individuals use marijuana treatments for approximately 24 days a month, with the majority of respondents using a marijuana product for at least 21 out of the past 30 days. On average, respondents spend at least \$246.00 on marijuana each month, and use at least 3 different modes of use. The most common method of marijuana administration is smoking (combusting) dried flower (65%), followed by vaporizing marijuana concentrate (62%) and eating marijuana products (51%).

(2) Incidents of Impaired Driving and Hospitalization

- Tools to reliably ascertain levels of marijuana exposure and impairment in the field do not currently exist. Marijuana has cognitive and behavior effects in the areas of automative behavior (i.e., well-learned skills), and executive function impacts (i.e., how the user interacts with traffic). These effects have not been reliably linked to a level of marijuana or THC in the body.
- In a survey of Massachusetts residents, among respondents that use marijuana, the prevalence of self-reported driving under the influence is 34.3%. Overall, 7.2% of the adult population drove under the influence of marijuana in the past 30 days, and 11.3% of adults rode with a marijuana-using driver in the past 30 days. This is similar to estimates from a survey of medical marijuana patients that found approximately 10% of respondents drove under the influence in the past 30 days.

- Retrospective evaluations of fatal crash data suggest that drivers who died in a fatal crash are much more likely to have had their blood tested for marijuana, than drivers who survived a crash in which there was at least one fatality.
- Marijuana-related treatment is a small portion of the overall volume of substance use disorder treatment episodes. In a statewide-survey of Massachusetts, no respondents reported marijuana-related use of emergency room or urgent care facilities.
- The number of marijuana-related calls to the Regional Poison Control Center in Massachusetts has been increasing over time. The calls include incidents of unintentional exposures among children, with the majority of calls related to 10-19 year old individuals, and/or exposure to dried marijuana flower. The proportion of calls increased after medical marijuana was available in the Commonwealth.

(3) Economic and Fiscal Impacts for State and Local Governments

- Economic projections suggest that marijuana will increase Massachusetts state revenue by about \$215.8 million in the first two years of retail sales. The increase will largely come from sales and excise taxes collected on retail purchases. Based on experiences from states with existing legalized adult use, sales tax revenue will be higher in the second year (\$154.2 million), as compared to the first year (\$61.6 million).
- Economic projections of the impacts to local government, suggest that local tax revenue over the first two years of retail sale are projected to be highest in the most densely populated regions (ranging from \$233,498 to \$2,875,048), with considerable fluctuation in two-year revenue projections among high-density suburban cities and towns (ranging from \$68,139 to \$991,873, over the two year period).

Acknowledgements

The MBHS was directed by DPH in consultation with an advisory panel consisting of representatives from the Executive Office of Health and Human Services, Executive Office for Administration and Finance, and the Executive Office of Public Safety and Security. The study was funded by the Medical Use of Marijuana Trust Fund.

The completion of this study would not have been possible without the assistance of study collaborators from the University of Massachusetts (UMass); Mathematica Policy Research (Mathematica); and JSI Research and Training Institute, Inc. (JSI).

Specific collaborators on the “Retrospective Analysis of Indicators of Use and Perceptions of Marijuana” include: Catherine Jett, Adama Brown-Hathaway, and Penny Brierley-Bowers of the University of Massachusetts Donahue Institute.

Introduction

A legislative mandate required the Massachusetts Department of Public Health (DPH) to conduct a baseline study to investigate three topics: (1) Patterns of use, methods of consumption, and general perceptions of marijuana; (2) Incidents of impaired driving and hospitalization related to marijuana use; and (3) Economic and fiscal impacts for state and local governments (Chapter 351 of the acts of 2016). This study, referred to as the Marijuana Baseline Health Study (MBHS), was conducted by DPH, under the leadership of the DPH Commissioner, in consultation with the Executive Office of Health and Human Services, the Executive Office for Administration and Finance, and the Executive Office of Public Safety and Security. Pursuant to the legislative mandate, DPH entered into an agreement with the following research entities to assist with the execution the study: University of Massachusetts Donahue Institute, Mathematica Policy Research Inc., and JSI Research and Training, Inc. Pursuant to Section 18 of Chapter 351 of the Acts of 2016, a Report of Findings was submitted to the legislature on June 29, 2018. This document serves as the Final Report

Topic 1: Patterns of Use and Perceptions of Marijuana

a. Retrospective Evaluation

A retrospective analysis of previous surveys of “marijuana use” was conducted by comparing national and state-specific information from three states which have legalized marijuana, compared to three states which have not. This evaluation was conducted to identify indicators which may be sensitive to factors associated with legalization of marijuana, thus providing a valuable reference to monitor trends in use and perceptions of marijuana as the legalization of marijuana progresses. This retrospective analysis suggests that thirteen different indicators from national surveys with information available at the state level appear to be responsive to factors associated with the legalization of marijuana and sensitive to changes over time. These indicators include evaluating if minors have “ever used marijuana,” and if they “believe occasional use poses no risk of harm.” The evaluation also suggests that monitoring similar indicators in adults is valuable, as well as monitoring indicators of “perceptions of great risk from smoking marijuana once a month” and “any use in the past year.”

b. Statewide Survey

A cross-sectional population-based survey of adults was conducted to assess past 30-day use of marijuana, alcohol, and other substances. For each of these three substance types, the survey collected information on frequency of use, spending on the substance, driving under the influence, riding as a passenger with a driver under the influence, and use of emergency room or urgent care services. The mail and web-based survey was designed to be representative of adults in Massachusetts, age 18 years or older. Participants were chosen randomly using address-based sampling from a list of Massachusetts residential households obtained through a sampling vendor. The sample was stratified by 6 regions (Boston, Central, Metrowest, Northwest, Southeast, and

Western). A simple random sample of 15,000 addresses were selected to participate with an equal number of households (n = 2,500) selected from each region.

Once duplicates were removed from the study results, there were 3,022 individuals that responded to the survey (21.8% response rate). The respondent data was weighted to allow estimates to be representative of the entire Massachusetts population. These weighted results suggest that 21% of adults in Massachusetts have used marijuana in the past 30 days; 26% of men and 17.0% of women. The proportion of marijuana use was highest among those 18-20 years of age and 21-25 years (54.4% and 49.1%, respectively), as compared to older age groups. Eighteen percent of adults aged 26 or older had used marijuana in the past 30 days. By region, residents in the Western area of the state report the highest prevalence of past 30-day marijuana use (~30%). Among marijuana users living in Massachusetts, most are White, 70.8%, and many fewer are Hispanic, 12.0%, Black, 7.1%, other, 6.9%, or Asian, 3.2%. In statistical analysis of the data (which accounted for the effect of other factors), race/ethnicity was not associated with marijuana use, suggesting that the likelihood of using marijuana is similar for each group (compared to Whites). Fifty-three percent of adults perceive marijuana to have slight or no risks. The patterns of marijuana consumption indicate that smoking is most common, although 43% of marijuana users report using more than just one method. More than half of all adult marijuana users (56.0%) report using marijuana only for adult non-medical purposes. Data suggest that men are more likely than women to report past 30-day use, and adults 18-20 years old are more likely to have used marijuana, compared to adults older than 26 years old. Marijuana use is positively associated with past 30-day alcohol use. Population groups such as men, White, non-Hispanic individuals and individuals age 18-20 years had the highest prevalence of marijuana use, when compared to other groups.

c. Survey of Medical Use of Marijuana Patients

An online survey of the patterns of use and perceptions of marijuana was sent to patients actively using medical marijuana. The survey remained open for approximately 5 weeks, with a stated goal of characterizing how regulated legal retail marijuana is consumed in Massachusetts. The survey included 81 questions focused on collecting information on demographics, product use, methods of use, perceptions of medical use, driving behavior, alcohol consumption, non-medical use of prescription drugs and other substances, and combined substance use.

A total of 6,934 participants completed the entire survey, for a response rate of 16%. There were no notable differences between respondent gender, age, or county of residence as compared to the eligible population (i.e., all patients). On average, respondents indicated marijuana use for 23.5 out of the past 30 days, with over 60% reporting marijuana use at least 21 out of the past 30 days. However, 8% of respondents reported no use of marijuana or marijuana products in the past 30 days. Over 65% of respondents reported using marijuana or marijuana products for medical purposes for at least 1 year, with approximately 1 in 5 of respondents using marijuana or marijuana products for medical purposes for at least 3 years. On average,

respondents reported spending \$246 on marijuana products in the past 30 days, with a significantly larger amount spent among respondents under 50 years old and among respondents with an educational attainment less than a Bachelor's degree. On average, participants reported using approximately 3 different modes of use in the past 30 days. Approximately 16% of respondents who indicated marijuana use in the past 30 days reported using only 1 method of administration, while over 30% reported using 4 or more methods. The most common method of marijuana administration was smoking dried flower (65%), followed by vaporized marijuana concentrate (62%) and edible marijuana products (51%). The amount of product used varied by gender, age group, and educational attainment. A significantly larger proportion of males compared to females reported using vaporized dried flower or a concentrated preparation of THC referred to as "dabbing", while a larger proportion of females compared to males reported using sublingual or orally administered uptake products and applying topical cannabis products to the skin. A significantly larger proportion of respondents 50 years old or younger reported smoking (combusting) dried flower cigarettes (or "joints"), vaporizing dried flower, vaporizing marijuana concentrate, dabbing, or consuming edible marijuana products. A significantly larger proportion of respondents with an educational attainment less than a Bachelor's degree reported smoking dried flower and dabbing compared to respondents with a Bachelor's degree or higher.

All respondents were asked questions related to their perceptions of the medical use of marijuana. Over 65% of respondents reported that they believed marijuana products have been "very effective" in treating their medical condition(s), while an additional 26% believed use of marijuana to be "effective." Almost 90% of respondents reported that they had "somewhat high" or "very high" confidence that they were receiving safe, uncontaminated products when purchasing marijuana or marijuana products at a registered medical marijuana dispensary. All respondents were asked questions related to positive and negative outcomes/consequences of their marijuana use. Overall, respondents reported high rates of positive outcomes/consequences of marijuana use, and little obvious harm. Among all respondents, 78% reported positive changes in their mood or mental health, and 67% reported improved physical health. In addition, 83% of respondents reported no negative outcomes/consequences related to their marijuana use. Approximately 10% of respondents reported driving or operating a car or other motor vehicle while under the influence of marijuana in the past 30 days.

Topic 2: Incidents of Impaired Driving and Hospitalization

a. Measuring Marijuana and Driving Impairment

Marijuana intoxication can impair psychomotor and cognitive functions related to driving and increase the risk of involvement in a motor vehicle crash. A literature review was conducted to examine the state of the science on quantifying marijuana and impairment leading to the inability to operate a motor vehicle. Various point-of-collection (POC) devices/kits were compared to standard analytical chemistry methods (e.g., gas chromatography mass spectrometry, or liquid chromatography- tandem mass spectrometry) to determine concentrations of $\Delta 9$ -tetrahydrocannabinol (THC), the

primary psychoactive compound in marijuana. While some of the POC devices showed a screening-level accuracy that meets or exceeds recommended standards, they are limited in their ability to serve as a diagnostic tool to indicate driving impairment. The review of studies assessing cognitive and behavioral impacts of marijuana that are relevant to driving indicate that marijuana has cognitive and behavior effects in the areas of automative behavior (i.e. well-learned skills), especially for occasional users, and there also are likely executive function impacts (i.e. how the user interacts with traffic) for some users. Additional research is needed to establish baseline levels of cannabinoids in blood, urine, and saliva, and the relationship between these levels and marijuana use. Additional data are also needed to characterize the variability in cannabinoid levels across product types and modes of consumption.

b. Baseline Assessment of Medical Use of Marijuana Patients

As a follow-up to the survey of Medical Use of Marijuana patients described above, DPH conducted a biomonitoring study to evaluate baseline levels of tetrahydrocannabinol (THC) and 1-nor-9-carboxy- Δ 9-tetrahydrocannabinol (THC-COOH) in the blood and urine of patients that were regular marijuana consumers. This study, referred to as the Baseline Assessment of Medical Marijuana Patients (BAMMP) Study, was conducted in two distinct phases. The first “recruitment” phase, involved leveraging the patient survey component of the MBHS sent to 42,519 active medical marijuana patients, and included opinion, attitude, and perception questions as well as questions specifically addressing the magnitude, frequency, type and method of marijuana use. The survey also collected data on the social and demographic characteristics of respondents, including: age, gender, race/ethnicity, employment status, income level as well as county and zip code of residence. Recruitment of BAMMP study participants from the 6,934 patient survey respondents was achieved by creating a pool of respondents that indicated an interest in participating in a follow-up research study (e.g., question No. 81 on the patient survey; see Appendix B). From this pool of 2,113 interested individuals, 333 participants were selected for follow-up for study participation based on a sampling methodology to generate a sample representative of the geography, race/ethnicity, age, and gender of the statewide population. The second “field-based” phase of the BAMMP study involved the recruitment, scheduling, and collection of detailed marijuana use information and biological specimens (e.g., blood and urine) from 134 of the 333 individuals. These field-based appointments were conducted across the state of Massachusetts, where each of the 134 participants executed a consent form, returned a completed 7-day marijuana use diary, responded to questions on a same-day questionnaire, and underwent a physical and cognitive evaluation to confirm that they were not impaired. Participants then provided clinical specimens of either urine (n = 16), or urine and blood (n = 118) for quantitative analysis of THC and THC-COOH. A full report of the BAMMP study findings are expected later this year.

c. Marijuana-Involved Motor Vehicle Crashes in Massachusetts

Baseline prevalence of self-reported DUI-marijuana and riding with a driver under the influence of marijuana (RUI-marijuana) was characterized to identify demographic risk factors associated with these behaviors. Retrospective trends and patterns of marijuana-involved motor vehicle crashes in Massachusetts were investigated between 2006 and 2016, using (1) DUI and RUI data collected as part of a statewide baseline survey of Massachusetts adults age 18 years and older; (2) Prevalence of marijuana, alcohol and drug-involved fatal crashes in Massachusetts from 2006-2016; and (3) Marijuana-involved non-fatal crashes in Massachusetts. The baseline data in Massachusetts suggests that approximately 7% of adults drove under the influence of marijuana in the past 30 days and about 12% of adults rode with a driver who was under the influence of marijuana. Nearly 35% of adults who reported marijuana use also reported DUI-marijuana, and a similar proportion reported RUI-marijuana. Retrospective evaluation of fatal crash data suggest that over the 11-year study period of 2006-2016, there were an average of 351 crashes per year in which someone died and an average of 373 traffic fatalities per year. Approximately 73% of the drivers who died in a crash were administered a post-mortem blood test. Of the deceased, blood-tested drivers, there was an increasing trend for the proportion of drivers testing positive for any cannabinoid post-mortem. In contrast, alcohol-involved crashes in Massachusetts have steadily decreased in frequency since 2006. In an examination of non-fatal crash data, an increasing number and proportion of crash reports describe marijuana. These reports preclude the accurate characterization of marijuana-involved, non-fatal crashes as the crash reports do not systematically include reporting of drug testing.

d. Marijuana-Related Health System Contacts in Massachusetts

The use of health care systems by frequent and occasional marijuana users was evaluated to determine the number and prevalence of (1) substance use treatment admissions for a primary diagnosis of cannabis use disorder; (2) emergency room and urgent care services due to marijuana, and (3) marijuana-related calls received by the regional poison control center (PCC). This phase of the study sought to provide a summary of valuable health system-related indicators from before retail sales of adult use marijuana. For this phase, three data sources were utilized for analyses. First, Massachusetts-specific data were extracted from a national substance use database to compile the number of marijuana-related treatments over 2004-2014. Second, baseline data from the statewide survey on emergency or urgent care related to marijuana use, alcohol use, and other substance use were evaluated. Finally, data from the Massachusetts and Rhode Island Regional Poison Control Center (PCC) were evaluated to characterize marijuana-related calls (for all exposure reasons) by age and year, trends in specific marijuana product type as the source of exposure (e.g. dried plant, edible preparation, etc.).

These evaluations suggest that marijuana-related treatment is a small portion of the overall volume of substance use disorder treatment episodes, with an estimated

prevalence of 45 admissions per 100,000 individuals. Of the 436 individuals who reported using marijuana in the past 30 days on the statewide-survey, no respondents reported marijuana-related use of emergency room or urgent care services in the prior year. Data from the PCC suggest that the number and proportion of marijuana-related calls has been increasing over time for all age groups. For example, during the 10-year study period (2007-2016) there were 641 calls to the PCC that involved marijuana exposure, equal to a prevalence of 9.4 calls per a 100,000 population. The evaluated calls include incidents of unintentional exposures among children age 0-9 years old (n = 27, 4.21%). The greatest number of calls were related to 10-19 year old individuals (n = 257, or 40.09%). The proportion of calls due to marijuana exposure in individual ages 0-5, 6-9, and 10-20 years old showed a statistically significant increase after medical marijuana was enacted in the Commonwealth. In all age groups, it was exposure to dried cannabis plant that resulted in the greatest number of calls to poison control, followed by edible preparations.

Topic 3: Economic and Fiscal Impacts for State and Local Governments

To evaluate the potential economic impacts on state and local government, a model was constructed to estimate the fiscal impacts during the first two years of retail sales. The model included three parts: (1) a main model, which included measures that were assumed to be major drivers of state economic impacts for which there is strong evidence to inform estimates (e.g., sales tax revenue, regulatory oversight costs and revenue, and reductions in marijuana-related law enforcement activities); (2) a supplemental model, which evaluated secondary impacts on public health, public safety, and income tax revenue for which the strength of the evidence is less definitive; and (3) a local model, which estimates local tax revenue for each city or town in Massachusetts (assuming the maximum local tax rate of 3%).

This approach suggests that marijuana will increase Massachusetts state revenue by about \$215.8 million in the first two years of retail sales. The increase will largely come from sales and excise taxes collected on retail purchases. Based on experience from states with existing legalized adult use, sales tax revenue will be higher in the second year (\$154.2 million), as compared to the first year (\$61.6 million). When measures calculated with less certainty are included in the model (because of either a lack of data or uncertain timing), the state revenue may increase by an additional \$65.3 million. Because the model includes multiple measures, the overall estimate compounds uncertainty from each of the measures. To address this, low and high ranges have been calculated. For example, the total fiscal contribution could range from \$95.7 to \$405.9 million, with two major assumptions heavily influencing the estimates. The first assumption involves the number of expected marijuana users in Massachusetts. While the model uses previous population surveys that show a prevalence of use ranging from 8.6% to 12.1%, data collected in Massachusetts suggest that it may be as high as 20.1%. When this Massachusetts-based estimate is used, revenue projections increased by 38% (from \$215.8 million to \$298.8 million). Another source of uncertainty is the changes that arise in a state when moving a regulated medical marijuana marketplace

to a combined medical and adult-use marketplace, versus changes in a state going from no sales to adult-use retail sales.

The model-based approach of estimating fiscal impacts to local government, projects that local tax revenue over the first two years of retail sale are projected to be highest in the most densely populated regions (ranging from \$233,498 to \$2,875,048), with considerable fluctuation in the two-year revenue projections in high-density suburban cities and towns (ranging from \$68,139 to \$991,873, over the two year period). These local analyses assume that approximately 65% of marijuana users would shift from purchasing their marijuana in the illicit marketplace to purchasing from a dispensary. In general, the estimated median local tax revenue over the first two years of retail sale ranges from \$72,835 in suburban communities with a low population density, to \$582,899 in urban communities with a high population density. Because these model estimates rely on the location and availability of dispensaries, each community-level estimate is dependent upon the availability of marijuana in that community and the demand for marijuana in nearby communities. For some of the 83 cities and towns included in the primary analysis, local tax revenue estimates fluctuated dramatically based on these community-level effects (for example, from about \$992,000 to \$108,000).

In general, the modeling efforts described here estimate that adult-use marijuana sales are driven primarily by the availability of dispensaries and the potential for medical marijuana dispensaries to expand and/or convert operations to include adult-use marijuana sales. The increase in revenue will largely be a result of retail purchases made by adults with heavy use (defined as consuming marijuana an average of 21 days or more each month). It is difficult to speculate what regulatory costs/benefits may have already been realized when Massachusetts implemented a medical marijuana program. For example, if revenue changes have already been realized, the assumption could be inflating some of the revenue projections by 7-28%. While it is important to consider all aspects of the fiscal impact of legalization, the estimated increase from sales and business tax revenue appear to be most significant.

Task 1: Prevalence and Perceptions of Marijuana Use

**Chapter 1: Retrospective Analysis of Indicators of Use and
Perceptions of Marijuana**

Introduction

In this chapter an exploratory, secondary data analysis of marijuana indicators using national and state-specific data from Massachusetts as well as three states which have fully legalized marijuana (Oregon, Washington, and Colorado) and three states which have made no changes to marijuana laws (Texas, Kansas, Oklahoma) is presented. The goal of the study was to identify indicators of use and perception of risk of marijuana that may be used by policymakers and program leaders to monitor the impact of the legalization of marijuana over time.

Background

During the past two decades, there have been many state policy changes with regard to marijuana use. Currently, 29 states and the District of Columbia have legalized medical marijuana and 8 states have legalized recreational marijuana. National data indicates that marijuana is the most commonly used illicit drug in the U.S. and the shifts in policy align with changes in public opinion regarding the acceptance and legality of marijuana. In addition, an increase in marijuana use prevalence and a decrease in the perceived harmfulness of marijuana use have also been noted (Hall & Kozlowski, 2015; Monte, Zane, & Heard, 2015). Recent polls show growing support for the legalization of marijuana, with some reports indicating that over 50% of Americans now view the use of marijuana as a non-moral issue (Swift, 2013; Pew Research Center, 2013). Between 2002 and 2014, marijuana use increased from 10.2% to 13.4% among adults, and the perception of harmfulness associated with marijuana use decreased from 40% to 27.8% (Swift, 2013).

Although trends in marijuana use for both adolescents and adults have been examined using national data as well as data specific to states that have legalized marijuana, few studies, if any, have conducted a comparative analyses of legalized states versus non-legalized states with regard to marijuana use (Swift, 2013; Pew Research Center, 2013; Allen & Holder, 2014; Keyes, et al. 2016). And while several studies have examined trends in marijuana use following its legalization in specific states, these trends have not been examined in relation to key policy milestones. The purpose of this study is to conduct a comparative, secondary data analysis of marijuana indicators using national and state-specific data from three legal states (Oregon, Washington, Washington) and three non-legal states (Texas, Kansas, Oklahoma). Recreational marijuana was legalized in Massachusetts in 2016, and a focal point of this study is to compare Massachusetts indicators to other states in order to identify indicators which are responsive to changes in legalization. Given changes in marijuana policies regarding recreational use, the primary purpose of this study is to identify indicators that may be sensitive to those changes and factors associated with marijuana. The data reported reflect marijuana indicators that were reported for both legal and non-legalized comparison states.

Methods

In order to identify the indicators which may be sensitive to factors associated with legalization of marijuana, a list of the most relevant potential indicators from four national data sets was detailed. This list was then honed to only those which met specific criteria for inclusion. The remaining indicators were then analyzed for responsiveness to factors associated with marijuana and change over time. In sum, the process included four steps:

1. Conduct an indicator inventory
2. Choose comparison states
3. Confirm data sources
4. Conduct statistical analyses

Along with identifying indicators that appear to be responsive to changes over time, this approach also provided a baseline for chosen indicators from which to assess future trends.

Indicator Inventory

The purpose of the inventory was to identify a comprehensive list of potential indicators and detail salient information to inform the selection of indicators for further analysis. Four data sets were selected from which to pull the comprehensive list of indicators:

- Massachusetts Youth Risk Behavior Survey (YRBS)
- Massachusetts Youth Health Survey (YHS)
- Massachusetts Behavioral Risk Factor Surveillance Survey (BRFSS)
- National Survey on Drug Use and Health (NSDUH)

Sixty-eight initial indicators were identified for consideration. From this list, indicators were chosen that met the following criteria:

- Represents population of youth and/or adults
- Availability in potential comparison states
- Sampling and weighting representative of the entire state
- Administration at regular intervals over the course of the last 10 years

The result of the prioritization was the identification of 22 indicators for further analysis.

Selection of Comparison States

The next step was to select comparison states. Two types of comparison states were selected: those that have legalized recreational marijuana and those that have not legalized nor decriminalized marijuana use. Many states have made some changes to marijuana laws either by decriminalizing, legalizing medical marijuana use, or ultimately legalizing recreational marijuana use. These changes appear to occur in a progression

and therefore our focus was to identify states on either end of the continuum. The map below (Figure 1) demonstrates the range of legalization across the United States.

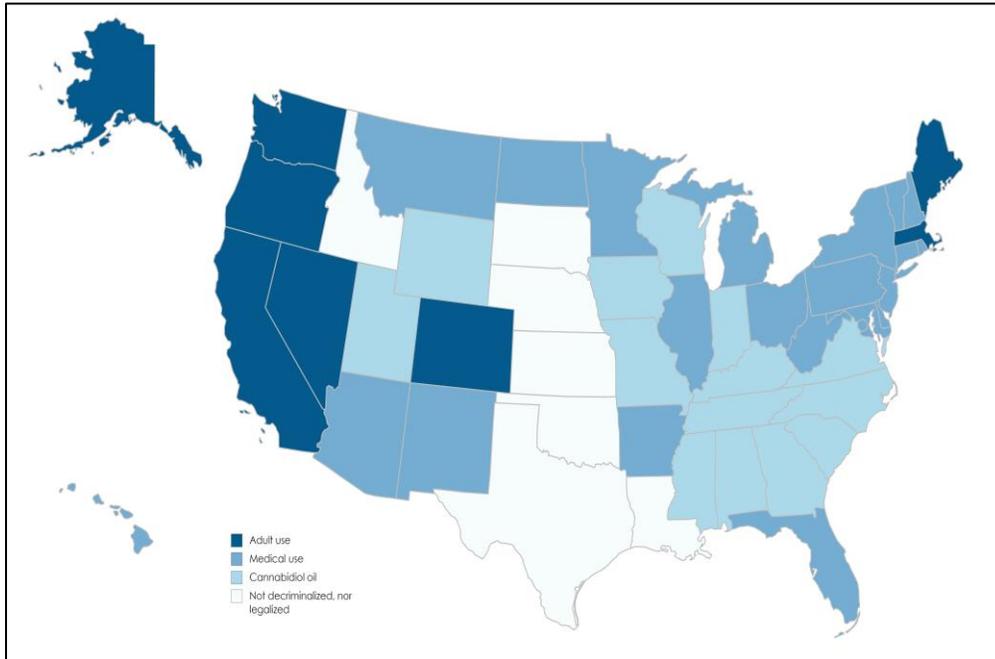

Figure 1: Current marijuana legalization status by state

For the purposes of this analysis, legalized comparison states considered included Washington, Oregon, California, Nevada, Colorado and Maine. However, only three states had legalized recreational use for sufficient time to make a trend analysis plausible: Washington, Oregon and Colorado.

A search found that there are seven states which have not decriminalized marijuana use or possession and have no recreational or medical marijuana laws, nor any legal cannabidiol oil use. These include: Idaho, Kansas, Louisiana, Nebraska, Oklahoma, South Dakota and Texas. It was assumed that states that meet this profile would be politically dissimilar (e.g. approach to criminal justice reform, social programs, etc.) from Massachusetts and therefore selecting on the basis on similarity of social factors would not be fruitful. Therefore, the selection criteria focused upon population density and unemployment rate. The table below details how each state met those criteria. Of the seven potential comparison states, the three selected had the most similar unemployment rate and population density to Massachusetts. Based on this information, the chosen non-legalization comparison states were Texas, Oklahoma and Kansas.

Table 1: Comparison State Census Information

State	Population	People per sq. mile	Unemployment rate
<i>Massachusetts</i>	6,547,629	839.4	4.3%
Idaho	1,567,582	19.0	3.1%
Kansas	2,853,118	34.9	3.7%
Nebraska	1,826,341	23.8	2.9%
Oklahoma	3,751,351	54.7	4.3%
South Dakota	814,180	10.7	3.0%
Texas	25,145,561	96.3	4.6%

Confirmation of Data Sources

Once the indicators and comparison states were chosen for analysis, the data sets were obtained. For adults, the final data sources include the NSDUH and the BRFSS. While raw NSDUH data were not available due to upgrades to SAMHSA’s online data portal and restricted data access system, a limited number of NSDUH indicators (with point estimates and confidence intervals) were available from SAMHSA’s public data access system for Massachusetts, the U.S., and all comparison states. BRFSS data regarding marijuana were only available for Washington state; other states did not include marijuana questions or included them too recently for a trend analysis to be conducted. For youth, the final data sources included the NSDUH, the YRBS, the YHS, the Healthy Youth Survey from Washington state. While the Healthy Kids Colorado Survey and the Oregon Healthy Teen Data Set were explored for use. Ultimately, they were not used due to their failing to meet the criteria set forth for the indicator inventory or their indicators did not align with Massachusetts indicators. The NSDUH data were available as described above through the public data access system for a limited number of indicators for youth aged 12-17. For high school youth, YRBS data were available for the U.S., Massachusetts, Texas, Kansas, and Oklahoma. Colorado deployed the YRBS through 2011, then switched to include the YRBS instrument in the Healthy Kids Colorado Survey, which is available for 2013 and 2015. In Washington State, the Healthy Youth Survey sampled students in grades 10 and 12; these data are not directly comparable to YRBS data but are presented on their own for trend analysis. The raw Healthy Youth Survey data were not available, but point estimates and confidence intervals available from published reports were used. For middle school youth, Massachusetts data are available from the YHS, and Washington state data are available from the Healthy Youth Survey for grades 6 and 8.

Statistical Analysis

Where raw data were available (for the YRBS, BRFSS, YHS), tests for linear and non-linear trends using logistic regression were conducted. Data were compiled and analyzed in two ways. Variables representing gender, race, and grade (in the case of youth data) were entered as control variables to adjust for demographic shifts in the underlying populations. Where raw data were not available, a significant trend was determined by non-overlapping confidence intervals; this analysis did not adjust for demographic variables. Because the sampling for each of the surveys involved complex sampling, SPSS Complex Samples version 21.0 was used to account for the sampling design and to ensure there was not an underestimation of the standard errors (Cambron, Guttmannova & Fleming, 2017).

Finally, a literature review of peer-reviewed journal articles related to marijuana legalization and block grant review was conducted to inform the selection of key milestones related to marijuana legislation in each state. Trends for each of the marijuana indicators were plotted alongside the key milestones to illustrate which indicators may be sensitive to state-level changes.

Results

The retrospective analysis resulted in identifying 13 indicators which appear to be responsive to factors associated to marijuana legalization and sensitive to change over time. Table 2 below presents a summary of the results of the analysis.

Table 2: Retrospective Analysis Results

Youth			Adult		
Indicator	Data Source	Type of Analysis	Indicator	Data Source	Type of Analysis
Ever Used Marijuana - Middle School Students	YHS	F-test, p=0.002	Ever Used Marijuana - Adults Ages 18 and Older	BRFFS	F-test, p=0.000
Used Marijuana Before Age 13 - High School Students	YRBS	F-test, p=0.005	Use in the Past Year - Adults Ages 18-25	NSDUH	State comparison, non-overlapping 95% confidence intervals
Current Marijuana Use - Middle School Students	YHS	F-test, p=0.000	Use in the Past Year - Adults Ages 26+	NSDUH	State comparison, non-overlapping 95% confidence intervals
Believe Occasional Marijuana Use Poses No Risk of Harm - High School Students	YHS	F-test, p=0.000	Current Marijuana Use - Adults Ages 18-25	NSDUH	State comparison, non-overlapping 95% confidence intervals
Believe it Would Be Easy to Obtain Marijuana - High School Students	YHS	F-test, p=0.001	Current Marijuana Use - Adults Ages 26+	NSDUH	State comparison, non-overlapping 95% confidence intervals
Perceptions of Great Risk of Smoking Marijuana Once a Month, Youth Ages 12-17	NSDUH (data not available for 2014-15)	State comparison, non-overlapping 95% confidence intervals	Perceptions of Great Risk of Smoking Marijuana Once a Month, Adults Ages 18-25	NSDUH (data not available for 2014-15)	State comparison, non-overlapping 95% confidence intervals
			Perceptions of Great Risk of Smoking Marijuana Once a Month, Adults Ages 26+	NSDUH (data not available for 2014-15)	State comparison, non-overlapping 95% confidence intervals

Indicators of Youth Marijuana Use

Marijuana use among youth has generally been stable over time, both in states that have legalized recreational marijuana use and those that have not. However, data from Massachusetts suggest that marijuana use may be declining among Massachusetts middle school aged youth. Please see Figure 2 below.

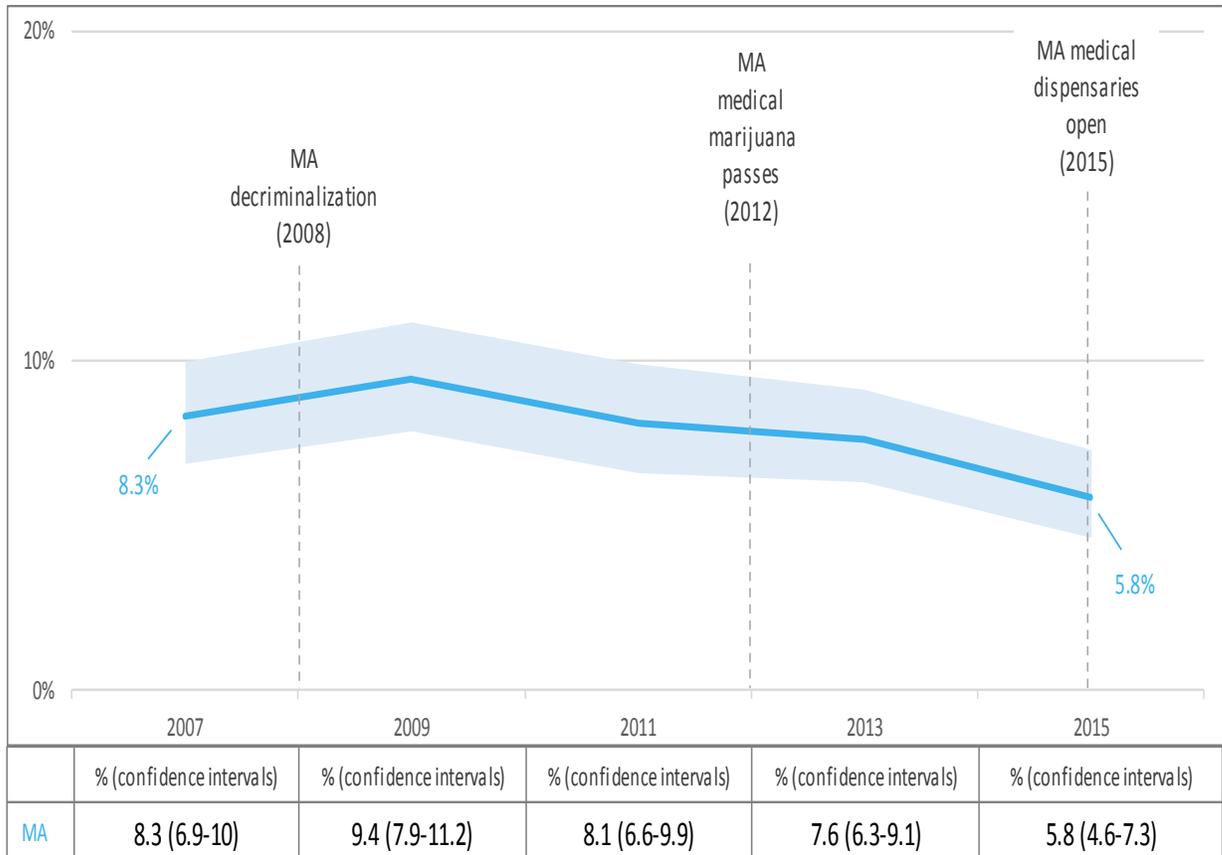

Figure 2: Massachusetts Ever Used Marijuana, Middle School Students

The specific indicators that show possible sensitivity to changes include:

- Ever Used Marijuana - Middle School Students
- Current Marijuana Use - Middle School Students
- Used Marijuana Before Age 13 - High School Students

Indicators of Youth Marijuana Perceptions

Perceptions that there is great risk in occasional marijuana use have been declining over time among youth. This trend is present in Massachusetts, nationally, and in legalized and non-legalized comparison states. More youth in non-legalized comparison states perceive that there is great risk for occasional marijuana use than youth in legalized states. Please see Figure 3 below. Massachusetts youth perceive the risk of occasional marijuana use to be lowest of all states included in analysis. In Massachusetts, this shift in perception of risk may be more pronounced in high school aged youth than in younger youth.

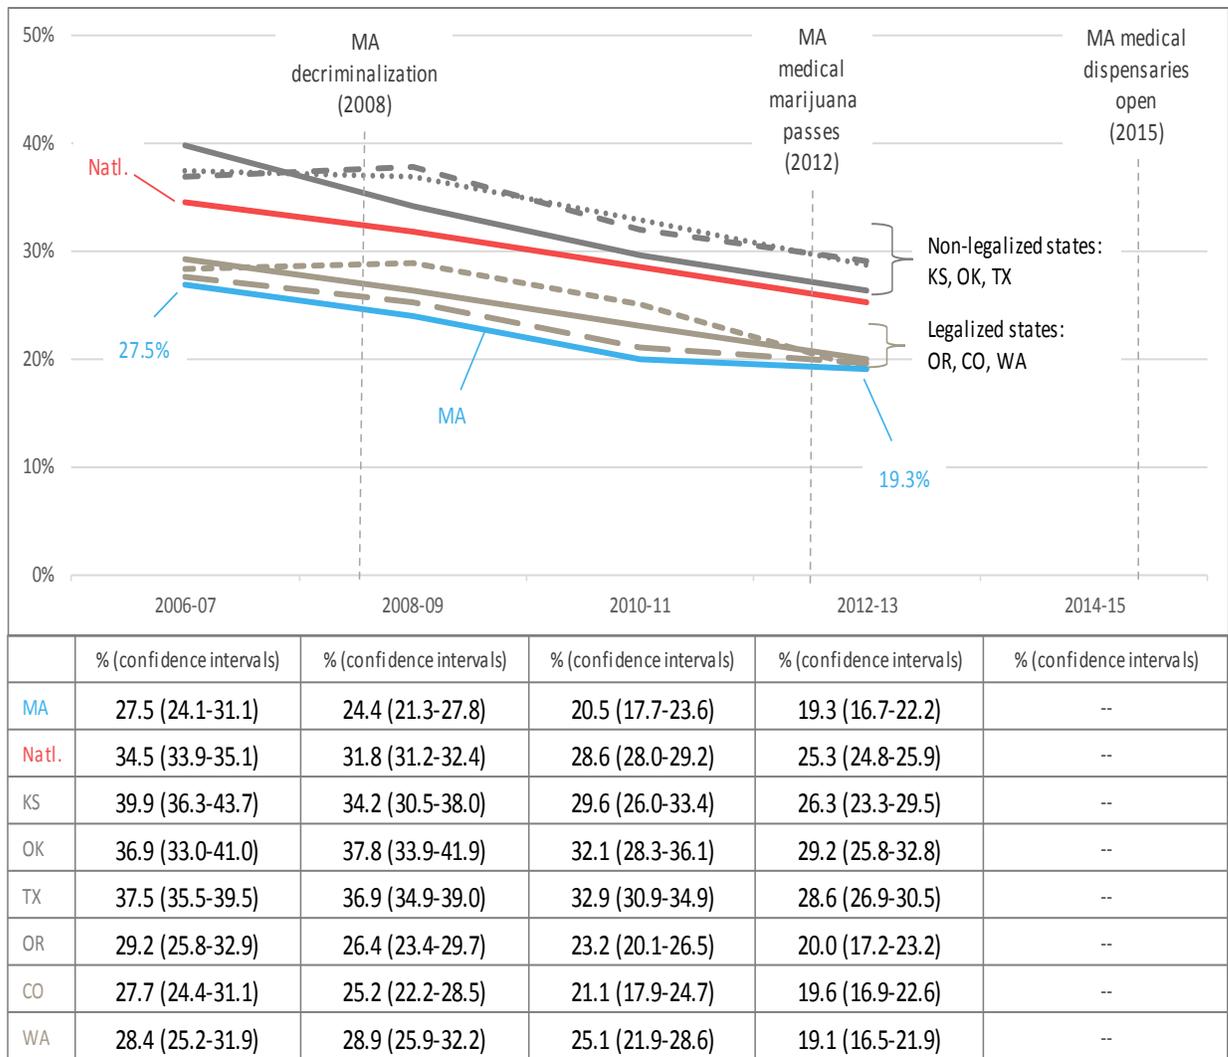

Figure 3: Massachusetts and Comparison States Perceptions of Great Risk of Smoking Marijuana Once a Month, Youth Ages 12-17

Given the parallel trends in several states, trends in these indicators may reflect larger national shifts rather than responses to state-level policy:

- Perceptions of Great Risk of Smoking Marijuana Once a Month, Youth Ages 12-17

Indicators of Adult Marijuana Use

Marijuana use seems to be increasing among some adult populations. Marijuana use among adults ages 26 and older has been increasing in Massachusetts and in states that have legalized recreational marijuana. This trend is also present nationally, though not in all non-legalized comparison states. Additionally, states that have legalized marijuana have higher rates of current use than states that do not. Finally, states that

have not legalized have rates of current use that is closer to the national average. Please see Figure 4.

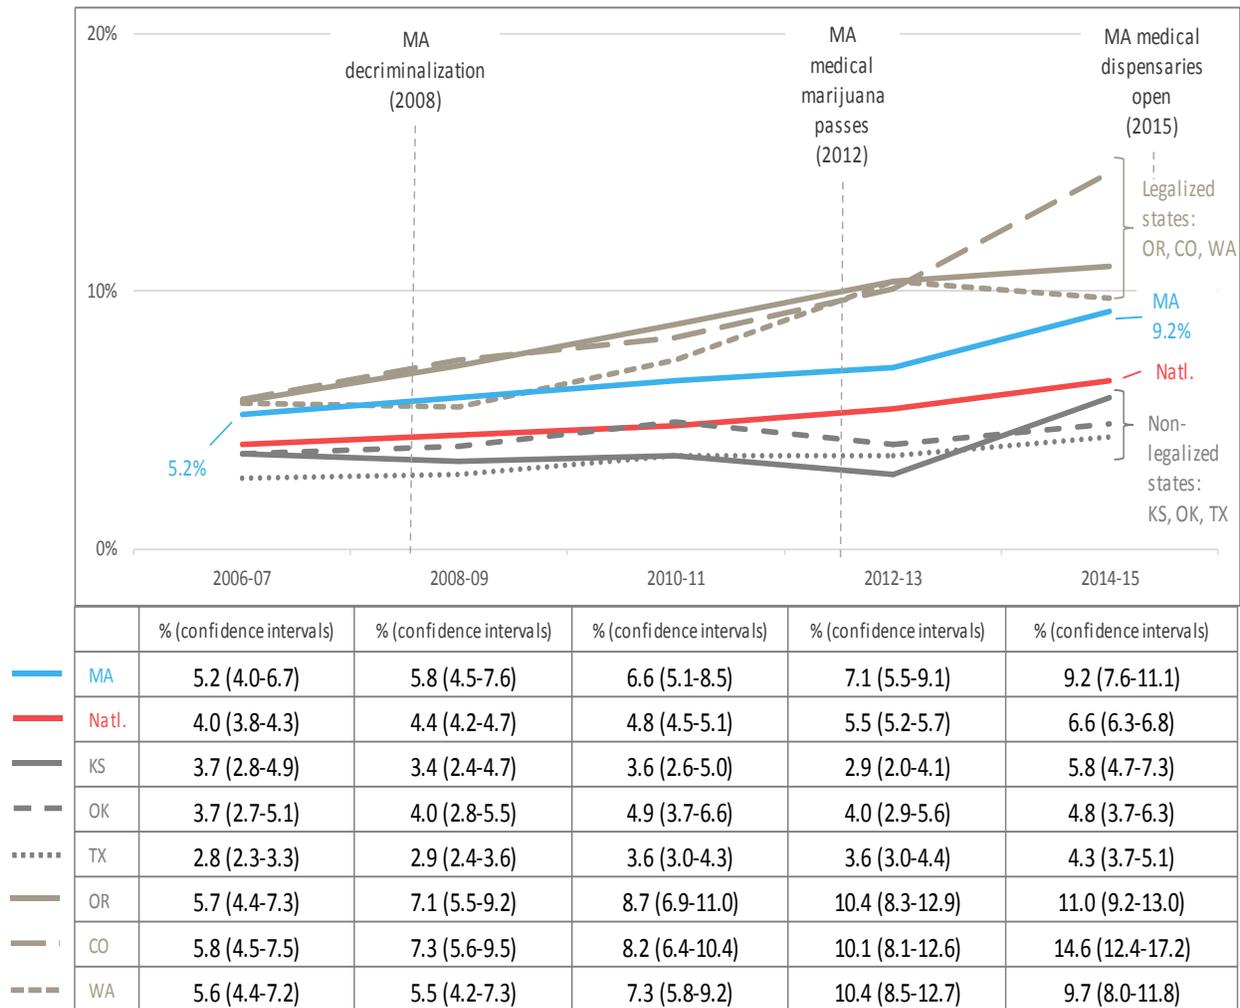

Figure 4: Massachusetts and Comparison States Current Use Ages 26 and Older

Among adults ages 18-25, who have higher rates of marijuana use than their older counterparts, use has increased in some legalized states but not in Massachusetts. Overall rates of use for all adults ages 18 and older have increased in Washington State, where recreational marijuana is legal.

The specific indicators that show possible sensitivity to policy changes include:

- Current Marijuana Use - Adults Ages 18-25 and Adults Ages 26+
- Use in the Past Year - Adults Ages 18-25 and Adults Ages 26+
- Current Marijuana Use - Adults Ages 18 and Older
- Ever Used Marijuana - Adults Ages 18 and Older

Indicators of Adult Marijuana Perceptions

As with youth, perceptions about the risks of marijuana use among adults seem to be shifting; fewer adults believe there is great risk in occasional use. This trend is occurring in Massachusetts, nationally, and in legalized and non-legalized states. Those adults in non-legalized states perceive the risk of occasional use to be higher than those in legalized states. Massachusetts adults' perceptions were closer to those in legalized comparison states than non-legalized. Please see Figures 5 and 6 below.

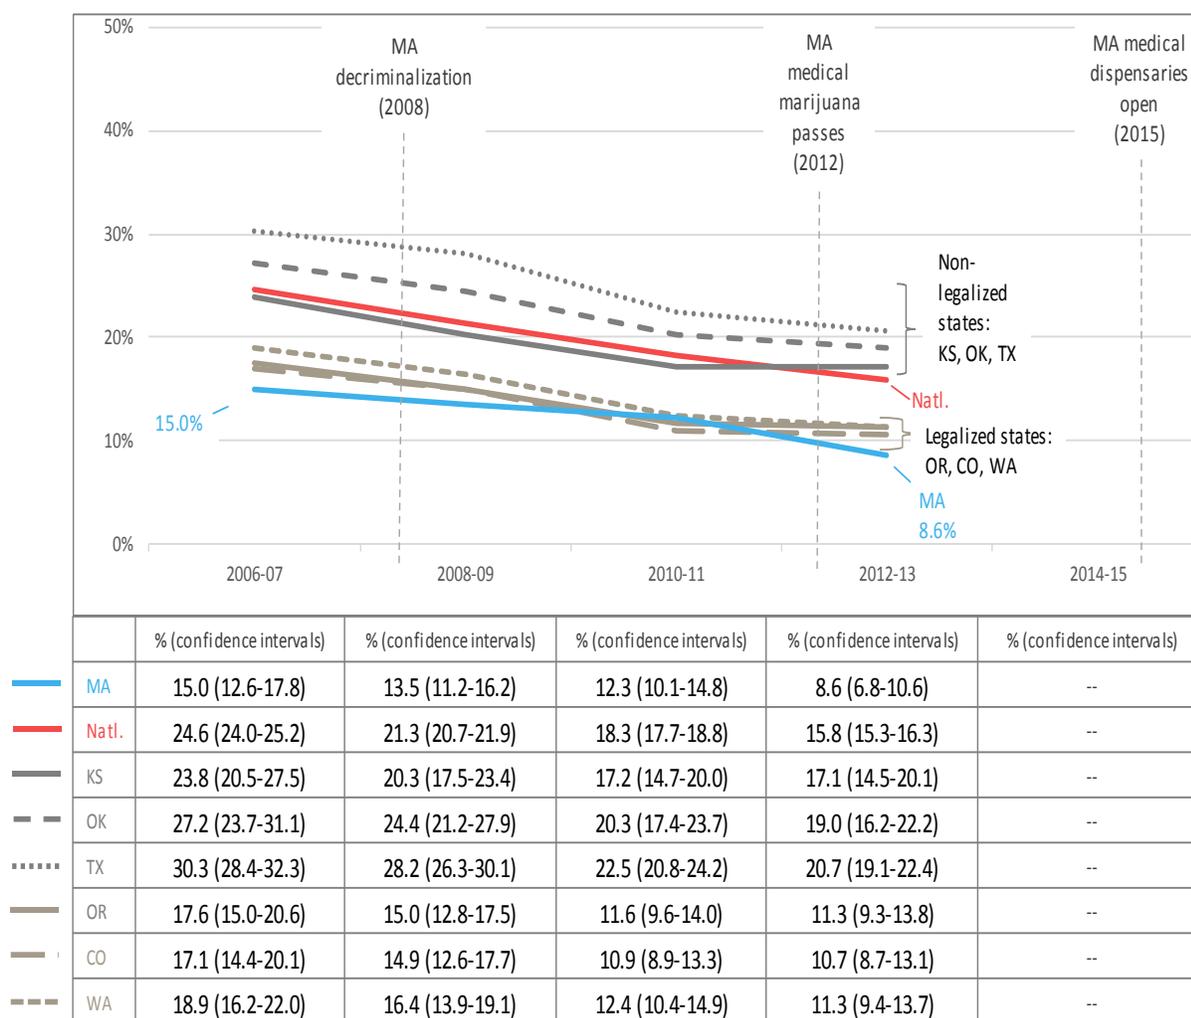

Figure 5. Massachusetts and Comparison States Perceptions of Great Risk of Smoking Marijuana Once a Month, Adults Ages 18-25

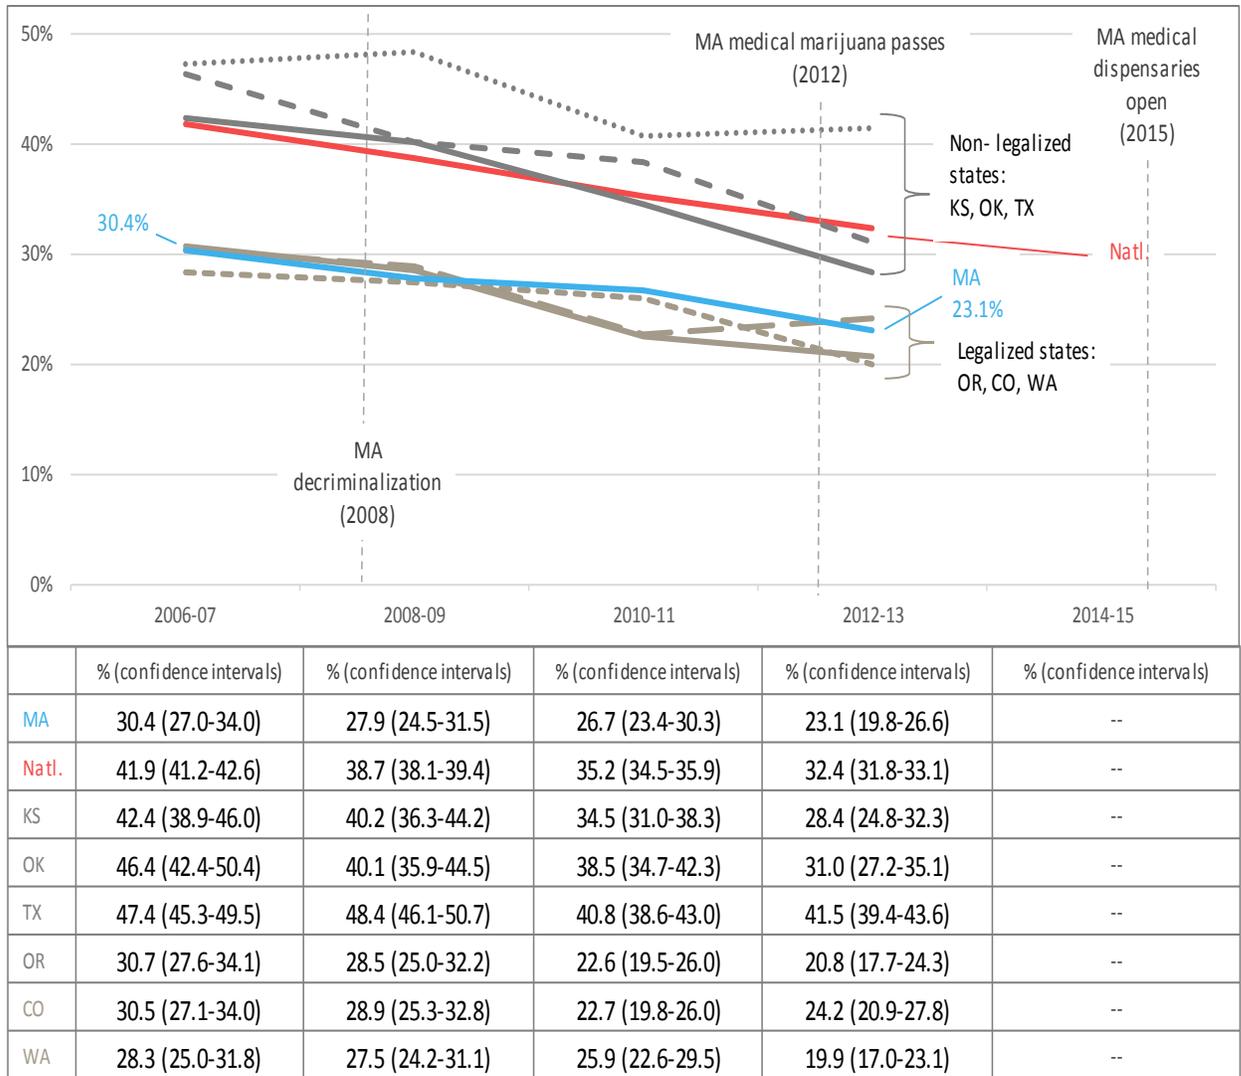

Figure 6: Massachusetts and Comparison States Perceptions of Great Risk of Smoking Marijuana Once a Month, Adults Ages 26+

Given the parallel trends in several states, trends in these indicators may reflect larger national shifts rather than responses to state-level policy:

- Perceptions of Great Risk of Smoking Marijuana Once a Month - Adults Ages 18-25 and Adults Ages 26+

Discussion

Massachusetts rates and trends consistently reflected those in comparison states that have legalized marijuana (Colorado, Oregon and Washington). And likewise legal states' trends (Kansas, Texas and Oklahoma), when comparisons were available, were different from trends in non-legal states. This suggests that some indicators may be responsive to factors associated with legalization of marijuana. The 6 indicators, 2 youth and 4 adult indicators, that differentiated between legal and non-legalized comparison states include:

- Used Marijuana Before Age 13, High School Students
- Perceptions of Great Risk of Smoking Marijuana Once a Month, Youth Ages 12-17
- Current Marijuana Use, Adults Ages 26+
- Use in the Past Year, Adults Ages 26+
- Perceptions of Great Risk of Smoking Marijuana Once a Month, Adults Ages 18-25
- Perceptions of Great Risk of Smoking Marijuana Once a Month, Adults Ages 26+

In some cases, the exact items from which the indicators are drawn, were not available for other states. For these indicators, analysis of the trends in response to policy changes was conducted. The study identified 7 indicators, 4 youth indicators and 3 adult indicators, which appear to be responsive to changes over time. These indicators include:

- Ever Used Marijuana - Middle School Students
- Current Marijuana Use - Middle School Students
- Believe Occasional Marijuana Use Poses No Risk of Harm - High School Students
- Believe it Would Be Easy to Obtain Marijuana - High School Students
- Current Marijuana Use - Adults Ages 18-25
- Use in the Past Year - Adults Ages 18-25
- Ever Used Marijuana - Adults Ages 18 and Older

One indicator, Current Marijuana Use - Adults Ages 18 and Older, was only available for Washington State and therefore it is difficult to assert that similar trends would be evident in Massachusetts. The data sets utilized were helpful when considering trends in use, consumption, and perceptions of marijuana for health and policy-related purposes. While these data are rich information, consistency with regard to the availability of the data and wording of the questions make drawing state comparisons challenging.

Chapter 2: Prevalence and Correlates of Marijuana Use among Adults in Massachusetts

Introduction

In this Chapter, we report on prevalence of marijuana use among adults in Massachusetts, the characteristics of marijuana users compared with non-users, and the correlates of marijuana use. Findings are based on data provided by Massachusetts adults who completed a survey in the fall of 2017. Despite the existence of several ongoing surveys of Massachusetts adults, such as the Behavioral Risk Factor Surveillance Survey (BRFSS) and the National Survey on Drug Use and Health (NSDUH), there are significant gaps in the information that they provide. For example, existing Massachusetts databases did not provide information about various modes of consumption (from smoking, to eating, to vaping and dabbing).

The purpose of this survey was to address these gaps and provide a “snapshot” of marijuana use and related behaviors in Massachusetts in the time before retail sales of adult use marijuana begin. This study provides a “baseline” or benchmark against which future studies can make comparisons. The information from this survey will enable ongoing study of impacts that can inform the Commonwealth’s policy and regulatory response over the course of the next several years.

Methods

We conducted a cross-sectional, population-based survey of adults in Massachusetts. This study was approved by the Institutional Review Board at the Massachusetts Department of Public Health. A copy of the survey instrument can be found in the Appendix A.

Data Collection and Participants

The University of Massachusetts Amherst partnered with the University of Massachusetts Donahue Institute to conduct a mail and web-based survey designed to be representative of adults in Massachusetts, age 18 years or older. Participants were chosen randomly using address-based sampling from a list of Massachusetts residential households obtained through a sampling vendor. The sample was stratified by 6 regions (Boston, Central, Metrowest, Northwest, Southeast, and Western). Addresses that were known to be vacant, seasonal, educational, or drop points were excluded from the sample. A simple random sample of 15,000 addresses were selected to participate with an equal number of households (n=2500) selected from each region. The survey was then administered in four waves over a four-week period.

Wave 1: Pre-notification postcard

A pre-notification postcard was sent to selected addresses informing participants about the survey eligibility to participate. On the postcard and all subsequent mailings an online survey link with a unique access code was provided for those who chose to complete the web-based version. Online survey participants could only complete the survey once, and quality checks were implemented to identify duplicate completions (by

mail and online) using the same code. The postcard and all subsequent materials included a means to opt out of participation by calling the researchers.

Wave 2: Mail Survey

The postcard was followed by a survey packet containing an informed consent letter, the full survey, a postage-paid business reply envelope, and an up-front cash incentive of \$2. The survey instructed the adult in the household with the most recent birthday to complete the survey. Responses were tracked with a unique identification number to allow for follow-up mailings.

Wave 3: Reminder Postcard

After the initial wave of survey mailing, a reminder postcard with the online link was sent to all non-responders.

Wave 4: Final Mail Survey

The final opportunity to respond was via paper-based survey with the informed consent cover letter and online link. This was sent to those who still had not responded or had not notified the researchers of their desire not to participate.

Data were collected between November 7, 2017 (first online response opportunity) and December 30, 2017. Completed mail surveys were scanned using a computerized system. The scanned dataset was combined with the online responses and an initial quality review removed all duplicate surveys from the dataset. The resultant dataset included 3,023 respondents with a 21.7% response rate.

Measures

The survey contained 37 items that assessed a limited number of demographic characteristics, past 30-day substance use (marijuana, alcohol, and other substances), and behaviors related to substance use such as driving under the influence and riding with a driver who was under the influence. When possible the wording of items was aligned with national population health surveys (e.g. Behavioral Risk Factor Surveillance Survey, National Survey on Drug Use and Health) to facilitate comparisons of estimates.

Demographic characteristics

Basic demographics were ascertained. Participant age was ascertained by asking the survey respondent to report their year of birth. Participants reported gender as female, male, or other. Race/ethnicity was asked with two questions. One asked “Are you Hispanic or Latino?” and required a yes/no response. The second question asked “Which one or more of the following would you say is your race?” with response options that included (1) white or Caucasian, (2) Black or African American, (3) Asian, (4) Native

Hawaiian or Other Pacific Islander, (5) Native American or Alaska Native, (6) Some other race. Participants could choose as many categories as were applicable. The survey ascertained the participants' highest degree or level of school completed, which was reported on the survey with 10 categories ranging from "never attended school or only attended kindergarten" to "doctorate degree". For analysis, this was coded to a 3-level variable that included: (1) high school or less, (2) any college, (3) graduate degree. The survey asked about annual household income using the following categories (1) less than \$15,000 (2) \$15-29,000 (3) \$30,000-49,000 (4) 50,000-99,000 (5) 100,000-150,000, or (6) 150,000 or more. Participants also reported zip code as well as home ownership (own, rent, something else). Participants reported their type of healthcare coverage as one or more of the following (1) private commercial or group plan (2) Medicare, (3) Medicaid, (4) Commonwealth Care Program (Health Connector), (5) Indian Health Service (6) Veterans Affairs (7) No health insurance, or (8) other plan.

Substance Use

The survey ascertained past 30-day use of marijuana, alcohol, and other substances. Marijuana use was assessed with the yes/no question "In the past 30 days, did you use marijuana or hashish at least once?" For those who responded "yes," the survey asked about the number of days on which the participant used marijuana in the past 30 days. The purpose of marijuana use was ascertained with a multiple response item indicating use for one or more of the following: adult use (non-medical), medical use (prescribed by a qualified physician), or medical use (not prescribed by a qualified physician). The mode of use (smoking, eating, drinking, vaporizing, etc.) was assessed with a multiple response item.

Past 30-day alcohol use was reported with the yes/no question "During the past 30 days, did you have at least one drink of any alcoholic beverage such as beer, wine, a malt beverage, or liquor?" For those who responded "yes," the survey asked them to provide the number of days per week that participants consumed an alcoholic beverage. Use of other substances was coded as "Yes" if participants reported use of crack/cocaine, heroin, non-medical use of anti-anxiety drugs (sedatives, tranquilizers, anxiolytics, or sleeping drugs such as benzodiazepines or barbiturates), non-medical use of prescription opioids, or other drugs (e.g. hallucinogens, non-medical use of stimulants). The instructions to participants in the section of the survey on other substances noted that "non-medical" prescription drug use means using it to get high or experience pleasurable effects, see what the effects are like, or use with friends. Items and results pertaining to driving under the influence of marijuana, alcohol, and other drugs are reported in Task 2 of this report, along with items pertaining to use of hospital emergency rooms and urgent care related to substance use.

Data Quality Assessment

The data was subject to a quality check process. Duplicates were identified and removed, leaving 3268 respondents. We verified that skip logic was properly applied. Other instances with out-of-range responses (e.g. reported having 33 children in the home) were also coded as missing. Any instances in which returned responses were

unreasonable were coded as a missing response on the illogical variable. In cases in which a respondent reported driving under the influence of a substance, but did not first report using that substance, we set the response to the question about use to yes. This affected a very small number of cases.

Statistical Procedures and Analysis

Weighting

Weights were assigned to each completed survey so that the survey responses closely represent the Massachusetts population relative to age, gender, race, and education. The weighting scheme included six steps that are summarized below. First, a weight was assigned to directly account for the sampling fraction of addresses. Second, using information on the sample addresses, adjustments were made for unknown eligibility of the addresses. Eligibility was classified into one of four categories: (1) eligible respondent, (2) eligible non-respondent, (3) known ineligible addresses, and (4) unknown status. Eligible respondents resided at the sample address, were 18 years or older, and lived in Massachusetts for 6 or more months per year. Addresses with unknown status included addresses where surveys were not returned (n=11,163), surveys bounced back to the post office (presumably based on refusal of recipient) (n=504), and surveys returned blank (n=65). The eligibility weighting accounted for the fact that our knowledge of eligibility status may be related to other address characteristics such as the type of postal route (rural, street, firm, high-rise, etc.). The third step in the weighting was to adjust for non-response. We defined a complete survey as one in which the respondent provided basic demographics (age, gender, race, and education) and answered the item on past 30-day marijuana use. We observed a difference in the survey completion rate for eligible addresses by region ($p=0.03$) and a weight was developed to account for this. Household size was accounted for next.

Raking was then used to align the weights to the distribution of four demographic variables (age, gender, race/ethnicity, and education) to the Massachusetts target population based on the 2016 American Community Survey Public Use Microdata Sample (PUMS) data. The last step trimmed weights to improve estimation accuracy.

Statistical Analysis

In most cases, variables were defined as shown on the survey. For example, past 30-day marijuana use was defined as “Yes” based on an answer of yes to the question, “In the past 30 days, did you use marijuana or hashish at least once?” For analysis purposes, we coded race as a 5-level categorical variable with the following categories (1) White, non-Hispanic, (2) Black non-Hispanic, (3) Any Hispanic/Latino (4) Asian, non-Hispanic, (5) Other.

First, we examined the bivariate differences in characteristics between adults who had used marijuana in the past 30 days and those who had not. Next, we used modified

Poisson regression with robust standard errors (Zou, 2004) to assess associations between use of marijuana (yes/no), gender, age, race/ethnicity, and other covariates (education, home ownership, children in household, region, alcohol and other substance use). This approach allowed estimation of relative risk, adjusting for potential confounders. We used a two-tailed significance level at $p < 0.05$ for all statistical tests. All analyses were weighted to account for the complex survey design, yielding results that have been adjusted to be representative of the adult population in Massachusetts. The analysis for this report was generated using SAS/STAT software, Version 9.4 of the SAS System for Windows (Copyright © 2016 SAS Institute Inc. Cary, NC, USA.) with the exception of the Poisson regression models which were generated using Stata 15 statistical software (StataCorp, LLC, College Station, TX).

Results

A total of 3,528 surveys were returned, of which 260 were duplicates. And additional 245 were determined ineligible or incomplete. After removing the duplicate, ineligible and complete surveys, 3,023 remained. The logic-checking process resulted in identification of one case in which multiple questions had unreasonable responses. This case was dropped, resulting in a final analytic sample of 3,022.

Prevalence of Marijuana Use

Of the 3,022 adults in the sample, 439 self-reported marijuana use in the past 30 days, and 2,583 did not. After data were weighted, results indicate that 21.1% of adults in Massachusetts have used marijuana in the past 30 days (95% Confidence Interval [CI] 18.6, 23.6), and 78.9% have not (95% CI 76.4, 81.4) (Table 1). Hereafter, we report only the population-level point estimates; confidence interval data are presented in each table.

We examined prevalence rates of past 30-day marijuana use among key socio-demographic groups. These analyses indicated that 25.9% of adult men in Massachusetts and 17.0% of women have used marijuana in the past 30 days. By age category, past 30-day marijuana use was reported by 54.4% of adults aged 18 to 20, 49.1% of those aged 21 to 25, 34.5% of those aged 26 to 29, 22.7% of those aged 30 to 39, 19.3% of those aged 40 to 49, 18.7% of those aged 50 to 59, 14.1% of those aged 60 to 69, and 3.4% of those aged 70 or older. To enable comparisons of age-specific marijuana prevalence with other estimates (presented in Chapter 1), we changed the categorization of age to create a category that captured aged 26 or older. Past 30-day marijuana use was reported by 18.0% (95% CI 15.7, 20.3) of adults aged 26 or older. By race/ethnicity, past 30-day marijuana use was reported by 20.1% of Whites, 27.1% of Hispanics, 10.4% of Asians, 25.8% of Blacks, and 37.5% of other race/ethnic groups. By educational attainment, past 30-day marijuana use was reported by 24.7% of adults with a High School education or less, 22.9% of those with a college degree, and 10.7% of adults with a post-secondary graduate degree. By income, past 30-day marijuana use was reported by 32.5% of adults earning less than \$15,000. Fewer people in each of the higher income categories reported past 30-day use, with

prevalence rates ranging between about 17.3% and 25%. By region, past 30-day marijuana use was reported by 29.8% of Western residents, 20.9% of Southeast residents, 20.5% of Boston residents, 20.1% of Northeast residents, 19.6% of Central residents, and 18.2% of Metrowest residents.

Socio-Demographic Characteristics

Table 2 presents socio-demographic characteristics of adults who had used marijuana in the past 30 days compared with adults who had not. A greater proportion of marijuana users than non-users are men, 57.7% versus 44.5% ($p < 0.001$). With respect to age, marijuana users tend to be younger than non-users, with a greater proportion of them in the youngest age categories ($p < 0.001$). Specifically, 9.6% of marijuana users are aged 18 to 20, versus 2.2% of non-users, 14.7% of marijuana users are 21 to 25, versus 4.2% of non-users, and 14.3% of marijuana users are 26 to 29, versus 7.4% of non-users. For the 30 to 59 age categories, differences between marijuana users and non-users are small ($< 5\%$). A smaller proportion of marijuana users than non-users are aged 60 to 69, 10.1% versus 16.7%, and a smaller proportion are 70 or older, 2.3% versus 17.2%.

A smaller proportion of marijuana users than non-users are White or Asian, and a greater proportion are Hispanic, African American, or other race/ethnicity ($p < 0.05$). Specifically, 70.8% of marijuana users are White, versus 75.5% of non-users, and 3.2% of marijuana users are Asian, versus 7.3% of non-users. Among marijuana users, 12.0% are Hispanic, 7.1% are African American, and 6.9% are another race/ethnicity. Among non-users, in comparison, 8.7% are Hispanic, 5.5% are African American, and 3.1% are another race/ethnicity.

Table 1. Prevalence Rate of Past 30-day Marijuana Use by Key Socio - Demographic Characteristics

Northeast	20.1	14.6	25.7
Southeast	20.9	14.7	27.2
Western	29.8	23.2	36.4

A greater proportion of marijuana users than non-users have attained a High School diploma or college degree, and a smaller proportion have attained a graduate degree ($p<0.001$). A smaller proportion of marijuana users than non-users own a home, and a greater proportion rent or have another type of living arrangements ($p<0.001$).

There are no differences between marijuana users and non-users in the remaining socio-demographic characteristics, including income, having children in the home, health insurance type, and region of residence. For both groups, most report an income of \$50,000 to \$99,999 or more, few have children in the home, private health insurance is the most common type of health insurance, followed by Medicare and Mass Health.

Marijuana Attitudes and Perceptions

Table 3 presents attitudes and perceptions about marijuana. More than half of Massachusetts adults, 58.5%, favor the legalization of marijuana. As for risk perceptions, 20.0% of Massachusetts adults perceive marijuana to have no risks, 32.5% perceive it to have slight risks, 26.4% perceive moderate risks, and 21.0% perceive great risks.

We stratified data to examine attitudes and perceptions among Massachusetts adults who had used marijuana in the past 30 days compared with adults who had not. A majority of marijuana users, 96.5%, favor the legalization of marijuana, whereas less than half of non-users, 48.2%, favor marijuana legalization (p<0.001). A greater proportion of marijuana users than non-users perceive marijuana to have no health risks, or slight risks (p<0.001).

Table 3. Marijuana Attitudes and Perceptions of Marijuana Users and Non-Users

	In the past 30 days, did you use marijuana or hashish at least once?								
	Yes: n=439, 21.1% (95% CI 18.6, 23.6)			No: n=2,583, 78.9% (95% CI 76.4, 81.4)			Total: n=3,022

Note: *p<0.05; **p<0.01; ***p<0.001

Use of Alcohol and Other Substances

Table 4 presents past 30-day alcohol and other substance use among Massachusetts adults. Among all adults, 69.4% had consumed alcohol in the prior 30 days, and 4.1% had consumed another substance. Other substance use was defined as past 30-day use of any of the following substance types: non-prescribed opioids, cocaine/crack, heroin, non-medical anti-anxiety drugs, and other illicit substances. Prevalence rates were relatively small for each of the other substance categories, i.e., 0.9% for cocaine/crack, 0.1% for heroin, 1.3% for non-medical use of anti-anxiety substances, 1.4% for non-medical use of opioids, and 0.4% for other illegal substances.

We stratified data to examine alcohol and other substance use by adults who had used marijuana in the past 30 days compared with adults who had not. A greater proportion of marijuana users than non-users had used alcohol. Specifically, 82.1% of marijuana users had used alcohol, versus 66.0% of non-users (p<0.001). Also, a greater proportion of marijuana users than non-users had used other substances. Specifically, 9.8% of marijuana users had used other substances, versus 2.6% of non-users (p<0.01). Analysis of each substance type revealed that 3.8% of marijuana users had used non-prescribed opioids, versus 0.8% of non-users (p<0.05), and that similar proportions of adults in each group had past 30-day use of cocaine/crack, heroin, non-medical anti-anxiety drugs, and other illicit substances. Given the low rates of past 30-day use of each of these substances, interpretation of these results should be made with caution.

Table 4. Use of Alcohol and Other Substances of Marijuana Users and Non-Users

	In the past 30 days, did you use marijuana or hashish at least once?								
	Yes: n=439, 21.1% (95% CI 18.6, 23.6)			No: n=2,583, 78.9% (95% CI 76.4, 81.4)			Total: n=3,022

Note: *p<0.05; **p<0.01; ***p<0.001. Other substances” is defined as any past 30-day use of cocaine/crack, heroin, non-medical anti-anxiety substances, non-medical opioids, and other illegal substances.

Marijuana Consumption Patterns, Methods, and Expenditures

Table 5 presents marijuana consumption patterns, methods, and expenditures reported by Massachusetts adults who had used marijuana in the past 30 days. About half (50.6%) of marijuana users consumed it only by smoking, while 42.9% used more than one method of consumption. Fewer marijuana users vaporized or ate marijuana, 2.9% and 2.6%, respectively. Less than 1% only drank or dabbled marijuana, or only used it topically or sublingually.

More than half of Massachusetts adult marijuana users, 56.0%, report using marijuana only for adult non-medical purposes. Adults also use marijuana for medical reasons; 4% only used prescribed marijuana, 11.5% only used non-prescribed marijuana. In other words, 15.5% used either prescribed or not prescribed marijuana for medical reasons. More than one-quarter, 28.5%, reported both adult and medical marijuana use. Of Massachusetts adult marijuana users, 35.5% spent no money on marijuana in the past month, 31.5% spent between \$1 and \$80, and 33.0% spent \$81 or more.

Table 5. Marijuana Consumption Patterns, Methods, and Expenditures

	Adults who used marijuana in past 30 days (n=439)		
	%	95% CI	
How used marijuana, past 30 days

\$81-800	33.0	26.2	39.7

Correlates of Marijuana Use

Table 6 presents results from the Poisson regression examining socio-demographics and other factors associated with past 30-day marijuana use (defined as a dichotomous variable, yes versus no) by Massachusetts adults. It is important to remember that because the survey used a cross-sectional design, the results shown here reflect factors that are associated with marijuana use and cannot be interpreted as being causally related to marijuana use. We report relative risk (RR) and 95% confidence intervals (CI). Men were more likely than women to use marijuana (RR=1.3; 95% CI: 1.1-1.6). Age is also associated with marijuana use. Compared to adults aged 18 to 20, adults aged 26 to 34 were less likely to use marijuana (RR=0.6; 95% CI: 0.4-0.9), as are those aged 35 to 64 (RR=0.3; 95% CI: 0.2-0.5), and adults aged 65 and older (RR=0.1; 95% CI: 0.1-0.2). Having a graduate degree, compared with having attained a High School education or less, was negatively associated with marijuana use (RR=0.5; 95% CI: 0.4-0.8). Renting a home, compared with owning a home, was positively associated with marijuana use (RR=1.5; 95% CI: 1.1-1.9). Having children in the home was negatively associated with marijuana use (RR=0.8; 95% CI: 0.6-1.0). Compared with living in Boston, living in the Northeast (RR=1.8; 95% CI: 1.2-2.7), Southeast (RR=1.8; 95% CI: 1.1-2.7), and Western (RR=2.0; 95% CI: 1.3, 3.0) regions of the state are each positively associated with marijuana use. Marijuana use is positively associated with

past 30-day use of alcohol (RR=1.9; 95% CI: 1.4-2.6) and other substances (RR=1.7; 95% CI: 1.3-2.4). See Table 6.

Table 6. Adjusted Relative Risk of Marijuana Use

	Adjusted Relative Risk	95% Confidence Interval

Discussion

We found that 21.1% of adults in Massachusetts had used marijuana in the past 30 days. Estimates are substantially higher than those provided by other surveys. For example, as presented in Chapter 1, 5.2% of Massachusetts adults aged 26 or older reported recent use of marijuana in 2006, and 9.2% reported recent use in 2014. In the present study, 18.0% of adults aged 26 or older had used marijuana in the past 30 days. Increases in marijuana prevalence among Massachusetts adults may be attributable to shifts in public opinion regarding marijuana, and in marijuana-related law and public policy.

Men in Massachusetts are more likely than women to use marijuana, as are individuals aged 18 to 20. Marijuana prevalence rates are 25.9% for men and 17.0% for women, 54.4% for those aged 18 to 20 and 49.1% for those aged 21 to 25. Findings regarding the greater likelihood of marijuana use by men and younger adults remained significant in regression analysis which accounts for the effect of other factors on marijuana use. Relationships are more complex between marijuana use and other factors, in particular, race/ethnicity and education.

By race/ethnicity, prevalence of marijuana use is highest among Hispanics, at 27.1%, followed by 25.8% of Blacks, 20.1% of Whites, 10.4% of Asians, and 37.5% of other race/ethnic groups. Among marijuana users living in MA, most are White, 70.8%, and many fewer are Hispanic, 12.0%, Black, 7.1%, other, 6.9%, or Asian, 3.2%. In the regression analysis, which accounted for the effect of other factors, race/ethnicity was not associated with marijuana use, suggesting that the likelihood of using marijuana is similar for each group (compared to Whites), when other factors are accounted for. As for educational attainment, prevalence data and bivariate analysis indicate that a greater proportion of adults with a High School degree or college education use marijuana than adults with a graduate degree. In regression analysis, which accounts for the effect of other factors on marijuana use, adults with a college education are as likely to use marijuana as those with a high school education or less. In contrast, adults with a graduate degree are less likely to use marijuana than those with a High School education or less. Relationships between marijuana use, educational attainment, and other indicators of economic status are known to be complex and poorly understood. For example, college students face added risks for marijuana use that have been attributed to a diverse set of factors that include: overestimation among college students regarding how often the average student uses drugs (McCabe, 2008); perceptions among college students that drug use during their college years is normative (Cook, Bauermeister, Gordon-Messer & Zimmerman, 2013; Pischke et al., 2012); the expectation among college students that drugs will reduce social anxiety and facilitate the formation of new peer friendships (Buckner, 2013); and greater exposure to drug-using opportunities that exist on college campuses (Arria et al., 2008).

Patterns of marijuana use among college graduates have been attributed to age-graded changes in social roles and associated normative behavior that generally accompany the life transitions that this event signifies (Kandel & Chen, 2000). The present study

was not designed to explore these types of relationships, and therefore findings should be interpreted with caution.

By region, residents in the Western area of the state report the highest prevalence rate of past 30-day marijuana use, at 29.8%, with rates in other areas of the Commonwealth ranging from 20.9% to 18.2%. In Poisson regression analysis, compared with living in Boston, living in the Northeast, Southeast, and Western regions of the state are each positively associated with marijuana use. Findings suggest that the public health impacts of marijuana use may not be evenly distributed across the state. Other factors associated with a lower likelihood of marijuana use are home ownership and having children in home. Given the cross-sectional design of the study, we cannot determine the nature of these relationships and therefore these findings should not be interpreted as being causally related.

About 7 out of 10 Massachusetts adults consume alcohol, and 4 out of 100 consume another substance (e.g., non-prescribed opioids, cocaine/crack, heroin, non-medical anti-anxiety drugs, and other illicit substances). Notably, a greater proportion of Massachusetts marijuana users than non-users consume alcohol and other substances, particularly non-prescribed opioids, and use of alcohol and other substances is associated with a greater likelihood of using marijuana. The co-occurring use of marijuana with alcohol and other substances, particularly during adolescence and young adulthood, is well-established (Swift et al., 2012; Tzilos, Reddy, Caviness, Anderson & Stein, 2014).

Just over half of Massachusetts adults favored the legalization of marijuana, with double the proportion of marijuana users than non-users supporting legalization. As there have been dramatic shifts in public opinion regarding marijuana and in marijuana-related law and public policy (Pacula et al., 2005; Pacula, Kilmer, Wagenaar, Chaloupka, & Caulkins, 2014; Pew Research Center, 2014), the incidence and prevalence of both marijuana use and also marijuana use disorders are expected to increase (Budney & Moore, 2002; Hasin et al., 2017; Martins et al., 2016; Volkow, Baler, Compton, & Weiss, 2014). Of those who ever use marijuana, about 21% develop a marijuana use disorder (Caulkins, 2018). However, the proportion of marijuana users who meet disorder criteria is different by age. For example, national prevalence data indicate that in 2016, approximately 7.2 million young adults aged 18 to 25 were current users of marijuana, or 20.8% of young adults, and of these, 1.7 million had a marijuana use disorder in the past year, or 5.0% (SAMHSA, 2017). Expressed another way, these data indicate that about 24% of young adults aged 18 to 25 who use marijuana meet disorder criteria. Longitudinal studies have documented that while marijuana use can extend over many years of the life course, for most individual's problematic marijuana use is generally limited to young adulthood (Chen & Jacobsen, 2012; DeWit, Offord & Wong, 1997; Schulenberg et al., 2005), and only about 9% of marijuana users remain dependent on the substance over the long-term (Hall & Degenhardt, 2009). However, once a marijuana use disorder does develop, it is associated with increased risk of several diseases and poor health outcomes, including impaired respiratory function, cardiovascular disease, adverse effects on adolescent psychosocial development and

mental health, and residual cognitive impairment (Hall & Degenhardt, 2013). In the present study, we only examined marijuana use, and we did not include measurement of marijuana use disorders.

More than half of adult marijuana users in Massachusetts report using marijuana only for adult non-medical purposes, but a significant proportion also report using it for medical reasons. At the same time, a greater proportion of marijuana users than non-users perceive marijuana to have no health risks, or only slight risks, and marijuana users are less likely to perceive that marijuana poses moderate or great risks. Marijuana is primarily used for adult use because it induces euphoria, drowsiness, and feelings of relaxation (Inaba & Cohen, 2011). Individuals who use marijuana therapeutically report that it relieves conditions and symptoms such as glaucoma, nausea, AIDS-associated anorexia and wasting syndrome, chronic pain, inflammation, multiple sclerosis, and epilepsy (Volkow, Baler, Compton, & Weiss, 2014). When taken in combination with prescribed medications, however, marijuana may increase the risk of bleeding, change the impact of medications to address blood sugar levels and low blood pressure, interfere with the body's ability to process certain medications, and have other negative impacts. Studies are underway now to better understand the health risks and benefits of marijuana use.

Finally, Accountable Care Organizations and ongoing health care reforms are expected to bring more marijuana users into primary care and other health care settings (Tai et al., 2014; Gordon, Conley & Gordon, 2013). The National Institute on Drug Abuse and other organizations have published evidence-based guidelines on the screening, brief intervention, and treatment of marijuana and other substance use. Also, the proliferation of electronic health records (EHRs) provides the opportunity to track marijuana use, assess its potential interaction with other therapies, and treat it when needed (Fihn et al., 2014; Halamka, 2014; Longhurst, Harrington & Shah, 2014; Weil, 2014). However, given the special regulations that govern addiction healthcare records (e.g., 42 CFR) and reluctance among patients and physicians to report the illicit and stigmatized behaviors that marijuana use once entailed, clinicians may not document marijuana use or refrain from discussing its potential health impacts with patients.

Limitations and Strengths

Findings must be considered within the context of several limitations. The survey response rate was 21.7%. While typical of general population surveys like this one, if there was a response bias on a measure not accounted for by the weighting, generalizability may be limited. For example, findings may be impacted by response bias if adults who used marijuana were more likely to return the survey than adults who do not use marijuana. This could lead to overestimation of the prevalence of marijuana use. The cross-sectional survey design precludes determining the temporal sequencing of experiences and prevents drawing of causal inferences. For this reason, it is appropriate to interpret findings as highlighting those factors that are associated with, but not necessarily causally related to, the outcomes of interest.

Marijuana and other substance use were both self-reported, and not corroborated by testing of biological samples. Social desirability bias can lead to underestimates in survey research, however a unique contribution of this study is that it is the first to be conducted in Massachusetts after legalization of marijuana for adult use. Data was collected in late 2017, nearly one year after marijuana became legal for adult use by, and several years after legalization of medical marijuana in Massachusetts. Reporting of illegal behaviors (e.g. use of illicit drugs; driving under the influence of alcohol or drugs) may be underreported.

Small cell sizes for categories of some variables likely mean that models including them are underpowered. The survey omitted individuals aged 17 or younger and adults living in non-residential settings (e.g., incarcerated settings, group home residents, etc.). Therefore, findings may underrepresent certain groups that may be more likely to use marijuana. We did not explore associations comparing mental health conditions, adulthood trauma, or other known risk factors for marijuana use, whether associations are different among subgroups of adults (moderation), or the processes through which factors are associated with the outcomes of interest (mediation), constituting several areas for future research.

**Chapter 3: Use and Perceptions of Marijuana among Adult Medical
Use of Marijuana Patients in Massachusetts**

Introduction

This report provides data and analysis on the 2018 Medical Use of Marijuana Patient Survey, a component of the Massachusetts Department of Public Health 2018 Marijuana Baseline Study. The aim of this survey is to better understand the patterns of marijuana use, perceptions, and behaviors among medical use of marijuana patients in Massachusetts. Massachusetts Department of Public Health contracted with JSI Research & Training Institute in April 2018 to administer a survey among participants of the Massachusetts Medical Use of Marijuana Program. 42,796 participants of the Massachusetts Medical Use of Marijuana Program were invited through email to take the survey using a computer, smartphone, or tablet.

Methods

Data collection efforts were conducted in April 2018 by JSI Research & Training Institute in conjunction with Massachusetts Department of Public Health. All registered participants of the Massachusetts Medical Use of Marijuana Program were invited to complete the survey via an emailed link to Survey Gizmo. The survey incorporated 81 items covering topics such as demographics, marijuana and marijuana product use, methods of marijuana administration, perceptions of medical use of marijuana, driving and other issues related to marijuana use, alcohol consumption, non-medical use of prescription drugs and other substances, and combination substance use. Respondents were sent 2 reminder emails and given the option at the end of the survey to enter a lottery drawing of \$500, \$250, or \$100.

The analyses look both at individual item response summaries as well as investigating differences between gender (male vs. female), age (≤ 50 years old vs. > 50 years old), and education level ($<$ Bachelor's (4-year college) degree vs. \geq Bachelor's degree) through cross-tabulation comparisons. Chi-square tests for equality of proportions were run to detect significant differences in item response distribution across groups. Exact significance tests were used to test equality of proportions in cases where response categories were too small for reliable chi-square testing. In cases where mean statistics are presented, independent t-tests were run to detect significant differences between comparison groups. Highly statistically significant results are highlighted in the summary text throughout this report, and all tables present item response frequency, percentages, and results of statistical testing.

Appendix B contains all survey questions administered as well as guiding logic used to prompt or restrict respondents to relevant next questions based on their answers to previous items.

Results

Response Rate

Table 1 shows demographic characteristics of the overall survey sample compared to all eligible survey participants. All adult registered medical use of marijuana patients in the Massachusetts Medical Use of Marijuana Program were eligible for participation in the 2018 Medical Use of Marijuana Patient Survey (N=42,796). 6934 of these patients responded to the 2018 Medical Use of Marijuana Patient Survey, for a response rate of nearly 16%. There were no noticeable differences between 2018 survey respondent distributions and the full eligible population across gender, age, and county, suggesting that respondent population demographics are comparable to the overall eligible population of medical use of marijuana patients in Massachusetts.

Table 1. DPH Patient Survey Response Rate and Comparison of Sample Population

	Full Eligible Population (N=42,796)		2018 Survey Respondents (N=6934)	
Response Rate	15.93%

Respondent Demographics

Approximately equal proportions of all respondents were male compared to female (55% vs. 45%) or under 51 years old (53% vs. 47%). A majority of respondents were Non-Hispanic White (87%), followed by Hispanic (5%), and Non-Hispanic Black or African American (3%). Less than 3% of respondents identified as more than one race, or other (Asian, Native Hawaiian, Pacific Islander, American Indian, Alaska Native, or other). 98% of all respondents reported their highest level of education as at least high school graduation or GED, while over 50% reported receiving a Bachelor's degree or higher. Less than 10% reported an annual household income below \$15,000, with the majority reporting over \$40,000. Less than 1% of women were currently pregnant or breastfeeding.

Table 2A shows results of significance tests comparing demographic characteristics by gender. A significantly larger proportion of female than male respondents reported their highest education as a professional degree beyond a Bachelor's degree (27% vs. 22%). Female respondents reported annual household incomes between \$15,000 and \$75,000 compared to males (46% vs. 38%), while a larger proportion of male respondents than female reported annual household incomes above \$75,000 (53% vs. 44%).

Table 2B shows results of significance tests comparing demographic characteristics by age group. The racial distribution of respondents under the age of 51 was significantly more diverse than respondents over the age of 50, as exhibited by the proportion of non-Hispanic White respondents (83% vs. 93%). Most notably, a larger proportion of Hispanic respondents were under age 51 than over 50. A larger proportion of respondents over the age of 50 than under had professional degrees beyond a Bachelor's degree (29% vs. 20%). Older respondents reported annual household income earnings above \$100,000 at a higher rate than younger respondents (38% vs. 34%).

Table 2C shows results of significance tests comparing demographic characteristics by educational attainment. A larger proportion of respondents with at least a Bachelor's degree than respondents without a degree were aged 65 years or older (20% vs. 12%) or between 26 to 35 years old (20% vs. 17%), while a larger proportion of respondents without a Bachelor's degree were aged between 18 and 25 (10% vs. 4%) and 51 to 64 (33% vs. 29%). A larger proportion of respondents with at least a Bachelor's degree identified as non-Hispanic White compared to respondents with an educational attainment below a Bachelor's degree (90% vs. 84%). Respondents with at least a Bachelor's degree also reported annual household incomes above \$75,000 at higher rates than participants without a Bachelor's degree (63% vs. 33%).

Marijuana and Marijuana Product Use

Table 3A, 3B, and 3C show results of survey responses pertaining to marijuana and marijuana product use, with comparisons by gender, age group, and educational attainment, respectively. All survey respondents were asked to report on the number of days in the past 30 days that they used marijuana or marijuana products. On average, respondents reported marijuana use for 23.5 days out of 30. Over 60% of respondents reported marijuana use for over 20 out of 30 days, while approximately 8% reported no use. A slightly higher rate of respondents under the age of 51 reported at least 11 days of use compared to respondents over age 50 (82% vs. 76%). A larger proportion of respondents without a Bachelor's degree than respondents with a Bachelor's degree reported use for over 20 out of 30 days (65% vs. 56%).

Respondents who indicated having used marijuana or marijuana products at least once in the past 30 days were asked to report their total monthly expenditures on marijuana and marijuana products. Almost 40% of these respondents reported spending at least \$201 on marijuana or marijuana products in the past 30 days, while only 10% reported spending nothing. On average, male respondents reported spending approximately \$20 more than females, with a larger proportion of males than females spending at least \$151 (56% vs. 51%). Respondents under age 51 reported spending an average of \$82 more than older respondents, with a larger proportion of younger respondents than older spending at least \$151 (60% vs. 47%). Respondents without a Bachelor's degree spent approximately \$71 more than respondents with a Bachelor's degree, with a larger proportion of respondents without a Bachelor's spending at least \$151 (61% vs. 48%).

All survey respondents were asked to indicate the purpose of their marijuana use in the past 30 days. 93% of respondents reported medical use of marijuana certified by a medical practitioner, 6% reported medical use not certified by a medical practitioner, and 17% of respondents reported recreational use of marijuana. Respondents younger than 51 years old reported higher rates of recreational use than older respondents (20% vs. 14%). Respondents with a Bachelor's degree reported higher rates of recreational use than respondents without a Bachelor's degree (20% vs. 14%).

Medical Conditions for Marijuana and Marijuana Product Use

Tables 4A, 4B, and 4C summarize results of survey responses pertaining to medical conditions for which marijuana and marijuana products were used, with comparisons by gender, age group, and educational attainment, respectively. Respondents who did not use marijuana or marijuana products for medical use in the past 30 days (whether certified or uncertified) were asked to indicate all medical conditions for which they used marijuana or marijuana products. Note that percentages in *Tables 4A, 4B, and 4C* add to more than 100% because of multiple conditions being treated at the same time.

The most common medical condition for which respondents indicated marijuana use was anxiety (60%), followed by chronic pain (46%), insomnia (43%), depression (42%), and stress (41%). Respondents also reported treating arthritis, headaches/migraines, muscle spasms, PTSD, and nausea at rates between 16 and 26%.

A significantly larger proportion of female respondents than male reported using marijuana or marijuana products to treat anxiety, arthritis, bowel distress, depression, fibromyalgia, headaches/migraines, multiple sclerosis, nausea, osteoarthritis, PTSD, vomiting, and “other”. A larger proportion of male respondents than female reported using marijuana or marijuana products to treat ADHD, alcohol dependency, diabetes, HIV/AIDS, and sleep apnea.

A larger proportion of respondents 51 years or older reported using marijuana or marijuana products to treat arthritis, cancer, chronic pain, diabetes, glaucoma, HIV/AIDS, hypertension, neuropathy, and osteoarthritis. A larger proportion of respondents under 51 years old reported using marijuana or marijuana products to treat ADHD, anxiety, bipolar disorder, bowel distress, depression, headaches/migraines, insomnia, loss of appetite, nausea, OCD, PTSD, stress, and vomiting.

Respondents with a Bachelor’s degree did not report using marijuana or marijuana products to treat any of the medical conditions at higher rates than respondents without a Bachelor’s degree. Respondents without a Bachelor’s degree reported using marijuana or marijuana products at higher rates than respondents with a Bachelor’s degree to treat ADHD, anxiety, arthritis, bipolar disorder, carpal tunnel, chronic pain, depression, diabetes, fibromyalgia, headaches/migraines, loss of appetite, muscle spasms, nausea, OCD, opioid use, PTSD, seizures, sleep apnea, and stress.

Methods of Marijuana / Marijuana Product Administration

Tables 5A, 5B, and 5C summarize results of survey responses pertaining to methods of marijuana and marijuana product administration used in the past 30 days, with comparisons by gender, age group, and educational attainment, respectively. Respondents were asked additional questions regarding their typical use of marijuana and the methods of marijuana or marijuana product administration used in the past 30 days. Further, for each method of administration reported, respondents were asked to provide further detail on the frequency and amount of marijuana product used. All respondents who indicated using marijuana at least once in the past 30 days were asked to indicate which methods of marijuana administration they used in the past 30 days. 16% of these respondents used only 1 method in the past 30 days, 26% used 2 methods, 26% used 3, and 31% used 4 or more. A larger proportion of respondents aged 51 or older than younger respondents reported using 1 or 2 methods (51% vs. 34%), while a larger proportion of younger respondents reported using 4 or 5+ methods (38% vs. 22%). A larger proportion of respondents without a Bachelor's degree than with a degree reported using 4 or more methods (34% vs. 27%), while a larger proportion of older respondents than younger reported using 2 or 3 methods (56% vs. 49%).

All respondents who indicated using marijuana or marijuana products at least once in the past 30 days were asked to report on the amount of THC and CBD in their typical marijuana or marijuana product use. 45% of these respondents reported typical use of marijuana or marijuana products that contain higher amounts of THC, 34% reported approximately equal amounts of THC and CBD, and 14% reported higher amounts of CBD. Almost 7% of respondents reported that they did not know. A larger proportion of males than females reported using products higher in THC (53% vs. 37%), while a larger proportion of females than males reported using products with higher amounts of CBD (17% vs. 11%) or equal amounts of THC and CBD (37% vs. 31%). A larger proportion of respondents under the age of 51 compared to older respondents reported using products higher in THC (50% vs. 40%), while a larger proportion of older respondents compared to younger reported using products higher in CBD (17% vs. 11%) or not knowing (9% vs. 5%). A slightly higher proportion of respondents without a Bachelor's degree than with a degree reported using products higher in THC or containing equal amounts of THC and CBD, while a slightly higher proportion of respondent with a Bachelor's degree reported using products higher in CBD.

Respondents who indicated using marijuana or marijuana products at least once in the past 30 days were asked about different methods of marijuana or marijuana product administration used in the past 30 days. Over 2 in 3 respondents reported smoking dried flower (65%) or using vaporized concentrate (62%). 51% reported consuming edible marijuana products. Approximately 1 in 4 respondents reported using vaporized dried flower (28%), applied topical cannabis oil, ointment, lotion, cream, salve, etc. to the skin (27%), and sublingual or orally administered uptake products (23%). 16% of respondents reported using dabbed marijuana products, 11% using oral capsules or tablets, and 5% drinking marijuana infused products.

A significantly larger proportion of male respondents than female reported using vaporized dried flower and dabbed marijuana products. A significantly larger proportion of female respondents than male reported using sublingual or orally administered uptake products and topical cannabis oil, ointment, lotion, cream, salve, etc. to the skin. A significantly larger proportion of respondents under age 51 than older respondents reported smoking dried flower, using vaporized dried flower, vaporized concentrate, dabbed marijuana products, edible marijuana products, and drinkable marijuana products. A significantly larger proportion of respondents without a Bachelor's degree than with a degree reported smoking dried flower and using dabbed marijuana products.

Smoking Dried Flower

Tables 6A, 6B, and 6C summarize results of survey responses pertaining to smoking dried flower, with comparisons by gender, age group, and educational attainment, respectively. 65% of respondents who reported using marijuana or marijuana products in the past 30 days reported using smoked dried flower in a joint, bong, pipe, blunt, etc. the past 30 days. Smoking dried flower was significantly higher among respondents under age 51 compared to older respondents (72% vs. 57%) and respondents without a Bachelor's degree compared to respondents with at least a Bachelor's degree (72% vs. 59%).

Thirty-one percent of respondents who reported smoking dried flower in the past 30 days reported smoking dried flower multiple times per day, while 21% reported smoking dried flower less than once per week. A significantly larger proportion of respondents without a Bachelor's degree than with a degree reported smoking dried flower multiple times per day (37% vs. 24%), while a larger proportion of respondents with a Bachelor's

degree than without reported smoking dried flower less than once per week (25% vs. 17%) and more than once per week (but not as much as once per day) (34% vs. 27%).

Thirty-seven percent of respondents who reported smoking dried flower in the past 30 days reported using less than 1/8 oz. of dried flower in the past 30 days, 30% reported using between 1/8 and 1/2 oz., 22% reported using between 1/2 and 1 oz., and 6% reported using more than one oz. A larger proportion of male respondents than female reported using more than 1 oz. (8% vs. 4%), while a larger proportion of female respondents than male reported using no more than 1/8 oz. (42% vs. 33%) or an unknown amount (8% vs. 4%). A larger proportion of respondents less than 51 years old than older respondents reported using between 1/2 and 1 oz. (23% vs. 20%) and more than one oz. (7% vs. 5%), while a larger proportion of respondents older than 50 reported using up to 1/8 oz. (41% vs 34%) or between 1/8 and 1/4 oz. (15% vs. 13%). A larger proportion of respondents without a Bachelor's degree than with a degree reported using between 1/4 and 1/2 oz. (17% vs. 14%), 1/2 and 1 oz. (26% vs. 17%), and more than one oz. (8% vs. 4%). A larger proportion of respondents with a Bachelor's degree reported using up to 1/8 oz. (46% vs. 29%) and between 1/8 and 1/4 oz. (16% vs. 13%).

Vaporized Marijuana Concentrate

Tables 8A, 8B, and 8C summarize results of survey responses pertaining to using vaporized marijuana concentrated, with comparisons by gender, age group, and educational attainment, respectively. 62% of respondents who reported using marijuana or marijuana products at least once in the past 30 days reported using vaporized marijuana concentrate in the past 30 days. Vaporized marijuana concentrate use was significantly higher among respondents under age 51 compared to older respondents (68% vs. 55%).

Thirty-six percent of respondents who reported using vaporized marijuana concentrate in the past 30 days reported using vaporized marijuana concentrate at least once per day, while 26% reported using vaporized marijuana concentrate less than once per week. A larger proportion of respondents without a Bachelor's degree than with a

degree reported using vaporized marijuana concentrate multiple times per day (25% vs. 19%) and once per day (16% vs. 13%), while a larger proportion of respondents with a Bachelor's degree than without reported using vaporized marijuana concentrate less than once per week (27% vs. 24%) and more than once per week (but not as much as once per day) (41% vs. 34%).

All respondents who reported using vaporized marijuana concentrate in the past 30 days were asked to indicate the amount of THC administered using vaporized marijuana concentrate over the past 30 days. The amount of THC reported by respondents should be interpreted with caution, as almost half of all respondents did not know how much THC they administered using vaporized marijuana concentrate. However, 40% of respondents reported administering between 1 and 150 mg of THC in the past 30 days using vaporized marijuana concentrate. A larger proportion of male respondents than female reported administering between 1 and 150 mg of THC (41% vs. 38%), while a larger proportion of female respondents than male reported that they did not know how much THC they administered using vaporized marijuana concentrate (51% vs. 42%). A larger proportion of respondents over the age of 50 than younger respondents reported that they did not know how much THC they administered using vaporized marijuana concentrate (50% vs. 43%).

All respondents who reported using vaporize marijuana concentrate in the past 30 days were asked to indicate the amount of CBD administered using vaporized marijuana concentrate over the past 30 days. The amount of CBD reported by respondents should be interpreted with caution, as more than 2 in 5 respondents did not know how much CBD they administered using vaporized marijuana concentrate. However, 38% of respondents reported administering between 1 and 150 mg of CBD in the past 30 days using vaporized marijuana concentrate. A larger proportion of male respondents than female reported administering between 1 and 150 mg of CBD (39% vs. 36%), while a larger proportion of female respondents than male reported that they did not know how much CBD they administered using vaporized marijuana concentrate (49% vs. 40%). A larger proportion of respondents over the age of 50 than younger respondents reported that they did not know how much CBD they administered using vaporized marijuana concentrate (48% vs. 41%), as did a larger proportion of respondents with a Bachelor's degree than without a degree (45% vs. 42%).

Dabbed Marijuana Products

Tables 9A, 9B, and 9C summarize results of survey responses pertaining to dabbing marijuana products, with comparisons by gender, age group, and educational attainment, respectively. 16% of respondents who indicated using marijuana or marijuana products at least once in the past 30 days reported using dabbed marijuana

products in the past 30 days. Dabbing was significantly higher among male respondents compared to female (19% vs. 12%), respondents under age 51 compared to older respondents (23% vs. 9%), and respondents without a Bachelor's degree compared to respondents with a degree (21% vs. 12%).

Twenty-eighty percent of respondents who reported dabbing marijuana products in the past 30 days reported dabbing marijuana products at least once per day, while 45% reported dabbing less than once per week. There were no significant differences in reported dabbing by gender, age, or education.

All respondents who reported dabbing marijuana products in the past 30 days were asked to indicate the amount of THC administered by dabbing marijuana products over the past 30 days. The amount of THC reported by respondents should be interpreted with caution, as more than 2 in 5 respondents did not know how much THC they administered through dabbing marijuana products. However, 39% of respondents reported administering between 1 and 150 mg of THC in the past 30 days by dabbing marijuana products. A larger proportion of respondents over the age of 50 than younger respondents reported that they did not know how much THC they administered using vaporized marijuana concentrate (47% vs. 41%).

All respondents who reported dabbing marijuana products in the past 30 days were asked to indicate the amount of CBD administered by dabbing marijuana products over the past 30 days. The amount of CBD reported by respondents should be interpreted with caution, as approximately 2 in 5 respondents did not know how much CBD they administered through dabbing marijuana products. However, 35% of respondents reported administering between 1 and 150 mg of CBD in the past 30 days by dabbing.

Edible Marijuana Products

Tables 10A, 10B, and 10C summarize results of survey responses pertaining to consuming edible marijuana products, with comparisons by gender, age group, and educational attainment, respectively. 51% of respondents who reported using marijuana

at least once in the past 30 days reported using edible marijuana products in the past 30 days. A larger proportion of female respondents than male (53% vs. 49%) and respondents under age 50 than older (59% vs. 42%) reported edible marijuana use.

Twelve percent of respondents who reported using edible marijuana products in the past 30 days reported using these products at least once per day, while 61% reported using these products less than once per week. A larger proportion of respondents less than 51 years old than older respondents reported using edible marijuana products less than once per week (66% vs. 52%), while a larger proportion of older respondents than younger reported these products more than once per week (31% vs. 25%) and once per day (14% vs. 7%).

All respondents who used edible marijuana products in the past 30 days were asked to indicate the amount of THC administered by using these products over the past 30 days. The amount of THC reported by respondents should be interpreted with caution, as almost 1 in 4 respondents did not know how much THC they administered. However, 59% of respondents reported administering between 1 and 150 mg of THC in the past 30 days by through edible marijuana products. A larger proportion of male respondents than female reported administering between 150 and 300 mg of THC (13% vs. 8%), while a larger proportion of female respondents than male reported that they did not know (27% vs. 22%). A larger proportion of respondents under the age of 51 than older respondents reported administering between 150 and 300 mg of THC (12% vs. 9%), while a larger proportion of older respondents than younger reported that they did not know how much THC they administered through edible marijuana products (27% vs. 23%). A larger proportion of respondents with a Bachelor's degree than respondents without a degree reported administering between 1 and 150 mg of THC through edible marijuana products (63% vs. 54%), while a larger proportion of respondents without a Bachelor's degree reported that they did not know (28% vs. 22%).

All respondents who used edible marijuana products in the past 30 days were asked to indicate the amount of CBD administered by using edible marijuana products over the past 30 days. The amount of CBD reported by respondents should be interpreted with caution, as approximately 1 in 3 respondents did not know how much CBD they administered through edible marijuana products. However, 45% of respondents reported administering between 1 and 150 mg of CBD in the past 30 days through edible marijuana products.

Drinkable Marijuana Products

Tables 11A, 11B, and 11C summarize results of survey responses pertaining to consuming drinkable marijuana products, with comparisons by gender, age group, and educational attainment, respectively. 5% of respondents who reported using marijuana or marijuana products at least once in the past 30 days reported using drinkable marijuana products in the past 30 days. Consuming drinkable marijuana products was significantly higher among respondents under age 51 compared to older respondents (6% vs. 3%) and respondents without a Bachelor's degree compared to respondents with a degree (6% vs. 4%).

Nine percent of respondents who reported drinking marijuana products in the past 30 days reported drinking marijuana products at least once per day, while 81% reported drinking marijuana products less than once per week.

All respondents who reported drinking marijuana products in the past 30 days were asked to indicate the amount of THC administered by drinking marijuana products over the past 30 days. The amount of THC reported by respondents should be interpreted with caution, as almost 1 in 5 respondents did not know how much THC they administered through drinking marijuana products. However, 60% of respondents reported administering between 1 and 150 mg of THC in the past 30 days by drinking marijuana products.

All respondents who reported drinking marijuana products in the past 30 days were asked to indicate the amount of CBD administered by drinking marijuana products over the past 30 days. The amount of CBD reported by respondents should be interpreted with caution, as approximately 1 in 4 respondents did not know how much CBD they administered through drinking marijuana products. However, 43% of respondents reported administering between 1 and 150 mg of CBD in the past 30 days through edible marijuana products. There were no significant differences in the amount of CBD administered by drinking marijuana products by gender, age, or education.

Sublingual or Orally Administered Uptake Marijuana Products

Tables 12A, 12B, and 12C summarize results of survey responses pertaining to use of sublingual or orally administered uptake marijuana products, with comparisons by gender, age group, and educational attainment, respectively. 23% of respondents who reported using marijuana or marijuana products at least once in the past 30 days reported using sublingual or orally administered uptake marijuana products in the past 30 days. Using sublingual or orally administered uptake marijuana products was significantly higher among female respondents compared to male respondents (28% vs. 20%), respondents 51 years or older compared to younger respondents (26% vs. 22%) and respondents with a Bachelor's degree compared to respondents without a degree (25% vs. 22%).

Twenty-five percent of respondents who reported using sublingual or orally administered uptake marijuana products in the past 30 days reported using these products at least once per day, while 47% reported using these marijuana products less than once per week. A larger proportion of respondents over the age of 50 than younger respondents reported using sublingual or orally administered uptake marijuana products once per day (23% vs. 10%) and multiple times per day (10% vs. 6%).

All respondents who reported using sublingual or orally administered uptake marijuana products in the past 30 days were asked to indicate the amount of THC administered by using these products over the past 30 days. The amount of THC reported by respondents should be interpreted with caution, as almost 1 in 4 respondents did not know how much THC they administered through sublingual or orally administered uptake marijuana products. However, 54% of respondents reported administering between 1 and 150 mg of THC in the past 30 days through sublingual or orally administered uptake marijuana products.

All respondents who reported using sublingual or orally administered uptake marijuana products in the past 30 days were asked to indicate the amount of CBD administered by using these products over the past 30 days. The amount of CBD reported by respondents should be interpreted with caution, as 30% respondents did not know how much CBD they administered through sublingual or orally administered uptake marijuana products. However, 48% of respondents reported administering between 1 and 150 mg of THC in the past 30 days through sublingual or orally administered uptake marijuana products.

Oral Capsules/Tablets

Tables 13A, 13B, and 13C summarize results of survey responses pertaining to use of oral capsules or tablets, with comparisons by gender, age group, and educational attainment, respectively. 11% of respondents reported using oral capsules/tablets in the past 30 days to administer marijuana. There were no significant differences in the proportion of respondents who reported using oral capsules/tablets by gender, age, or education.

Twenty-four percent of respondents reported using oral capsules/tablets at least once per day, while 56% reported using these marijuana products less than once per week.

All respondents who reported using oral capsules/tablets in the past 30 days were asked to indicate the amount of THC administered by using these products over the past 30 days. The amount of THC reported by respondents should be interpreted with caution, as almost 1 in 5 respondents did not know how much THC they administered through oral capsules/tablets. However, 55% of respondents reported administering between 1 and 150 mg of THC in the past 30 days through oral capsules/tablets, and 15% reported administering 0 mg of THC. There were no significant differences the amount of THC administered by using capsules/tablets by gender, age, or education.

All respondents who reported using oral capsules/tablets in the past 30 days were asked to indicate the amount of CBD administered by using these products over the past 30 days. The amount of CBD reported by respondents should be interpreted with caution, as almost 1 in 4 respondents did not know how much CBD they administered through oral capsules/tablets. However, 47% of respondents reported administering between 1 and 150 mg of CBD in the past 30 days through oral capsules/tablets, and 16% reported administering 0 mg of CBD.

Topical Cannabis, Oil, Ointment, Lotion, Salve

Tables 14A, 14B, and 14C summarize results of survey responses pertaining to applying topical cannabis, oil, ointment, lotion, salve, or other marijuana products to the skin, with comparisons by gender, age group, and educational attainment, respectively. 27% of respondents who reported using marijuana at least once in the past 30 days reported applying topical cannabis to the skin in the past 30 days. A significantly larger proportion of female respondents compared to males report applying topical cannabis (35% vs. 20%).

Twenty-six percent of respondents who reported using topical cannabis in the past 30 days reported applying topical cannabis to the skin at least once per day, while 42% reported applying topical cannabis less than once per week. A larger proportion of respondents without a Bachelor's degree than respondents with a degree reported applying topical cannabis to the skin multiple times per day (14% vs. 7%), while a larger proportion of respondents with a Bachelor's degree than without reported applying topical cannabis to the skin less than once per week (46% vs. 36%).

All respondents who reported applying topical cannabis, oil, ointment, lotion, salve, etc. to the skin in the past 30 days were asked to indicate the amount of THC administered by using these products over the past 30 days. The amount of THC reported by respondents should be interpreted with caution, as more than 2 in 5 respondents did not know how much THC they administered through topical cannabis. However, 38% of respondents reported administering between 1 and 150 mg of THC in the past 30 days through topical cannabis, and 13% reported administering 0 mg of THC. A larger proportion of male respondents than female reported administering between 1 and 150 mg of topical cannabis to the skin (46% vs. 33%), while a larger proportion of females than males did not know how much THC they administered through topical cannabis (49% vs. 38%).

All respondents who reported applying topical cannabis, oil, ointment, lotion, salve, etc. to the skin in the past 30 days were asked to indicate the amount of CBD administered by using these products over the past 30 days. The amount of CBD reported by respondents should be interpreted with caution, as almost one half of all respondents did not know how much CBD they administered through topical cannabis. However, 42% of respondents reported administering between 1 and 150 mg of CBD in the past 30 days through topical cannabis.

Rectal/Vaginal Cannabis

Tables 15A, 15B, and 15C summarize results of survey responses pertaining to using rectal/vaginal cannabis, with comparisons by gender, age group, and educational attainment, respectively. 1% of respondents who reported marijuana or marijuana product use at least once in the past 30 days reported using rectal/vaginal cannabis in the past 30 days. There were no significant differences in the proportion of respondents who reported use of rectal/vaginal cannabis by gender, age, or education.

Eighty-nine percent of respondents who reported using rectal/vaginal cannabis in the past 30 days reported using rectal/vaginal cannabis less than once per week. There were no significant differences in the frequency of rectal/vaginal cannabis use by gender, age, or education.

All respondents who reported using rectal/vaginal cannabis in the past 30 days were asked to indicate the amount of THC administered by using these products over the past 30 days. The amount of THC reported by respondents should be interpreted with caution, as almost 1 in 5 did not know how much THC they administered through rectal/vaginal cannabis. However, 70% of respondents reported administering between 1 and 150 mg of THC in the past 30 days through rectal/vaginal cannabis. There were no significant differences in the amount of THC administered by using rectal/vaginal cannabis by gender, age, or education.

All respondents who reported using rectal/vaginal cannabis in the past 30 days were asked to indicate the amount of CBD administered by using these products over the past 30 days. The amount of CBD reported by respondents should be interpreted with caution, as almost one third of all respondents did not know how much CBD they administered through rectal/vaginal cannabis. However, 39% of respondents reported administering between 1 and 150 mg of CBD in the past 30 days through rectal/vaginal cannabis, while 24% reported administering 0 mg. There were no significant differences in the amount of CBD administered by using rectal/vaginal cannabis by gender, age, or education.

Perceptions of Medical Marijuana Use

All respondents, regardless of their use of marijuana in the past 30 days, were asked to report on various perceptions and behavior related to medical use of marijuana. Results are summarized in *Tables 16A, 16B, and 16C*, with comparisons by gender, age group, and educational attainment, respectively.

Sixty-six percent of survey respondents reported using marijuana or marijuana products for medical purposes for at least a year, with 20% reporting use for over 3 years. 7% of respondents reported medical use of marijuana or marijuana products for 3 months or less. A larger proportion of male respondents than female reported medical use for at least 3 years (21% vs. 16%), while a larger proportion of respondents under the age of 51 compared to older respondents reported medical use for at least 3 years (22% vs. 16%). Finally, a larger proportion of respondents without a Bachelor's degree than with reported medical use for at least 3 years (22% vs. 17%).

Ninety-four percent of survey respondents reported feeling safe or very safe when buying medical marijuana products at a licensed dispensary, while 5% reported feeling very unsafe. A larger proportion of respondents over the age of 50 than younger respondents reported feeling very unsafe (7% vs. 4%), while a larger proportion of younger respondents than older reported feeling very safe (89% vs. 86%). A larger proportion of respondents without a Bachelor's degree than with a degree reported feeling very unsafe (7% vs. 4%), while a larger proportion of respondents with a Bachelor's degree than without reported feeling very safe (90% vs. 85%).

Sixty-six percent of survey respondents reported somewhat high or very high knowledge of products when selecting products for medical use, while 7% reported somewhat low or very low knowledge. A larger proportion of male respondents than female reported very high knowledge (42% vs. 32%), while a larger proportion of female respondents than male reported average knowledge (31% vs. 23%). A larger proportion of respondents under the age of 51 than older respondents report very high knowledge (43% vs 32%), while a larger proportion of older respondents than younger report average knowledge (29% vs. 24%).

Eighty-nine percent of survey respondents indicated that they had somewhat high or very high confidence that they were receiving safe, uncontaminated products at licensed dispensaries, while less than 2% reported that they had somewhat low or very low confidence. A larger proportion of respondents younger than 51 compared to older respondents reported very high confidence (71% vs. 67%), while a larger proportion of older respondents reported average confidence (11% vs. 8%). A larger proportion of respondents with a Bachelor's degree than without a degree reported very high confidence in receiving safe, uncontaminated products (71% vs. 68%).

Ninety-one percent of survey respondents reported that marijuana use has been effective or very effective in treating their medical condition, while 2% reported that marijuana use has had little effect or no effect at all. A larger proportion of male respondents than female reported that marijuana use has been effective (27% vs. 24%).

A larger proportion of respondents less than 51 years old than older respondents reported that marijuana use has been very effective (72% vs. 58%), while a larger proportion of older respondents than younger reported that marijuana use has been effective (30% vs. 22%) or somewhat effective (10% vs. 5%).

Driving Issues Related to Marijuana Use

All survey respondents were asked to report on their driving behaviors related to marijuana use. Results are summarized in *Tables 17A, 17B, and 17C*, with comparisons by gender, age group, and educational attainment, respectively.

Ten percent of survey respondents indicated that in the past 30 days they had driven or operated a car or other motor vehicle while under the influence of marijuana or marijuana products. A larger proportion of respondents without a Bachelor’s degree than with a degree reported driving while impaired (11% vs. 10%).

Eleven percent of survey respondents indicated that in the past 30 days they had ridden as a passenger in a car or other motor vehicle while the driver was under the influence of marijuana or marijuana products. A significantly larger proportion of respondents under age 51 compared to over 50 (14% vs. 7%) reported riding as a passenger with an

impaired driver in the past 30 days, as did a larger proportion of respondents without a Bachelor's degree compared to with a degree (13% vs. 9%).

Other Issues Related to Marijuana Use

All respondents were asked a series of questions pertaining to outcomes and consequences related to marijuana use, as well as other issues related to marijuana use. Results are summarized in *Tables 18A, 18B, and 18C*, with comparisons by gender, age group, and educational attainment, respectively.

All survey respondents were asked to choose from a list negative outcomes/consequences related to their marijuana use. 83% of respondents reported experiencing no negative outcomes related to marijuana use. A significantly larger proportion of respondents over the age of 51 than under reported no negative outcomes related to marijuana use (86% vs 80%). A significantly larger proportion of respondents under the age of 51 than over reported negative occupational/job-related issues related to marijuana use (1% vs. 0%). A significantly larger proportion of respondents with a Bachelor's degree than without a degree reported negative changes in cognition related to marijuana use (8% vs. 5%).

All survey respondents were asked to choose from a list of positive outcomes/consequences related to their marijuana use. 78% reported positive changes in mood or mental health, 67% reported improved physical health, 30% reported positive changes in cognition, 41% reported positive changes in social relationships,

and 3% reported no positive outcomes or consequences. A significantly larger proportion of respondents younger than 51 years old reported positive changes in mood or mental health (87% vs. 70%), positive changes in cognition (37% vs. 22%) and positive changes in social relationships (52% vs. 29%). A larger proportion of respondents older than 50 years old reported no positive outcomes (4% vs. 2%). A significantly larger proportion of respondents without a Bachelor's degree than with a degree reported positive changes in cognition (35% vs. 25%) and positive changes in social relationships (46% vs. 38%).

Less than 1% of survey respondents indicated being treated in an emergency room or urgent care facility for reasons related to marijuana use. 14% of respondents who have used marijuana or marijuana products for medical purposes for at least 6 months reported needing to consume larger amounts of marijuana in the past 12 months in order to feel the same effects. A significantly larger proportion of respondents under the age of 51 than older respondents reported needing to consume larger amounts (19% vs. 8%).

Eighteen percent of respondents who have used marijuana or marijuana products for medical purposes for at least 6 months reported trying to cut down on their use of marijuana in the past 12 months. A significantly larger proportion of male respondents than female reported trying to cut down on their use of marijuana (20% vs. 16%), and a larger proportion of respondents under the age of 51 than older respondents reported trying to cut down their use of marijuana (23% vs. 13%). 9% of respondents have used marijuana or marijuana products for medical purposes for at least 6 months and who indicated trying to cut down on their marijuana use in the past 12 months reported feeling sick or experiencing withdrawal symptoms because of reduced marijuana use. There were no significant differences by gender, age, or education.

Alcohol Consumption

All respondents were asked to report on their alcohol consumption in the past 30 days and other related behaviors. Results are summarized in *Tables 19A, 19B, and 19C*, with comparisons by gender, age group, and educational attainment, respectively.

Forty-one percent of survey respondents reported no days in the past 30 days in which they consumed an alcoholic beverage, 42% reported consuming alcohol between 1 and 10 days, and 17% reported consuming alcohol more than 10 days in the past 30. A larger proportion of respondents over the age of 50 than younger respondents reported consuming no alcoholic beverages in the past 30 days (43% vs. 39%) and consuming alcohol for at least 21 days out of the past 30 (10% vs. 4%). A larger proportion of respondents under the age of 51 than older respondents reported consuming an alcoholic beverage between 1 and 10 days out of the past 30 (47% vs. 36%). A larger proportion of respondents without a Bachelor's degree than respondents with a degree reported consuming no alcoholic beverages in the past 30 days (53% vs. 31%), while a larger proportion of respondents with a Bachelor's degree than respondents without a degree reported consuming an alcoholic beverage between 1 and 10 days out of the past 30 (47% vs. 36%), between 11 and 20 days out of the past 30 (14% vs. 6%), and over 21 days out of the past 30 (8% vs. 5%).

Fifty-one percent of survey respondents reported spending \$0 on alcohol in the past 30 days, 42% of respondents reported spending between \$1 and \$100, and 6% reported spending more than \$100. A larger proportion of females than males reported spending \$0 (54% vs. 49%), and a larger proportion of males than females reported spending more than \$100 (8% vs. 4%). A larger proportion of respondents over the age of 51 than under reported spending \$0 on alcohol in the last 30 days (54% vs. 48%), while a larger proportion of younger respondents reported spending between \$1 and \$100 (44% vs. 41%). A larger proportion of respondents without a Bachelor's degree than with a degree reported spending \$0 on alcohol in the past 30 days (63% vs. 41%), while a larger proportion of respondents with a degree reported spending between \$1 and \$100 (50% vs. 35%), between \$101 and \$200 (7% vs. 2%) and over \$200 (3% vs. 1%).

Ninety-four percent of respondents who reported having at least one alcoholic beverage in the past 30 days reported that they did not drive while under the influence of alcohol in the last 30 days, while 6% reported that they had. There were no significant differences in the proportion of respondents driving under the influence of alcohol by gender, age, or education. 7% of survey respondents reported riding as a passenger in a vehicle while the driver was under the influence in the past 30 days.

Only 0.1% of survey respondents indicated being treated in an emergency room or urgent care facility for reasons related to alcohol use in the past 30 days. There were no significant differences in the proportion of respondents treated in an emergency room or urgent care facility for any reason related to alcohol use by gender, age, or education.

Non-Medical Use of Prescription Drugs and Other Substances

All respondents were asked to report on their non-medical use or and behaviors related to prescription drugs and other substances in the past 30 days. Results are summarized

in *Tables 20A, 20B, and 20C*, with comparisons by gender, age group, and educational attainment, respectively.

Ninety percent of survey respondents reported no use of cocaine or crack, heroin, anxiety drugs, sleeping drugs, prescription opioids, or other drugs for non-medical purposes in the past 30 days. 3% of respondents reported using anxiety drugs such as sedatives, tranquilizers, and anxiolytics, and 2% reported using sleeping drugs such as benzodiazepines and barbiturates in the past 30 days. Less than 2% reported using prescription opioids such as Oxycodone, OxyContin, Hydrocodone, Vicodin, Morphine, Methadone, or Fentanyl in the past 30 days. Less than 1% reported using cocaine, crack, or heroin in the past 30 days.

Thirty-five percent of respondents who reported any use of cocaine or crack, heroin, anxiety drugs, sleeping drugs, prescription opioids, or other drugs for non-medical purposes in the past 30 days reported non-medical use of prescription drugs between 1 and 10 days out of the past 30, while 65% reported non-medical use of prescription drugs and other substances for more than 10 out of 30 days.

One percent of respondents who reported any use of cocaine or crack, heroin, anxiety drugs, sleeping drugs, prescription opioids, or other drugs for non-medical purposes in the past 30 days being treated in an emergency room or urgent care facility for reasons related to non-medical use of prescription drugs and other substances in the past 30 days. There were no significant differences in the proportion of respondents treated in emergency rooms for non-medical use of prescription drugs or other substances in the past 30 days by gender, age, or education.

Fifty-nine percent of survey respondents reported cutting down or stopping the use of other prescription drugs, over the counter medications, or other substances since beginning marijuana use. A significantly larger proportion of female respondents compared to male (63% vs. 55%).

Sixty percent of survey respondents reported spending \$0 on prescription drugs or other substances, and 31% of respondents reported spending between \$1 and \$100, and 9% reported spending over \$100 in the past 30 days. A larger proportion of male respondents than female reported spending \$0 on any other prescription drugs (63% vs. 57%), while a larger proportion of female respondents than male reported spending between \$1 and \$100 on any other prescription drugs (34% vs. 28%) in the past 30 days. A larger proportion of respondents under age 51 than over reported spending \$0 on any other prescription drugs (67% vs. 53%), while a larger proportion of older respondents than younger reported spending between \$1 and \$100 on any other prescription drugs in the past 30 days (36% vs. 25%). A larger proportion of respondents without a Bachelor's degree than respondents with a degree reported spending \$0 on any other prescription drugs in the past 30 days (65% vs. 56%), while a larger percent of respondents with a Bachelor's degree than without reported spending between \$1 and \$100 (34% vs. 27%).

Four percent of respondents who indicated using prescription drugs or other substances for non-medical purposes in the past 30 days reported operating a vehicle while under the influence or prescription or other drugs in the past 30 days. 2% of survey respondents reported riding as a passenger in a vehicle while the driver was under the influence or prescription or other drugs in the past 30 days.

Combination of Substances

All respondents were asked to report on their combination use of alcohol, marijuana, or other drugs in the past 30 days. Results are summarized in *Tables 21A, 21B, and 21C*, with comparisons by gender, age group, and educational attainment, respectively.

Thirty-seven percent of survey respondents reported using a combination of alcohol, marijuana, or other drugs in the past 30 days. A significantly larger proportion of respondents younger than 51 years old compared to older respondents reported combination use between 1 to 10 days out of the past 30 (25% vs. 19%), as did a significantly larger proportion of respondents with a Bachelor's degree compared to respondents without a degree (27% vs. 16%). A larger proportion of respondents older than 50 years old compared to younger respondents reported combination use for at least 11 days out of the past 30 (19% vs. 11%), as did a larger proportion of respondents with a Bachelor's degree compared to respondents without a degree (16% vs. 13%).

Nine percent of respondents who indicated using a combination of alcohol, marijuana, or other drugs in the past 30 days reported operating a vehicle while under the influence of combination substances in the past 30 days. There were no significant differences in the proportion of respondents who reported driving/operating a car or other motor vehicle under the influence of any combination of alcohol, marijuana, or other drugs by gender, age, or education.

Discussion

There were no notable differences between respondent distributions of gender, age, or county of residence groups comparing all respondents of the 2018 Medical Use of Marijuana Patient Survey to the full eligible population, suggesting that, although the response rates was low at 16%, the sample of 6934 respondents in this study was representative of the Massachusetts Medical Use of Marijuana patient population. In this survey respondents were asked to type in their Medical Marijuana Registration number and that may have led to concerns about confidentiality.

Respondents indicated using marijuana for an average of 23.5 days out of the past 30, with over 60% reporting marijuana use at least 21 out of the past 30. Over 90% of respondents indicated some certified medical use of marijuana, 6% some uncertified medical use, and 17% indicated some recreational use. These categories are not mutually exclusive, suggesting that while most respondents are using marijuana to treat medical conditions, but some are also using recreationally.

Results from this survey suggest that respondents appear to be treating a wide range of medical conditions, and often more than one at a time. The top 5 medical conditions being treated were anxiety (60% or all respondents), chronic pain (46%), insomnia (43%), depression (42%), and stress (41%), and the average number of conditions being treated by medical marijuana is 4.7.

Patients registered with the Massachusetts Department of Public Health Medical Use of Marijuana Program were certified by a qualified physician or clinician because of a debilitating medical situation, which often has multiple associated medical conditions for which marijuana use can assuage. Results from this study confirm this, suggesting that patients believe marijuana use is alleviating multiple.

While a qualified physician or clinician may certify a patient with a debilitating medical condition for medical use of marijuana, they are not required to write a prescription specifying the product type the patient must use (although they may make recommendations as the patient is under their care). As such, patients have access to a wide range of marijuana administration methods. Results from this study indicate that respondents use multiple methods of administration, over the course of 30 days, with an average of 2.9 methods. In fact, less than one fifth of all respondents reported only one method of marijuana administration, while over 30% reported using 4 or more. The most common method of marijuana administration was smoking dried flower (65%), followed by vaporized marijuana concentrate (62%) and edible marijuana products (51%).

All respondents were asked questions related to perceptions of the Medical Use of Marijuana Program. In general, respondents reported favorably towards medical use of marijuana. Almost all respondents considered the use to be effective in treating their conditions with over 65% of respondents reported that they believed use of marijuana or marijuana products has been “very effective” and an additional 26% believed use of marijuana to be “effective”. Also almost 90% of respondents reported that they had “somewhat high” or “very high” confidence that they were receiving safe, uncontaminated products when purchasing marijuana or marijuana products at a licensed dispensary. 94% reported feeling “somewhat safe” or “very safe” when purchasing medical marijuana at a licensed dispensary, and 66% reported “somewhat high” or “very high” knowledge of their recommended marijuana or marijuana product based on the information provided by their certified practitioner. Findings from this study also suggest that respondents perceive marijuana use to have very high rates of positive outcomes and little obvious harm. 78% of respondents reported positive changes in their mood or mental health, 67% reported improved physical health, and 83% reported no negative outcomes or consequences related to their marijuana use. Thus, respondents are highly satisfied with their access to marijuana products and information and believe they have largely benefitted from medical use of marijuana with very little, if any negative effects.

Finally, almost 60% of respondents who reported use of prescription drugs, over-the-counter, medications, or other substances (for medical use only) also reported cutting down or stopping use of other prescription drugs, over the counter medications, or other substances since beginning to use marijuana.

Conclusion/Public Health Implications

The Massachusetts Medical Marijuana Program is considered to be a very important and valuable asset to the mental and physical health of participants. Respondents of the 2018 Medical Use of Marijuana Patient Survey indicate general satisfaction with the program, few negative outcomes, and in particular have reported a reduction in the use of other drugs and medications as a result of marijuana use.

Task 2: Incidents of Impairment and Hospitalization

Chapter 1: Measuring Marijuana Exposure and its Effects Related to Driving Impairment: A State of the Science Review

Introduction

In states that have chosen to legalize marijuana, one concern among public health and public safety professionals and citizens is the potential impact of marijuana legalization on motor vehicle crashes (MVCs). Studies suggest that recent cannabis use is associated with an increased crash risk between 22%-100% (Asbridge, Hayden, & Cartwright, 2012; G. Li, Chihuri, & Brady, 2017; Rogeberg & Elvik, 2016). However, there are challenges to the detection and deterrence of marijuana-impaired driving. Although a substantial body of literature related to methods for identifying acute marijuana exposure and impairment exists, best practice for doing so has yet to be established. As such, states that are implementing legalization of marijuana are doing so without established guidelines for detecting marijuana-impaired driving in a manner that is relatively non-invasive and sufficiently accurate to prove impairment. Washington State has selected 5ng/mL as a per se limit; Colorado uses this level as “presumptive evidence” of impairment. This report reviews the relevant scientific literature on the topic of measuring marijuana as it relates to driving impairment.

Scientific Foundation

The content of this report is predicated on several accepted premises that are derived from current scientific knowledge. First, with regard to marijuana pharmacokinetics, it is established that combustion (burning) of the dried flower of the cannabis plant converts tetrahydrocannabinolic acid to Δ^9 -tetrahydrocannabinol (THC) (Huestis, 2007). THC is then metabolized in the liver to psychoactive 11-OH- Δ^9 -tetrahydrocannabinol (OH-THC; pronounced “hydroxy THC”) and non-psychoactive 11-nor-9-carboxy- Δ^9 -tetrahydrocannabinol (THC-COOH, pronounced “carboxy THC”) which is excreted in urine (Grotenhermen, 2003; Huestis, 2007).

The Δ^9 -THC is the main source of the pharmacological effects caused by cannabis consumption. Cannabinoids exert many effects through activation of G-protein-coupled cannabinoid receptors in the brain and peripheral tissues (Grotenhermen, 2003). There is also evidence for non-receptor-dependent mechanisms (Grotenhermen, 2003). Cannabis is usually inhaled or taken orally. The pharmacokinetics of THC vary by route of administration (Grotenhermen, 2003; Huestis, 2007; Newmeyer et al., 2017a). After inhalation, plasma THC concentration peak within a few minutes (Grotenhermen, 2003). Psychotropic effects begin within seconds to a few minutes, reach a maximum after 15-30 minutes, and taper off within 2-3 hours (Grotenhermen, 2003). Following oral ingestion, psychotropic effects onset after 30-90 minutes, reach a maximum after 2-3 hours, and last for about 4-12 hours, depending on dose and specific effect (Grotenhermen, 2003; Hollister et al., 1981; Wall, Sadler, Brine, Taylor, & Perez-Reyes, 1983).

With regard to biological measurement of marijuana exposure, we take blood to be the “gold standard” in terms of the matrix that has been best studied. Urine and oral fluid have also been studied to a great extent. The relationship between route of administration and measurement of cannabis in oral fluid is an area of ongoing research and will be described below.

Prevalence of Cannabis-Positive Drivers in Motor Vehicle Crashes

In the U.S. estimates of the prevalence of marijuana involvement in MVCs vary. As part of the background information for this state of the science review (SSR) we systematically collected all studies reporting prevalence of cannabis involvement in MVCs in the U.S. At the national level, one study found that the prevalence of cannabis-involved motor vehicle crashes in 1982 was 10% and that by 2001, the prevalence had increased to 19.6% (Macdonald et al., 2003). Conversely, another nationwide study found that the overall prevalence of cannabis in motor vehicle crashes between the years 1993-2014 remained constant at 10.4% which suggests that prevalence had not increased significantly since 1982 (G. Li et al., 2017).

Studies have also been conducted at the state level in locations that have made substantial changes to their marijuana policy by allowing the legal sale of marijuana for medical and/or recreational purposes. States that have undergone such policy changes provide insight that may be especially relevant for Massachusetts. In Colorado, one study conducted between the years 1994-2011 found that there was an increase in prevalence of cannabis related motor vehicle crashes from 4.5% in 1994 to 10% in 2011, after medical marijuana was commercialized in mid-2009 (Salomonsen-Sautel, Min, Sakai, Thurstone, & Hopfer, 2014). Findings from another study in Colorado show that in 2006 the prevalence of cannabis related motor vehicle crashes in Colorado was 6.9% and increased to 19% by 2014; Colorado's citizens voted in 2012 to legalize marijuana for non-medical use (Rocky Mountain High Intensity Drug Trafficking Area, 2015).

Results from studies in Washington State indicate that about 10% of drivers in fatal crashes between 2010-2014 had delta-9-THC in their blood. The prevalence such crashes was stable prior to legalization of recreational marijuana use, but approximately 9 months after legalization took effect it began increasing by nearly 10 percentage points per year (Tefft, Arnold, & Grabowski, 2016). Another study from 2013-2014 showed the prevalence of cannabis related motor vehicle crashes in Washington State to be between 7-8% (Banta-Green, Rowhani-Rahbar, Ebel, Andris, & Qiu, 2016). Overall, there is conflicting evidence, but studies reviewed here indicate that the prevalence of cannabis-positive drivers in motor vehicle crashes has increased in states where marijuana policy has become more permissive. It is important to note that in these prevalence studies, whether drivers were actually impaired by cannabis at the time of the crash was not determined. Collecting a blood test from surviving drivers presents a challenge due to the invasive nature of blood collection; time delays between a crash and blood testing are common and problematic since delta-9-THC levels rapidly decrease after smoking (Wood, Brooks-Russell, & Drum, 2016).

Study Purpose

The establishment of fair and appropriate methods to detect marijuana-related driving impairment could help ensure public safety in environments with legal marijuana and

provide important information about prevalence. This review of the literature is undertaken for the purpose of summarizing the available scientific evidence. Specifically, we sought to: 1) Describe the analytical methods used to quantify marijuana exposure in laboratory and field settings; 2) Describe measurements of marijuana-related impairment that are relevant to operating a motor vehicle; and 3) Provide an integration and discussion of evidence for approaches that link marijuana-related measurements of exposure with measurements of impairment that are relevant to operating a motor vehicle.

Research Questions

RQ1: What is the most current science on quantifying marijuana exposure in an analytical chemistry laboratory or clinical laboratory setting in different matrices (blood, oral fluid, urine) through quantitative measurement of marijuana and its metabolites?

RQ2: What methods (e.g., devices, tests, kits, etc.) are currently available for quantifying marijuana exposure in the field and what is the precision and accuracy of these methods for detecting marijuana exposure (compared to laboratory-based methods)?

RQ3a: What are the cognitive and behavioral indicators of marijuana exposure that are relevant to operating a motor vehicle? How have these been characterized at baseline (non-impaired) levels?

RQ3b: How are the cognitive and behavioral effects of marijuana impairment measured in laboratory settings and in field settings? What validation has been conducted? What is the level of accuracy for determining impairment/non-impairment?

Methods

We approached the research questions above through a systematic literature search process. In instances when a high-quality review article was already published on the topic of interest, we used the review as a starting point and extracted information from the studies gathered by the review authors. We then conducted a search that covered the time period between the publication of the latest paper included in the review and December 2017. We conducted the searches in the following order: RQ2, RQ3a, RQ3b, RQ1. More information is provided below, and details of the search terms are provided in

Table 1. Search Strings.

Research Question 1: Quantifying Marijuana Exposure in a Laboratory Setting

Our systematic search conducted for R2 identified studies that were relevant to research question 1. Specifically, all identified R2 studies utilized similar confirmatory laboratory testing methods to identify marijuana exposure in blood, urine, and or saliva.

Given the consistency in the studies identified in R2, we were confident in our assessment that said methods were the state of the science. As such, the goal of our research specific to R1 was to identify one or more studies that confirmed our assessment. We did not deem a systematic review of the literature necessary to accomplish this goal. Instead, we developed several search strings to identify studies that provided an overview of current methods as well as potential future directions for laboratory marijuana exposure quantification, particularly in regards to new quantification and interpretation methods for THC metabolites.

We tested both complex and simple search strings to accomplish this goal. All search strings were tested on PubMed. We found that one particular simple search string performed best. The string identified 22 total references. Titles and abstracts were reviewed for relevance and a recent article written by a leading expert in the field was identified. Given that the content of this article matched closely to what we were attempting to procure, we chose to utilize it as the center piece of our response to this question. Other identified references, either from the broad R1 search or the systematic, targeted R2 search were utilized as appropriate.

Research Question 2: Methods for Quantifying Marijuana Exposure in a Field Setting

We conducted a systematic search of the current literature related to on-site testing devices, sometimes called point-of-collection tests (POCT), for measuring marijuana. We did not restrict the search to specific biological matrices (i.e. only blood, only oral fluid). We conducted our search in both PubMed and Web of Science, and searched the relevant gray literature (e.g. AAA Foundation, National Highway Transportation Safety Administration, etc.) for relevant studies. The search was limited to studies published in or after 1995.

Search strings were developed in consultation with a University of Massachusetts Amherst librarian with expertise in health science search string development. Searches were conducted on each separate database and abstracts were screened for appropriateness. To be considered for full text review, abstracts had to convey that the study met the following criteria: (1) was published in English, (2) was conducted in humans, (3) examined field devices or kits, and (4) examined marijuana exposure.

Studies identified as candidates for inclusion after the abstract screening process subsequently had their full text reviewed for appropriateness. After full text review, studies were excluded if: (1) Device assessed was only for collection and storage of sample; (2) Study did not assess devices capability as a rapid on-site test; (3) Study assessed devices used to measure synthetic cannabinoids; (4) Device assessed was a laboratory device (5) Study did not assess any on-site device; (6) Study did not provide sensitivity or specificity measurements of THC for tested device, or (7) Text of study was not in English.

Of 154 combined peer reviewed results identified through our initial searches, 84 were selected for full text review. A majority (61%) of these studies were obtained through PubMed. We identified one study from the gray literature for full text review.

During full text review, we identified a systematic review and meta-analysis conducted on our topic of interest in 2017 (latest year of included studies was 2015). We used this study as the centerpiece of our review and subsequently reviewed identified studies from 2015-2017 to update and supplement this already completed review. We identified 6 studies that were published beyond the 2015 review. Thus, these 7 studies form the basis of our review for this question. We reviewed the reference list of the 6 more recent, original studies and cross-checked this with the review article to ensure that all important papers relevant to the topic were included either in the existing review article or in the original research studies we identified and included.

We extracted information about sensitivity and specificity of the POCT devices as compared to laboratory methods, and we report accuracy when possible. Sensitivity refers to the percentage of cannabis-using individuals that were correctly identified as positive for cannabis. Specificity refers to the percentage of individuals who did not use cannabis that were correctly identified as non-users by a negative test result.

Given the complexity of the studies in this area, we summarized the results in several tables. In synthesizing and interpreting the studies, as a whole, we weighted studies with a larger sample size, controlled laboratory conditions, and comparisons between multiple devices as more salient than others.

Research Question 3A: Cognitive and Behavioral Effects Relevant to Driving

A systematic search of the current literature related to cognitive and behavioral indicators of marijuana exposure was conducted. Following advice from a health sciences librarian, we conducted our searches in both PubMed and Web of Science. We also sought input from the librarian for developing and refining our search string. Searches were conducted on each separate database and abstracts were screened for appropriateness. We did not limit the date range on this search.

Early in the review process, we identified a recent systematic review (Bondallaz et al., 2016) whose content matched closely with what we were attempting to procure. We judged this review to be of high quality, and therefore used it as the basis for our response to RQ3a. We extracted all individual studies from the review and reviewed them independently. We subsequently conducted an update search, using a search string developed in consultation with a health sciences librarian to identify any studies on the subject of interest published after 2013 (the newest study reviewed in the review article).

In total, 24 studies were extracted from the Bondallaz review. Our update search (2013-2017) initially yielded 367 results from PubMed and 316 from Web of Science. After abstract screening and removal of duplicates, we identified 15 studies for full text review from PubMed and 2 studies for full text review from Web of Science. After full text

review, we identified an additional 5 studies that had been published on the topic since the Bondallaz review for a total of 29 studies included in our review.

Detailed information such as THC dosage, user population, sample size, study setting, indicator tested, measurement approach, and results were extracted from studies included in final review. In order to standardize the information extraction, we defined the relevance of cognitive / behavioral indicators measured according to the recommended behavioral measurements outlined in Guidelines for Research on Drugged Driving (J Michael Walsh, Verstraete, Huestis, & Mørland, 2008). These include automotive behavior, control behavior, and executive planning. The only additional category defined outside of the three listed above was, “driving safety/performance metric.” This was only defined for driving simulator and on road studies which measured direct driving metrics such as mean speed and SD lateral position. This approach was adapted from the Bondallaz review which identified said behavioral measurements and grouped typical neurocognitive tests (Tower of London Task, Critical Tracking Task etc.) according to their corresponding behavioral measurement (Bondallaz et al. 2016 – Table 1) (Bondallaz et al., 2016). We expanded on this by incorporating these behavioral measurement categories into our analytic table.

After information from all studies was extracted to the large summary table, we further refined the analysis in order to enhance the digestibility of the results. We created four separate analytic tables grouped by study setting (lab, simulator, on road, and observational). Each table presents a refined analysis, where detailed results are omitted in favor of a simple summary of the results with regard to the impact of marijuana on task performance. We documented whether marijuana exposure hurt performance, improved performance, or had no effect on performance on specified tests. These tables are designed to allow the reader to digest the results at a higher level and examine trends otherwise invisible at increased levels of granularity.

Research Question 3B: Field Measurement of Marijuana’s Effects and Accuracy for Determining Impairment

The first component of research question 3b, which addresses how cognitive and behavioral effects of marijuana exposure are measured in a laboratory setting, was answered using the search results from research question 3a. Please refer to RQ3a methods for details on the search methods. Search efforts for this research question focused only on the latter part of the question, which attempts to determine how the cognitive behavioral impacts of marijuana exposure are measured in field settings and the validation and accuracy of those tools.

To accomplish this, four separate search strings / strategies were developed to answer this question (Table 1. Search Strings). PubMed was searched. The first string scanned the peer reviewed literature for studies of screening tools that measure cognitive/behavioral indicators of marijuana exposure. After abstract screening, this search did not return any results.

The second string searched the peer reviewed literature for studies of screening tools that measured indicators of cognitive / behavioral deficits. This was done to gain a broader understanding of currently available validated tools. The overall goal was to identify tools that may have utility when applied to measuring marijuana exposure. After abstract screening, this search returned 2 results.

The third string searched the peer reviewed literature for studies that assessed the validity of standardized field sobriety tests (SFSTs) for measuring marijuana. This search was conducted due to the fact that SFSTs are currently used by law enforcement to determine impairment. After abstract screening, this search returned 3 results.

The fourth component of this approach was to scan of the grey literature / internet for tools and or screening devices that might have utility in measuring cognitive or behavioral impacts of marijuana exposure. These included mobile applications. This search returned 5 results, but we excluded 2 apps that were designed generally for cognitive impairment but did not touch directly on tasks used to measure marijuana-related effects in laboratory settings. Results from the four searches were extracted into two separate analytic tables, one for peer reviewed results, and the other for non-peer reviewed results.

Table 1. Search Strings

Research Question	Database	Search String / Search Terms
RQ1	PubMed	Marijuana AND Biological Matrices
RQ2	PubMed	(((marijuana OR cannabis OR Cannabinoids OR Tetrahydrocannabinol OR THC) AND (On-site OR rapid OR field) AND (method OR test OR evaluation OR screening OR measurement OR "Point-of-Care Testing" AND (Device OR kit))))
RQ2	Web of Science	(((marijuana OR cannabis OR Cannabinoids OR Tetrahydrocannabinol OR THC) AND (On-site OR rapid) AND (test OR evaluation OR "screening" OR "measurement" OR "Point-of-Care Testing") AND (Device OR Kit))))
RQ2	NHTSA	Marijuana, Cannabis, Tetrahydrocannabinol. Cannabinoids, On site, Rapid, Test, Evaluation, Measurement, Device
RQ2	AAA Foundation	Marijuana, Cannabis, Tetrahydrocannabinol. Cannabinoids, On site, Rapid, Test, Evaluation, Measurement, Device
RQ3A	PubMed (Initial Search)	(cognitive OR cognition OR behavior) AND motor vehicle AND (operation OR driving OR drive)
RQ3A	Web of Science Initial Search	(cognitive OR cognition OR behavior) AND motor vehicle AND (operation OR driving OR drive)

RQ3A	PubMed (Update Search)	((neurocognitive OR neurocognition OR cognitive OR cognition OR Behavior OR Behavioral OR Performance)) AND ((driving OR drive)) AND ((marijuana OR cannabis OR Cannabinoids OR Tetrahydrocannabinol OR THC))
RQ3A	Web of Science (Update Search)	((neurocognitive OR neurocognition OR cognitive OR cognition OR Behavior OR Behavioral OR Performance)) AND ((driving OR drive)) AND ((marijuana OR cannabis OR Cannabinoids OR Tetrahydrocannabinol OR THC))
R3B	PubMed (Search String A)	(Cognitive OR Behavioral) AND (Marijuana OR Cannabis) AND (Field or On-site or road side) AND (Screening OR Test OR app OR measurement OR evaluation)
R3B	PubMed (Search String B)	(mobile) AND (Cognitive OR Behavioral) AND (Dysfunction OR Impairment) AND (app OR Test OR screening OR application OR evaluation OR measurement)
R3B	PubMed (Search String C)	(Marijuana OR Cannabis) AND (Impairment OR Effect OR Influence) AND (Standard Field Sobriety Test or SFST) AND (Accuracy OR Validity OR Effectiveness)
RQ3B	Google (Search D)	Mobile, app, test, screening, (name of specific test) Example: "mobile Stroop test"

Results

Research Question 1: Quantifying Marijuana Exposure in a Laboratory Setting

There are currently three widely accepted laboratory methods for measuring cannabinoids in human biological matrices: immunoassays, chromatography, and mass spectrometry (Huestis & Smith, 2018). Historically, Gas Chromatography with Mass Spectrometry (GC-MS) has been most frequently utilized method. However, recent desire to identify increasingly informative markers of marijuana exposure has led to more frequent utilization of liquid chromatography tandem mass spectrometry (LC-MS/MS) and high-resolution mass spectrometry (HR-MS) measurement methods. Among other advantages, the LC-MS/MS method allows simultaneous quantification of free and conjugated analytes in a single assay (Huestis & Smith, 2018). These methods also offer high sensitivity and specificity for detecting markers of cannabis use (Huestis & Smith, 2018).

LC-MS/MS and HR-MS methods are intriguing because they offer the ability to identify the Phase II THC metabolite (THC-Glucuronide) as well as cannabigerol (CBG), cannabinol (CBN), and tetrahydrocannabivarin (THCV) (Huestis & Smith, 2018). As research on marijuana metabolism continues to advance, particularly as it relates to quantifying exposure, identification of these metabolites becomes increasingly valuable. For instance, quantification of these metabolites can offer information that helps ascertain recent cannabis intake and or the transfer of cannabinoids to alternative matrices such as hair (Huestis & Smith, 2018).

The wide acceptance of these methods is apparent in examining confirmatory laboratory methods utilized in R2 studies. In 100% of the studies we identified in our systematic search of the literature for R2, at least one variation of these methods was used as the gold standard laboratory comparator for performance assessment of point of care detection devices. One recent systematic review related to POCT device assessment restricted their search to include only studies where some type of chromatographic assay was used as the confirmatory method (Scherer et al., 2017). Moreover, among the four most recently published independent studies assessing POCT devices against laboratory methods, 50% utilized the LC-MS/MS method (Edwards, Smith, & Savage, 2017; S. Gentili, Solimini, Tittarelli, Mannocchi, & Busardo, 2016; Newmeyer et al., 2017a; Swortwood et al., 2017). Coupled with the recent analysis from leading experts in quantitative cannabinoid measurement (Huestis & Smith, 2018) these results confirm that measurement of cannabinoids in human biological matrices (blood, oral fluid, and urine) using immunoassays, chromatography, and or mass spectrometry, particularly LC-MS/MS, is the current state of the science.

Research Question 2: Methods for Quantifying Marijuana Exposure in a Field Setting

Point-of-collection testing (POCT) devices make it possible to rapidly screen for cannabis exposure without the use of standard laboratory equipment. These devices typically test oral fluid or urine as these matrices are easier to obtain in a field setting than blood. Compared with urine analysis, oral fluid (OF) collection presents fewer concerns about privacy and adulterations. Drug testing in OF samples usually detects parent drugs, whereas testing of urine samples usually detects metabolites. This makes OF more reflective of recent drug use (Allen, 2011; Bosker & Huestis, 2009; Drummer, 2010; Scherer et al., 2017).

Our systematic search revealed one systematic review plus meta-analysis of 31 studies that was published in mid-2017 (Scherer et al, 2017). The papers that met inclusion criteria for this study were papers evaluating one or more POCT devices and using a validated chromatographic assay as the confirmatory method. Devices had to assess oral fluid as the biological matrix. Studies had to include analysis of cannabinoids as well as cocaine, amphetamines, benzodiazepines (BZD), and opioids. We extracted the results for cannabinoids alone from that publication for inclusion in this report. After exclusions, we also reviewed 6 original studies that were not already covered in the review article.

In the studies we included in this review, we found evidence for 16 POCT devices (i.e. tests, kits, etc.) that evaluate cannabis exposure in a field setting, with varying levels of evidence and validity testing. In their 2017 review, Scherer et al. noted that the most commonly evaluated devices were the Alere™ DDS2 (DDS2), the Dräger DrugTest 5000™ (DT5000), and the Drugwipe™ manufactured by Securetec. (Scherer et al., 2017) Across the studies we reviewed, the Alere™ DDS2 and the Dräger DrugTest 5000™ have the most research evidence available of the POCT devices described in the literature in terms of the number of studies, the number of participants in those studies, and the relevant variables included (i.e. frequent vs. chronic cannabis users,

route of cannabis exposure). These devices also performed well according to the Scherer review and thus are the focus of our description.

Our systematic search also returned one study comparing two urine tests (the EZCup and the Multi4Card) which we briefly describe below, though there was less evidence for these approaches to point-of-collection OF testing. We concur with the authors of prior studies who note that the ease of use of OF tests makes them a better candidate for field applications (M. A. Huestis et al., 2013).

Oral Fluid POCT Devices

In the Scherer review, the authors included studies that evaluated the following devices: Rapiscan™, OralLab™, SalivaScreen™, Toxiquik™, Oratect™, Uplink™, Drugwipe™, Dräger DrugTest 5000™, OraLine™, OralSTAT™, Impact™, Uplink™, RapidStat™, BIOSENS Dynamic™, DDS 806™, OrAlert™, and DDS™. The Drugwipe™ (Securetec, Germany) was the most commonly evaluated device among the studies (n = 17), followed by the DrugTest 5000™ (Dräger Safety AG & Co., Germany; n = 12), the Rapiscan™ (Cozart Biosciences Ltd., UK; n = 8) and the Rapid Stat™ (Mavand Solutions, Germany; n = 7) (Scherer et al., 2017). All other devices were evaluated in five or fewer studies. Most other articles we reviewed focused predominantly on the DT5000 or the Alere™ DDS2 (DDS2).

The Alere™ DDS2 is a battery operated handheld device that provides a rapid qualitative assessment (positive/negative) of the presence or absence of delta-9-THC in oral fluid above a concentration of 25ng/mL. Samples are collected using a swab cartridge. After collection, the cartridge is inserted into the device for analysis. Results are available in five minutes and the device does not require oversight while the analysis is taking place. The device features a simple user interface, is lightweight, and has the ability to store up to 10,000 unique samples in its memory at once ("Alere DDS@2 Mobile Test System: Rapid Screening for Drugs of Abuse in Oral Fluid," 2018).

The Dräger DrugTest 5000™ (DT5000) is a portable device that provides a rapid qualitative assessment (positive/negative) of the presence or absence of delta-9-THC above a concentration of 5ng/mL. Samples are collected using a test cassette. After collection, the cassette is inserted into the device for analysis. Results are available in less than 9 minutes in most cases and the device does not require oversight while the analysis is taking place. The device features a simple graphical display that communicates results in plain text and has the ability to store up to 500 results at one time. Stored results are tagged with date and time. Results can also be printed using the Dräger Mobile Printer ("Dräger DrugTest® 5000: Analysis system for detecting drugs," 2018).

Study Designs for Evaluating POCT Devices

A variety of study designs were included in the articles we reviewed. The review article by Scherer et al. included studies of oral fluid POCT drug tests among varied populations (e.g. drivers, drug users, laboratory participants, etc.). Generally speaking,

the methodology of the reviewed studies was a slight variation of the following: Participants ingested cannabis either by smoking, vaporizing, or consumption of foods such as brownies in a controlled environment. Upon cannabis consumption, oral fluid specimens were qualitatively analyzed (i.e. pass or fail) using the specified on-site device. Quantitative analytic specimens were concurrently collected to be used as comparators. Analytic samples were either blood or oral fluid (If oral fluid, usually collected with a Quantisal device) ("Quantisal™ Oral Fluid Collection Device," 2018) and were analyzed at a later date using standard, validated laboratory techniques. Results were obtained by comparing the performance of the on-site OF device to the validated laboratory method to determine sensitivity and specificity of the POC device. Most studies defined cut-off values for a "true positive" using only delta-9-THC, although one did conduct additional analyses that included combinations of delta-9-THC and other cannabinoids (we did not report on these results in our analysis). Of note, two studies did not administer cannabis in a controlled setting but rather screened for it in field settings (Edwards et al., 2017; S. Gentili et al., 2016). Otherwise, the general outline of their analyses were the same.

The choice of a confirmation cut-point matters for the correct identification of cannabis exposure via a POCT device. The European Union's Driving Under the Influence of Drugs, Alcohol, and Medicines (DRUID) program has suggested an 80% target for analytical sensitivity, specificity, and efficiency when evaluating devices (Blencowe, Pehrsson, & Lillsunde, 2010). The DRUID project utilized a confirmatory cutoff of 1ng/mL of delta-9-THC (Verstraete et al., 2011). The U.S. Substance Abuse and Mental Health Services Administration (SAMHSA) has recommended a cutoff of 2ng/mL as a definition for a positive cannabis test in a workplace setting (Department of Health and Human Services, 2015). Thus, the papers we reviewed most commonly report sensitivity and specificity at a variety of cutoffs: 25 ng/mL (the device's own cutoff for the DDS2), 5 ng/mL (the device cutoff for the DT5000), 2 ng/mL (SAMHSA), 1 ng/mL (DRUID), and 0.2 or 0.5 ng/mL (the limit of quantitation). Walsh's guidelines for research on drugged driving suggest that for drugs with therapeutic use, the confirmatory testing cut-off concentrations should be at least as low as the low end of the therapeutic range. For recreational drugs without any therapeutic use, the guidelines suggest use of a low analytical cut-off (J. M. Walsh, 2008; J Michael Walsh et al., 2008). For cannabis, which is used both medically and recreationally in Massachusetts, and has wide interpersonal variation in pharmacokinetics, establishing a cutoff presents a challenge. We, therefore, present sensitivity and specificity estimates at multiple cut-offs when possible.

Testing revealed, not unexpectedly, that sensitivity and specificity were highest when the cut-off level was highest (25ng/mL in the studies of OF POCT devices). The tests perform better at correctly identifying the presence of THC when higher levels of THC are present in the matrix. The 25ng/mL cutoff was assessed only for the DDS2 device, since this is the level above which it is designed to report a positive test.

Another important factor in examining the performance of POCTs is the cannabis use history of the study participants. Prior studies have documented that POCT device

sensitivity is higher in chronic frequent as compared to occasional cannabis smokers due to longer detection windows and higher true positive rates. (M. A. Huestis et al., 2013) Because THC is fat soluble, it is stored in adipose tissue and can leak back into circulation over time, even long after the psychoactive effects of acute cannabis use have ceased (Gunasekaran et al., 2009; Wong et al., 2014; Wong et al., 2013). However, at least one study has concluded that the cannabinoid concentration changes that result from THC reentering circulation are not likely to negatively impact the ability to correctly interpret a drug test (Westin, Mjønes, Burchardt, Fuskevåg, & Slørdal, 2014). In addition, since cannabis is consumed via different routes of exposure (e.g. smoked, vaporized, edible), POCT devices may not assess all possible routes of exposure.

Overall POC Test Performance

Table 2 shows the results from studies of OF POCT devices included in this review, number of participants), route of administration, and the sensitivity, specificity, and accuracy of the device for detecting marijuana exposure as compared to laboratory-based confirmation methods. In this table, we include the overall results from studies that included both chronic and frequent users, as well as results from the meta-analysis and studies conducted in naturalistic settings (e.g. pubs, bars; individuals arrested for driving impairment).

Scherer and colleagues pooled data from the studies in their meta-analysis to examine performance of individual POCT devices for cannabinoid detection. They found that the DDS2 had a sensitivity of 92.5% and specificity of 92.1%. The DT5000 had a sensitivity of 86.5% and specificity of 95.2%. Two other devices, the DrugWipe5+ and RapidStat also performed well for cannabis detection. The RapidStat was not reviewed in any other studies since Scherer's publication. The DrugWipe5A was examined in one naturalistic setting (social venues) and had low sensitivity (29%) and acceptable specificity (88%) (Stefano Gentili, Solimini, Tittarelli, Mannocchi, & Busardò, 2016). We do not discuss it further in this review.

Among all cannabis users, including frequent and occasional users, and across exposure routes, using a confirmation cut-off of 5ng/mL, the DDS2 had a sensitivity of 84.4% and specificity of 94.5% (Swortwood et al., 2017). The DT5000 had a sensitivity of 80.0% and specificity of 91.9% at the same cut-off (Swortwood et al., 2017). The DDS2 was also tested among individuals arrested for operating a motor vehicle while intoxicated (OWI) and compared to blood test values. Using a cutoff of 25 ng/mL that mirrors the devices own cutoff level, Edwards and colleagues report a sensitivity of 88.4 and specificity of 86.9 (Edwards et al., 2017).

Huestis and colleagues (2013) tested the DT5000 among 24 cannabis users (10 occasional, 14 frequent) and provided information about sensitivity 6-8 hours post-inhalation of smoked cannabis because this time frame is relevant for detecting drivers who may be under the influence of recently used marijuana (Huestis et al., 2013) They found the device sensitivity within 6 and 8 hour time frames was 85.6 and 84.7%, respectively, at the confirmation cutoff of 2ng/mL (SAMHSA). Sensitivity within 6 and 8 hour time frames was 84.0 and 82.5%, respectively, at the cutoff of 1ng/mL (DRUID) (Huestis et al., 2013). This can be interpreted to mean that the DT5000 provides a

positive test result that accurately identifies approximately 85% of cannabis users who are 6-8 hour post smoking, with 15% false negatives (i.e. the test provides a negative results but the individual has THC levels above the confirmation cutoff).

The DRUID project recommended a threshold of 80% sensitivity, 80% specificity, and 80% accuracy has been established as minimum acceptable level of testing performance for a roadside drug screening test. Across all studies, the DT5000 had a sensitivity range from 80.0%-85.5% and specificity range from 82.5%-95.2%. The DDS2 had a sensitivity range from 84.4%-92.5% and specificity range from 86.9-94.5%.

Note: Studies that tested multiple populations and devices may appear more than once. Table reflects same studies and participants as prior table stratified by frequency of cannabis use. Accuracy not available in these studies for these subpopulations. DT5000=Drager™ DrugTest 5000; DDS2= Alere™ DDS2; OF=Oral Fluid; LC-MS/MS=liquid chromatography-tandem mass spectrometry; The limit of quantitation (LOQ) was ~ 0.2 ng/mL.

Chronic Frequent Users versus Occasional Users

Table 3 shows the results from studies testing the accuracy of the OF POCT devices, grouped by participant cannabis use history (e.g. frequent user vs. occasional) and by device. This table reflects the two key studies found by our search that differentiated results based on the participants' cannabis use history. These are the same studies as reported above, but broken out for the subpopulations included rather than overall results.

Swortwood's study for the DDS did not show substantially different performance (e.g. more than few percentage points) between chronic vs. frequent users at a 25ng/mL or 5ng/mL confirmation cutoff. In both groups, sensitivity approached 100% for the 25ng/mL cutoff, and sensitivity was 82%-86%. The same study suggested that at the 5ng/mL cutoff, the DT5000 had a sensitivity of 79.1 for frequent users vs. 82.9 for occasional users; specificity of 89.5 for frequent users vs. 94.0 for occasional users. In their study of smoked cannabis, Huestis et al. report that the sensitivity of the DT5000 was 6-11% higher in frequent as compared to occasional cannabis users and suggest that this was due to having a longer detection windows and higher true positive rates (Huestis et al., 2013; Huestis et al., 2013). The DDS performed slightly better than the DT5000 among frequent users at the 5ng/mL cutoff in the two original studies we reviewed that directly compared the devices. Taking all evidence into account, both devices perform reasonably well for both frequent and occasional users.

Edible Route of Exposure

As shown in Table 3, the DT5000, in a study that focused only on edible cannabis, had a sensitivity of 64.9% and specificity of 97.2%, for an overall accuracy of 77.5% (Hartman et al., 2015). A smaller study found a sensitivity of 89.3 and specificity of 94.7. This is in contrast to the DDS2 which, in the smaller study, had a sensitivity of 96.8 and specificity of 86.5. The DT5000 may perform slightly better than the DDS2 when edible cannabis has been consumed, as its specificity was higher (96.9% vs. 77.1%) in the study by Newmeyer and colleagues that focused on the edible route of exposure (Newmeyer et al., 2017a).

Vaporized Route of Exposure

Hartman and colleagues (2015) reported that the DT5000 showed sensitivity of 64.9, specificity of 97.2, and efficiency of 77.5% after vaporized cannabis, using the 5ng/mL confirmatory cutoff (Hartman et al., 2015). These authors noted that cannabis vapor may interact with oral mucosa differently to smoke, altering the performance of the POCT (Hartman et al., 2015). While the sensitivity in this study was reduced due to false negatives compared to other studies that tested the device after smoked or edible routes of administration, the high specificity indicates that false positives were rare.

POC Urine Testing

One study returned by our searches evaluated POTC urine tests, the EZ Cup and the Multi4Card (Kim et al., 2017). The study utilized commercially available samples (Detectabase) and information about the individuals who originally provided the samples was not available. The cut-off value for these tests was 50 ng/mL of THC-COOH. The results were assessed on a grading scale (G2-G4) where lower grade meant a higher drug concentration for confirmation testing. The EZ Cup had a sensitivity ranging from 98.5 (G2) to 100 (G4) and a specificity ranging from 93.0 (G2) to 53.0 (G4). The Multi4Card had a sensitivity range from 6.0 (G2) to 92.0 (G4) and a specificity range from 99.2 (G2) to 87.7 (G4). The EZ cup had with consistently low false negative tests, but, as concentration decreased, there were more false positives. The EZ Cup therefore exhibited better performance, but it is important to note that the inactive metabolite THC-COOH can be detected for days to weeks after cannabis administration (Goodwin et al., 2008) and a positive screening result alone (absent other information) does not permit inference regarding time of cannabis use.

Other Considerations

Across all studies, authors note that frequent smokers had significantly later median t_{last} (time of last cannabis detection) compared to occasional smokers. This means that frequent marijuana users may show positive results on POCT results for longer after cannabis administration compared to occasional users who used the same amount.

The studies described here utilize THC as the confirmation marker of cannabis exposure. Hartman (2015) and colleagues note that THC-COOH has been proposed as a potential additional confirmatory criterion, to be used with THC because it helps rule out passive environmental exposure, detects oral cannabis use, and can extend detection windows in chronic frequent cannabis smokers (Lee et al., 2011; Moore et al., 2011). However, in Hartman's study of vaporized cannabis, THCCOOH was not always detected; including THCCOOH as a requirement for confirmation decreased sensitivity. At this point, the use of additional metabolites as a confirmatory method with POCT devices is not firmly established in the literature.

Research Question 3a: Cognitive and Behavioral Effects Relevant to Driving

We reviewed 29 studies that contained information about the cognitive and behavioral indicators of marijuana exposure that are relevant to operating a motor vehicle. The study designs utilized can be grouped into four categories: laboratory studies, studies conducted in a driving simulator, on-road studies, and observational studies. The cognitive and behavioral effects of marijuana that relate to driving fall into three domains which include automotive behavior, control behavior, and executive function/planning. These domains were described in Walsh's 2008 Guidelines for Research on Drugged Driving (Walsh et al., 2008). Based on the literature we obtained through our search, for the purpose of this review, we address an additional behavioral domain which is driving performance/safety. Table 4 describes the domains and provides examples of tasks/tests that measure them.

Multiple effects may be measured in one study, and different study designs are well-suited to evaluate different types of effects. For example, only the simulator and on-road studies can address driving performance and safe driving. We also considered the elements of the standardized field sobriety test (SFST) which is reflective of control behavior. The SFST includes activities such as a one leg stand, walk and turn, and the modified Romberg balance test.

Table 4. Domains of Driving-Related Cognitive and Behavioral Effects of Marijuana

Domain	Definition	Example Tasks Used for Measurement
Automotive Behavior*	Well-learned skills	<ul style="list-style-type: none"> Tracking, steering (road tracking, critical tracking, compensatory tasks). Vigilance or sustained attention (e.g. Mackworth Clock Test).
Control Behavior*	Maintaining distance, passing, etc.	<ul style="list-style-type: none"> Motor performance, maneuvers (reaction time, car following tasks). Divided attention (dual attention tasks). Perception (time to collision-type tasks).
Executive Function/Executive Planning *	Interactive functions with ongoing traffic.	<ul style="list-style-type: none"> Risk taking, impulsivity (e.g. stop signal, Iowa gambling tasks). Information processing, attention (choice, reaction time, selective or focused attention tasks). Cognition, judgement
Driving performance/safety	Appropriate and safe operation of a vehicle	<ul style="list-style-type: none"> Maintaining proper headway Lane positioning Speed and braking
Note: *Definitions from Walsh et al. 2008 "Guidelines for Research on Drugged Driving"		

Automotive Behavior

In lab-based studies, we found evidence for 15 different measurements of automotive behavior across 6 studies. For frequent users, 5 out of 6 saw no effect, and 1 found hurt performance, although it must be noted that two of these studies included low doses of cannabis. For occasional users, 5/5 tests indicated that marijuana hurt performance. In 4 studies in which the population cannabis use history was not specified, both low and medium dose administration resulted in generally worse task performance (3/4). Two simulator studies that included measurement of automotive behavior both found decreased performance after marijuana administration.

Sim.= Driving simulator study.

Control Behavior

In 18 lab-based measurements of control behavior, 11 focused on frequent or not specified user population, and 4 observed poorer performances after marijuana administration, 1 with improved performance, and 6 with no effect. Of note, the largest study had 136 participants and demonstrated poorer performance. Among tests in occasional users, 6/7 demonstrated poorer performance with one demonstrating no effect. Simulator-based studies showed an even split between hurt performance and no

effect. In three on-road studies, control behavior, and specifically reaction time, was not impacted.

In lab studies, 9/9 tests that used elements of the SFST to assess control behavior among frequent users demonstrated no effect. In occasional users, this was 3/9. And in two observational studies that together accounted for results on seven tests of control behavior as measured with a SFST, decreased performance was noted in all tests, though it must be noted that the study design did not allow assessment of most potential limitations.

Executive Function and Planning

In 16 tests of executive function among frequent cannabis users, six hurt performance and 10 showed no effect. Among occasional users, six hurt performance, and six showed no effect. For non-specified users, 9/10 studies showed hurt performance. These results indicate more evidence for decreased executive function regardless of use history, with about half or more of the studies finding decreased performance.

Driving Performance and Safety

In simulator studies, mean speed decreased in 6/14 studies conducted among occasional users. We did not characterize decreased speed as either an improvement or detriment to driving performance, since in a real-world environment this behavior could be associated either with safer driving or with an increased crash risk, depending on the circumstance. There were three studies with decreased performance, including on a measure of collisions, and all other results showed no effect. In two studies that did not specify the cannabis use history of participants, there was decreased performance on 5/7 measures. These included mean headway and lateral position, and speed measures. In 10 driving performance tasks conducted in on-road studies of occasional users, the authors observed impaired performance for five tasks and no effect for five tasks.

Note: DAT=divided attention task; *Result classified as: HP=hurt performance, IP=improved performance, NE=no effect. Magnitude of results only provided if statically significant. ** Issues potentially impacting study quality were noted as: SS=small sample size; NT = no validated tool used; LD = low dose marijuana, UP=user population not defined, DR= use of subjective high with no dose response gradient; OT=other quality issues.

Research Question 3b: Field Measurement of Marijuana's Effects and Accuracy for Determining Impairment

Laboratory based measurement of marijuana's cognitive and behavioral effects are described above. While there are many tools used to measure the domains of impairment in laboratory settings, as evidenced in Tables 5-7, field measures lag behind.

In the peer reviewed literature, we identified three studies testing SFST for detecting marijuana impairment. Accuracy was, at best approximately 50% for the one leg stand portion of the test. We also conducted a web search that identified several mobile applications that offer versions of some of the tests for automative behavior, executive function, and control behavior that were measured above, as being impacted by marijuana. Although only one tool: DRUID (Milburn, 2017), was developed explicitly for measuring marijuana-related effects, these tools in general may have promise. DRUID is being tested in an NIH-funded study at Brown University Medical School.

Table 8. Field Tests for Cognitive and Behavioral Indicators of Marijuana Effects, Peer-Reviewed Literature

Tool Type	Tested for MJ	Study	Year	Accuracy for MJ Impairment	Overall Result
SFST	Yes	Porath-Waller and Beirness	2014	Classification Rate: HGN: 1% OLS: 55.4%* WAT: 39.7%	Cannabis adversely affected performance on the OLS test but not the WAT and HGN tests
SFST	Yes	Bosker et al.	2012	HGN: 15% OLS: 50%* WAT: 35%	Cannabis significantly impaired performance on the OLS
SFST	Yes	Papafotiou	2005	Overall SFST Battery: Time 1 (5 min post smoking): 46.2% Time 2 (55 min post smoking): 41% Time 3 (105 min post smoking): 28.2%	The results indicated that the consumption of cannabis containing either 1.74% THC or 2.93% THC impaired performance on the SFSTs.

Notes: HGN=horizontal gaze nystagmus; WAT=Walk and Turn; OLS= one leg stand

Table 9. Field Tests of Cognitive and Behavioral Indicators of Marijuana's Effects, Non-Peer Reviewed

Tool Type	Tool Name	Designed for MJ	Relates to R3A Task Category / Test	URL	Notes

Discussion

Well-established laboratory methods for quantifying marijuana exist and offer high sensitivity and specificity for measurement of delta-9-THC. Among the most popular techniques currently in use are chromatographic methods such as gas chromatography mass spectrometry (GC-MS) and liquid chromatography with tandem mass spectrometry (LC-MS/MS). In relation to quantifying exposure, the absence of ability to discern potentially key pieces of information from measuring THC alone however has spurred interest in the utility of THC metabolite quantification. The phase-two THC metabolite (THC-Glucuronide) as well as cannabigerol (CBG), cannabiol (CBN), and tetrahydrocannabivarin (THCV) offer promise in discerning recency of use and movement of metabolites to alternative matrices (Huestis & Smith, 2018). As research related to marijuana metabolism continues to advance, such inferences may prove useful in efforts to establish legal driving limits and standards. Despite this promise however, the inability to quantify THC metabolites in a field setting remains a chief limitation.

This review identified two point-of-collection devices with substantial evidence that they perform with sensitivity and specificity above 80% at a confirmation cut-point of 5ng/mL. The DT5000 has a slightly lower sensitivity and higher specificity; the DDS2 has a slightly higher sensitivity and lower specificity. Most screening tests require tradeoffs between these two aspects of correct identification. A higher sensitivity reduces false negatives (i.e. a cannabis user with delta-9-THC above the cut-off who screens negative); a higher specificity reduces false positives (e.g. an individual with a delta-9-THC level below the cut-off who screens positive). Choice between the two devices should depend upon the specific use case and consequences of misclassification. The findings from this study indicate that OF devices may be effective for use in field settings with reasonable accuracy.

For context, recent studies showed that after smoking or vaporizing cannabis in a controlled environment, chronic frequent users maintained blood THC levels of 25 ng/mL for an average of ~ 30-45 minutes. By ~6-10 hours, levels have fallen to 5 ng/mL and at 72 hours post smoking, blood THC levels remained between 5 ng/mL and the LOQ (1 ng/mL) (Newmeyer et al., 2016). Frequent users that orally ingested cannabis in a controlled environment showed similar long term pharmacokinetic profiles, with blood THC levels between 5 ng/mL and the LOQ (1 ng/mL) 72 hours post ingestion. However, average peak concentrations were lower (~25ng/mL) and average time to peak concentration (~ 3-4 hours) was greater with average blood levels remaining under 10 ng/mL leading up to the peak (Newmeyer et al., 2017a; Newmeyer et al., 2016).

In occasional users, THC blood levels in controlled environments after smoking and vaporization peaked on average in ~10 minutes and stayed above 25 ng/mL for ~30 minutes. At approximately one hour, THC levels remained close to 5 ng/mL but by ~ 3 hours on average, THC blood levels had fallen below the LOQ and by ~ 12-15 hours, THC was undetectable (Newmeyer et al., 2016). Blood THC levels of occasional users ingesting THC in a controlled environment followed a similar peaking pattern to that of frequent users. On average, concentrations did not peak until ~ 3 hours post ingestion.

However, by ~ 5 hours blood THC levels had fallen below 5ng/mL and by ~ 11 hours, THC was not detectable in the blood (Newmeyer et al., 2016).

Blood cannabinoid concentration cannot be estimated from OF data (Newmeyer et al., 2017b). The studies reviewed indicated that for smoked and vaporized cannabis, OF and blood THC concentrations were significantly correlated for up to 8 hours cannabis administration (Hartman et al., 2016), with THC concentrations in both matrices peaking during or shortly after use followed by rapid decreases. Edible cannabis, however, displays a different profile with OF THC C_{max} (maximum concentration) occurring by 0.3 hours, while blood THC C_{max} occurs 1-5 hours later. These different pharmacokinetic time courses explain the lack of correlation between OF and blood concentrations during the first 5 h after edible cannabis (Newmeyer et al., 2017b). Thus, the route of cannabis administration has a large impact on how well oral fluid correlates with blood THC. At present, most marijuana users smoke or vaporize marijuana, making oral fluid testing a reasonable option, though other routes of administration may become more frequent as retail sales of adult use marijuana begin in Massachusetts.

The evidence suggests that marijuana has cognitive and behavioral effects in the areas of automative behavior, especially for occasional users, and there also are likely some executive function impacts for some users. In simulated road environments, marijuana exposure was associated with decreased speed; which may be either positive or negative for driving performance and crash risk, depending on the circumstance. Marijuana exposure also unquestionably hurt driving performance in some ways. The overall picture was one of mixed results that on balance fall between no effect and decreased performance. It is worth noting that when reported, magnitude of impaired performance was generally small. In controlled environments, the marijuana use was not associated with performance decreases on elements of the standardized field sobriety test, though observational studies reached a different conclusion.

Chapter 2: Driving Under the Influence of Marijuana and Marijuana-Involved Motor Vehicle Crashes in Massachusetts

Introduction

Experimental research suggests that marijuana (cannabis) use impairs functions related to safe driving (Huestis, 2002). Epidemiological evidence for the increase in the magnitude of motor vehicle crash risk from marijuana use ranges from 22% to 100% (a doubling) (Asbridge et al., 2012; G. Li et al., 2017; Rogeberg & Elvik, 2016). In studies of Colorado adults (Davis et al., 2016) as well as college students (Whitehill, Rivara, & Moreno, 2014), and high school students (K. Li, Simons-Morton, Gee, & Hingson, 2016), driving under the influence of marijuana (DUI-marijuana) is common among marijuana users. These individuals, as well as passengers who ride with a driver under the influence of marijuana (RUI-marijuana), would experience any increased risk for involvement in a motor vehicle crash that exists when the driver has used marijuana.

As Massachusetts implements legal retail marijuana sales for all adults, it is important to understand the prevalence of driving under the influence of marijuana and riding with a marijuana-using driver prior to the start of retail marijuana sales for non-medical use among adults age 21 and over. These topics are not well-measured in other Massachusetts datasets that have been previously collected for other purposes. Such information will be necessary to measure the extent to which there are changes in the prevalence of these events after retail adult-use marijuana sales are implemented. Another useful “baseline” measure related to marijuana and motor vehicle crashes is how frequently crash-involved drivers test positive for marijuana. Although such testing does not indicate that the driver was intoxicated by or impaired by marijuana at the time of the crash, such data nonetheless provides some information on information relevant to maintaining safe roadways, such as the extent to which drivers are tested for cannabinoids and cannabinoid disposition among drivers.

This chapter describes two studies related to driving and marijuana use. First, we present an analysis of data from the statewide population survey conducted as part of the MBHS that addresses DUI-marijuana and RUI-marijuana. Second, we present an analysis of Massachusetts data from the Fatality Analysis Reporting System which includes information on fatal crashes (i.e. crashes in which one occupant died within 30 days of the crash) and the state’s Crash Data System which includes information on all crashes on Massachusetts roadways.

Methods

Population survey of Massachusetts adults

We conducted a population-based, mail and Internet survey of Massachusetts residents age 18 years and older. This study was approved by the Institutional Review Board at the Massachusetts Department of Public Health. A copy of the survey instrument can be found in Appendix A. Details on the methods of survey design, data collection, measures, and statistical procedures, including survey weighting, can be found in Task 1, Chapter 2 of this Marijuana Baseline Health Study report. In addition to the measures

described therein, several questions were added to the survey for the purpose of addressing DUI-marijuana and RUI-marijuana.

Measures

DUI-marijuana was assessed with the item “During the past 30 days, how many times have you driven a car or other motor vehicle while you were under the influence of marijuana?” Response options included 0 times, 1 time, 2-3 times, 4-5 times, or 6 or more times. RUI-marijuana was ascertained with the question “During the past 30 days, how many times did you ride as a passenger in a car or other motor vehicle when the driver was under the influence of marijuana” with the same response options as listed above.

Parallel questions were asked for alcohol and other substances. We also asked about driving after the concurrent use of multiple substances with response options that included: marijuana and alcohol, marijuana and other drugs, alcohol and other drugs, or marijuana, alcohol, and other drugs.

Statistical analysis

Please see the methods section in Chapter 2, Task 1 for details on weighting and statistical procedures for this survey. As noted therein, a total of 3,268 non-duplicate survey questionnaires were returned with 212 determined ineligible. After screening for completion and eligibility, there were a total of 3,023 eligible surveys. The logic-checking process resulted in identification of 1 case in which multiple questions had unreasonable responses. This case was dropped, resulting in a final analytic sample of 3,022.

Several variables relevant to this chapter were re-coded from the original data. DUI-marijuana was dichotomized as a yes/no variable indicating any driving under the influence of marijuana in the past 30 days. RUI-marijuana was similarly dichotomized. Frequency of marijuana use in the past 30 days was categorized as a 3-level variable (0 days, 1-20 days, 21 or more days). Frequency of alcohol use, originally measured in days per week, was categorized as a 3-level variable (0 days, 1-4 days, 5-7 days).

First, we examined bivariate differences in driving under the influence of substances and riding with a substance-using driver between adults who had used marijuana in the past 30 days and those who had not. Next, we examined bivariate differences in socio-demographics and substance use behavior by DUI-marijuana and RUI-marijuana status. Differences were tested with chi-squared tests for categorical variables. Finally, to assess which factors were associated with DUI-marijuana and RUI-marijuana, we estimated relative risk (RR) using Poisson regression with robust standard errors (Zou, 2004). We examined associations between driving under the influence of marijuana (yes/no) and age, gender, race/ethnicity, education, frequent marijuana use, alcohol use, and riding under the influence of marijuana. When variables were not significant in initial models they were not retained in the final model, with the exception of age, gender, and race, and alcohol use. We used a similar multivariable regression approach with RUI-marijuana as the dependent variable. We used a two-tailed significance level

at $p < 0.05$ for all statistical tests. All analyses were weighted and were conducted using commands that accounted for the complex survey design, yielding results that are adjusted to be representative of the adult population in Massachusetts. The analysis for this report was generated using SAS/STAT software, Version 9.4 of the SAS System for Windows (Copyright © 2016 SAS Institute Inc. Cary, NC, USA.) with the exception of the regression models which were generated using Stata 15 statistical software (StataCorp, LLC, College Station, TX).

Fatality Analysis Reporting System (FARS)

To estimate the prevalence of marijuana, alcohol and other drug use by drivers in fatal crashes, 11 years of data (2006-2016) from the Fatality Analysis Reporting System (FARS) were studied. FARS is a national database maintained by the states and administered by the National Highway Traffic Safety Administration (NHTSA). It contains detailed information on every person and vehicle involved in a fatal crash in 26 linkable datasets. The various datasets are compiled at the state level; a state FARS analyst coordinates with the various agencies to gather the necessary data. For example, the police will provide information on the crash (manner of collision, time, location, etc.) and the medical examiner will provide toxicology information (blood alcohol content, presence of drugs, etc.).

For this analysis, two FARS datasets were utilized, the “Person” and “Accident” files. The “Person” file contains an entry for each individual involved in a fatal crash whether they are the driver, a passenger, or a non-motorist. This dataset contains information such as demographics, seating position, drug and alcohol test results. The “Accident” file contains crash level information such as time and location of the crash, manner of collision and overall number of fatalities. A full list of fields and datasets can be found in the FARS Analytical User’s Manual (National Highway Traffic Safety Administration, 2016).

Measures

From the FARS “Accident” dataset only the field reflecting the number of fatalities resulting from the crash (FATALS) was used. All other variables came from the FARS “Person” dataset, which included an indicator of “person type” which denotes whether the person was a driver, passenger or non-motorist (PER_TYP). We used an indicator of injury severity to identify individuals who died in a crash.

Demographic measures

The FARS fields for the person’s age, sex, and race/ethnicity were included in this analysis. Within FARS, race is only coded for deceased persons. There are 18 options for race and an additional six options that indicate whether the person was of Hispanic/Latino descent. The available categories were condensed into five categories: White, non-Hispanic; Black, non-Hispanic; Asian, non-Hispanic; Other, non-Hispanic; and any Hispanic/Latino.

Cannabis and other drug measures

FARS includes information on the type of drug testing conducted stored in three variables (DRUGTST1/ DRUGTST2/ DRUGTST3). Persons involved in a fatal crash can have up to three types of drug tests (e.g. blood, urine, etc.) recorded in FARS in these fields. Also included are up to three results from the reported drug tests (DRUGRES1/ DRUGRES2/ DRUGRES3). The DRUGRES fields report a code to indicate the specific drugs detected, although the level of drug concentrations are not available within the dataset. There are over 600 different drug types and an exhaustive list can be found in the 2016 FARS/CRSS Coding and Validation Manual (National Highway Traffic Safety Administration, 2016).

This analysis focused upon cannabinoids which are indicated in FARS with the following codes:

- 600 – Delta 9
- 601 – Hashish Oils
- 602 – Hashish
- 603 – Marijuana/Marihuana
- 604 – Marinol
- 605 – Tetrahydrocannabinols (THC)
- 695 – Cannabinoid, Type Unknown

A summary variable was created to indicate whether a drug test result was positive for any of the seven cannabinoid codes listed above. Delta-9-THC is a primary psychoactive compound from the cannabis plant that contributes to the ‘high’ that users experience. As described in Chapter 1, it is metabolized in the body into other cannabinoids that can be detected in laboratory testing but are not necessarily psychoactive. Generally, delta-9-THC is measurable in blood for a shorter duration after marijuana use than other metabolites, but this is complicated by individual characteristics such as frequency of cannabis use. Prior studies of marijuana involvement in crashes using FARS data in other states tend to focus on delta-9-THC because it is associated with the effects of cannabis (Tefft et al., 2016). However, it is important to note that driver *impairment* in the crash cannot be discerned from values of delta-9-THC or other compounds. Delta-9-THC, when present, is generally indicative of recent marijuana use.

Two years of FARS data (2011 and 2012) appeared anomalous in that there were near-zero levels of code 600 indicating a positive test for Delta-9-THC among drivers given a blood test for drugs. This was inconsistent with other years of Massachusetts FARS data in this analysis and inconsistent with published reports of FARS data from other states (Grondel, Hoff, & Doane, 2018). This absence of code 600 for delta-9-THC in two years of FARS data is likely to be a result of data collection or data entry practices and not indicative of true rates. Additionally, in the 11 years of Massachusetts data, there were only two recorded cases of a person testing positive for codes 601, 602, 603, or 604. In light of these potential irregularities in the cannabis codes observed in FARS, we

report on the presence of “any cannabinoid” which, though less specific than the code for delta-9-THC, appeared more reliable.

Alcohol measures

The presence of alcohol in a person is recorded in two fields within the FARS database. ATST_TYP reports the type of alcohol test given (blood, breath, etc.) and ALC_RES indicates the results of alcohol testing such as the blood alcohol content obtained from the given alcohol test. Due to problems that arise from missing data, blood alcohol content (BAC), estimates of alcohol-impaired driving are typically reported after NHTSA uses a multiple imputation process for cases in which testing was not conducted or reported (Subramanian, 2002). Imputation was not used in the present study for alcohol because the focus was on marijuana-involved crashes. NHTSA does not presently have a standardized imputation procedure for cannabis-related test results, although such procedures are being developed and tested with promising results (Chen, Williams, Liu, Chihuri, & Li, 2018). To facilitate comparison across substances within this report, only known BAC values were used in this analysis. The estimates in this report for fatalities with alcohol involvement, therefore, may not match the publicly available estimates which incorporate imputed BAC values.

Analysis

The total number of fatal crashes, number of fatally-injured persons, number of fatal crash-involved drivers, and number of deceased drivers were tabulated. Numbers and percentages of drivers who received a blood test for alcohol or drugs were calculated and graphed, as appropriate. Numbers and proportions of drivers testing positive for any cannabinoid, by driver sex, race/ethnicity, and age, and the extent to which cannabinoids were found in conjunction with alcohol, and with other drugs were calculated.

Crash Data System (CDS)

In addition to FARS, the Massachusetts Crash Data System (CDS) was utilized to examine trends in frequency of marijuana-related crashes. Unlike FARS, CDS contains every reported motor vehicle crash, and not just crashes with a fatality. However, CDS is based on the Massachusetts crash report form which is completed by the police officer who responded to the crash. This crash report form does not contain the same level of detail as FARS; it does not contain any fields related to known or suspected drug use.

As an alternative to a specific drug use field, the crash narrative was utilized. The crash narrative is a free form field where the responding officer can include any information they felt to be important that couldn't be captured within the existing crash report fields. A query was written which identified crash reports which had a crash narrative containing the keywords “marijuana”, “weed”, and “cannabis”. The keywords “high” and

“pot” were originally queried as well but these resulted in a high rate of false positives so they were excluded from the final query.

While it is not possible to determine how many non-fatal crashes occurred which involved marijuana, the aforementioned method provides insight into the number of crashes in which the responding officer suspected marijuana involvement.

Results

Population survey of Massachusetts adults

Sample Characteristics

The demographic patterns of survey respondents by reported marijuana use in the past 30 days are provided in Table 1. In reporting survey results, all estimates are weighted and all percentages represent population estimates.

Prevalence of driving under the influence and riding with a substance-using driver

Among the estimated 21.1% of the adult population that used marijuana, the prevalence of driving under the influence of marijuana in the past 30 days was 34.3% (Table 2). Overall, 7.2% of the adult population drove under the influence of marijuana in the past 30 days. For assessment of RUI-marijuana, both non-users and users of marijuana were considered to have engaged in the behavior if they reported riding as a passenger

with a driver that is under the influence of marijuana. Results show that 11.3% of Massachusetts adults rode with a marijuana-using driver in the past 30 days. The proportion who RUI-marijuana was statistically significantly higher among marijuana users (36.7%) compared to non-users (4.2%) [$p < 0.001$].

We found that 6.9% of the population drove under the influence of alcohol (DUI-alcohol) and 7.9% of all adults rode as a passenger with a driver under the influence of alcohol (Table 2). Marijuana users were more likely to report DUI-alcohol (15.2%) compared to non-users (4.7%) ($p < 0.001$) and to report RUI-alcohol (14.6%) compared to non-users (6.1%) ($p < 0.001$).

Subpopulation prevalence

By age, we found that 25.6% of young adults age 18-20 years reported driving under the influence of marijuana, and 24.1% of those age 21-25 years. The proportion of adults in each age group who drove after marijuana use subsequently drops off among older age groups. (Table 3). Among females, 5.5% reported DUI-marijuana, which was statistically significantly less than the percentage of males reporting DUI-marijuana (9.1%) ($p = 0.04$).

We observed that as the number of days per month of marijuana use increases, the proportion of individuals who drive under the influence of marijuana also increases. Among individuals who use marijuana 21 days per month or more, just over 50% reported DUI-marijuana.

By age, we also found that nearly 36% of 18-20 year old adults reported riding with a marijuana-using driver in the past 30 days. Prevalence was 38% among those age 21-25 years, then lower for older age groups (Table 3). We did not observe a difference by gender or race/ethnicity. Prevalence of RUI-marijuana was lowest among those with a post-graduate degree (5.7%).

A higher proportion of those who drove under the influence of marijuana reported riding as a passenger with marijuana-using driver (67.5%) compared to marijuana users who did not drive under its influence (21.2%) ($p < 0.001$) (Table 4). We found that 42.8% of individuals who drove under the influence of marijuana reported driving under the influence of alcohol and marijuana, used simultaneously

Characteristics of individuals who drive under the influence of marijuana (DUI-marijuana)

Table 4 also shows characteristics and substance use behaviors of marijuana users who drove under the influence of marijuana compared to those who did not. We found no differences in the distribution of gender or ethnicity by DUI-marijuana status. Of those who drove under the influence of marijuana, 47.1% did so six or more times in the

past 30 days, 32.7% did so 2-5 times, and 17% did so just once. Of these individuals, 67.5% also rode with a driver who was under the influence of marijuana once or more in the past 30 days; 8% did so only one time.

Note: Table displays column percentages. DUI-=Drove under the influence; RUI-marijuana=Rode as a passenger with a driver under the influence.*based on ≤25 responses

Among those who used both marijuana and alcohol in the past 30 days, 46.8% of those who drove under the influence of marijuana also drove under the influence of alcohol. In comparison, users of both marijuana and alcohol who did not drive under the influence of marijuana had a much lower prevalence of driving under the influence of alcohol, at only 3.7%.

Characteristics of individuals who ride with driver under the influence of marijuana (RUI-marijuana)

Table 5 shows a comparison of demographic and substance use characteristics between individuals who rode with a driver under the influence of marijuana and those who did not. The distribution of RUI-marijuana by age showed that higher proportions of younger individuals tended to engage in this behavior versus older individuals. . Most individuals (70.6%) who RUI-marijuana had used marijuana in the past 30 days; this is in contrast to 15.5% of individuals who did not RUI-marijuana who reported past-30 day marijuana use.

Factors associated with driving under the influence of marijuana (DUI-marijuana) and riding with a driver under the influence of marijuana (RUI-marijuana)

Our multivariable Poisson regression model (Table 6) with DUI-marijuana as the outcome included age, gender, race/ethnicity, frequent marijuana use and alcohol use (Table 6). In preliminary models, we found no association between education level and DUIM and dropped it from subsequent models. We found that Black, non-Hispanic individuals had an 81% lower risk of DUI-marijuana compared to White, non-Hispanics (RR=0.19; 95% CI:0.05-0.75). Frequent marijuana use (defined as using on 21 or more days in the past month) was associated with a 63% increased risk of DUI-marijuana compared to using on 20 days or fewer (RR=1.63; 95% CI:1.15-2.32). Of the model covariates, riding with a marijuana-using driver demonstrated the strongest association with DUI-marijuana. Individuals who rode with a driver under the influence of marijuana had more than triple the risk of DUI-marijuana compared to marijuana users who did not ride with a marijuana-using driver (RR=3.42; 95% CI: 2.28-5.15).

Used alcohol	1.35	0.80	2.28	0.256
Rode with driver under influence of marijuana	3.42	2.28	5.15	<.0001

Note: Results from multivariable, modified Poisson regression. Only marijuana users included. All substance use and DUI or RUI variables refer to behavior in the past 30 days

Our multivariable Poisson regression model with RUI-marijuana as the outcome included age, gender, education, race/ethnicity, frequent marijuana use, alcohol use, and riding as a passenger with driver under the influence of alcohol (RUI-alcohol) (Table 7). We found that being age 25 years or older was associated with a nearly 50% reduction in the risk of RUI-marijuana, controlling for other factors. Using marijuana between 1-20 days per month was associated with having more than 5 times the risk of RUI-marijuana (RR=5.79; 95% CI: 3.70-9.07) compared to not using at all; using 21 or more days per month increased the risk more than 8 times (RR=8.57; 95% CI: 5.42-13.55). Riding with a driver who used alcohol was associated with more than twice the risk of riding with a marijuana using driver.

Fatality Analysis Reporting System (FARS)

From 2006-2016, there were an average of 373 traffic fatalities per year. 2015 had the lowest number of traffic deaths since 2009, 345, but in 2016 this number increased to 389, the highest number since 2007 when there were 434 traffic-related fatalities (Figure 1, Table 8).

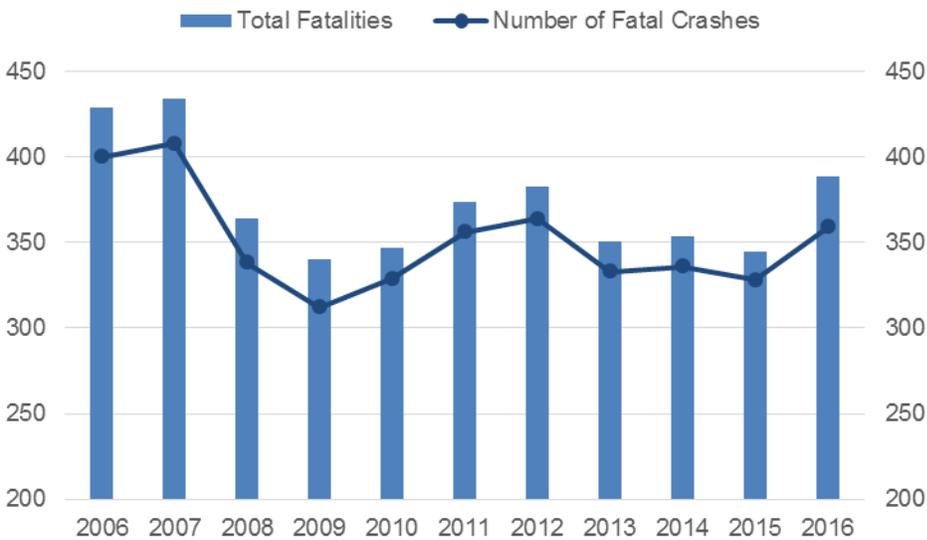

Figure 1. Total fatalities and number of motor vehicle crashes with a fatality in Massachusetts by year (2006-2016)

Table 8. Number of fatal crashes and total number of fatalities in Massachusetts, 2006-2016

Year	Number of Fatal Crashes	Traffic Fatalities in MA	Number of Drivers Involved in a Fatal Crash	Number of Deceased Drivers
2006	403	429	568	284
2007	408	434	570	277
2008	338	364	442	218
2009	313	340	447	216
2010	330	347	448	220
2011	356	374	499	239
2012	365	383	497	225
2013	334	351	445	212
2014	336	354	456	212
2015	328	345	457	210
2016	359	389	501	234

The number of drivers involved in a fatal crash followed a similar trend to the number of fatalities per year (Table 8, Figure 2.) Overall, there were an average of 484 drivers involved in a fatal crash each year from 2006 to 2016 and an average of 231 drivers were deceased from motor vehicle crashes.

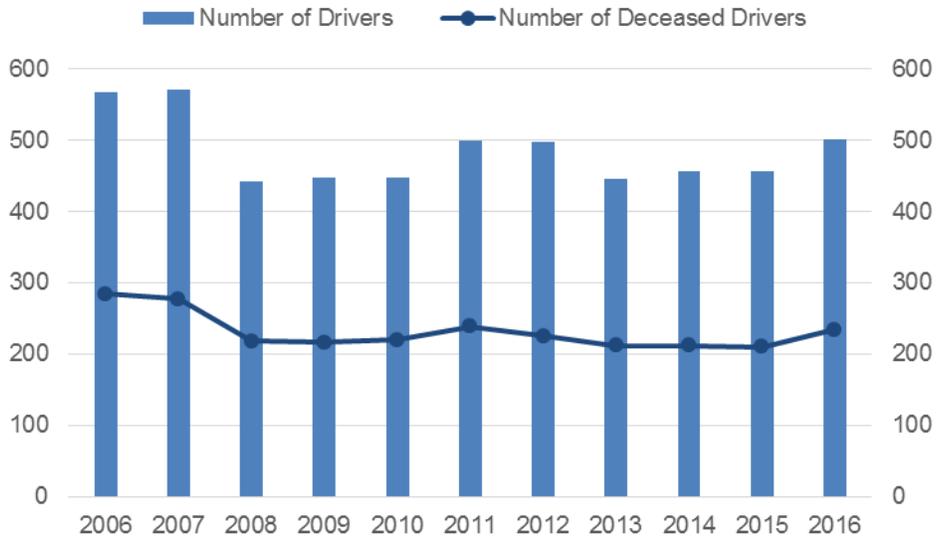

Figure 2. Number of drivers involved in fatal crashes and number of deceased drivers in MA by year (2006-2016)

Toxicological Testing

When drivers in a fatal crash are given a blood test, it is indicated in FARS under the ATST_TYP (alcohol test type) and DRUGTST (drug test type) fields. There were three

instances in the 11-year sample where a driver was given a blood test for drugs but not for alcohol, and 54 instances of the reverse, when a driver's blood was tested for alcohol but not drugs. Nearly 1900 drivers had their blood tested for both drugs and alcohol after a fatal crash in the 11-year sample, out of 5330 total crash-involved drivers, which is approximately 36% (Table 9.).

Table 9. Blood test types for drivers involved in fatal crashes in MA (2006-2016)

Year	Alcohol Test Only	Drug Test Only	Alcohol and Drug Test	Total Drivers	Percent tested for alcohol and drugs
2006	3	1	215	568	37.9
2007	9	0	207	570	36.3
2008	16	0	156	442	35.3
2009	9	0	155	447	34.7
2010	2	0	186	448	41.5
2011	3	1	149	499	29.9
2012	1	0	172	497	34.6
2013	1	0	164	445	36.9
2014	4	0	142	456	31.1
2015	6	0	159	457	34.8
2016	0	1	192	501	38.3
Total	54	3	1897	5330	35.6

Within the FARS database there are three options that can be selected to indicate that a person was tested for the presence of drugs: (1) blood test, (2) urine test, and (3) both blood and urine tests. Among these three options, for both surviving and deceased drivers, blood tests were used, almost exclusively, to determine the presence of drugs. In the 11-year sample, 1897 drivers were given only a blood test, three were given a urine test only and only one person was given both a blood and urine test to determine if drugs were present in their system after being involved in a fatal crash.

Overall, approximately 73% of the drivers who were deceased in a crash were given a post-mortem blood test for alcohol or drugs. By contrast, less than 1% of drivers who survived a crash in which there was at least one fatality were given a blood test for alcohol or drugs according to the FARS data (Figure 3). During the 11-year study period (2006-2016), the highest proportion of deceased drivers given a blood test for alcohol or drugs was 83% in 2010 and the lowest was 63% in 2011. The highest proportion of surviving drivers given a blood test for alcohol or drugs was 2% in 2005 and the lowest was 0% in 2009 and 2015. In 2016, the proportion of deceased drivers given a blood test for alcohol or drugs was 82%, which was a slightly higher testing rate for deceased drivers than in the preceding five years, and less than 1% of surviving drivers were tested.

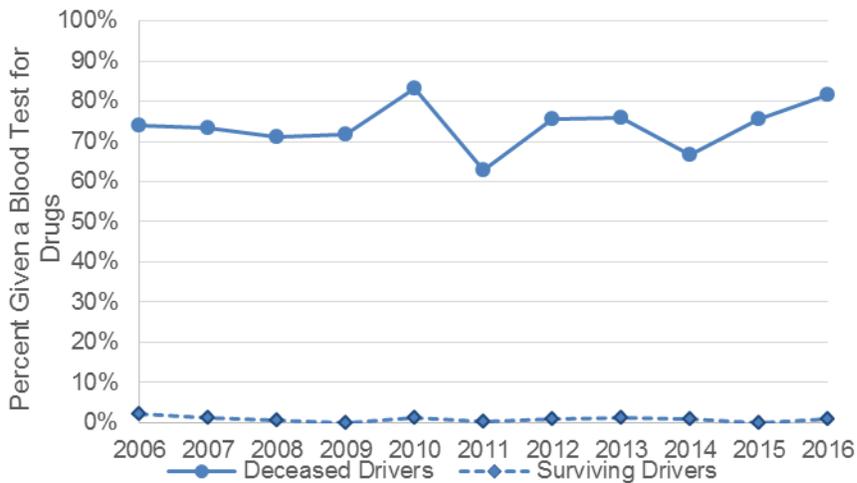

Figure 3. Percentage of deceased and surviving drivers in fatal crashes given a Blood test for drugs

To detect potential demographic differences in blood-testing trends, testing rates were examined by race/ethnicity. Figure 4 displays the percent of all deceased drivers who were given a blood test by race/ethnicity. The “Other, non-Hispanic” category was lower than others, due to this category containing the “Unknown” race option which was strongly correlated with having an “unknown drug test type.”

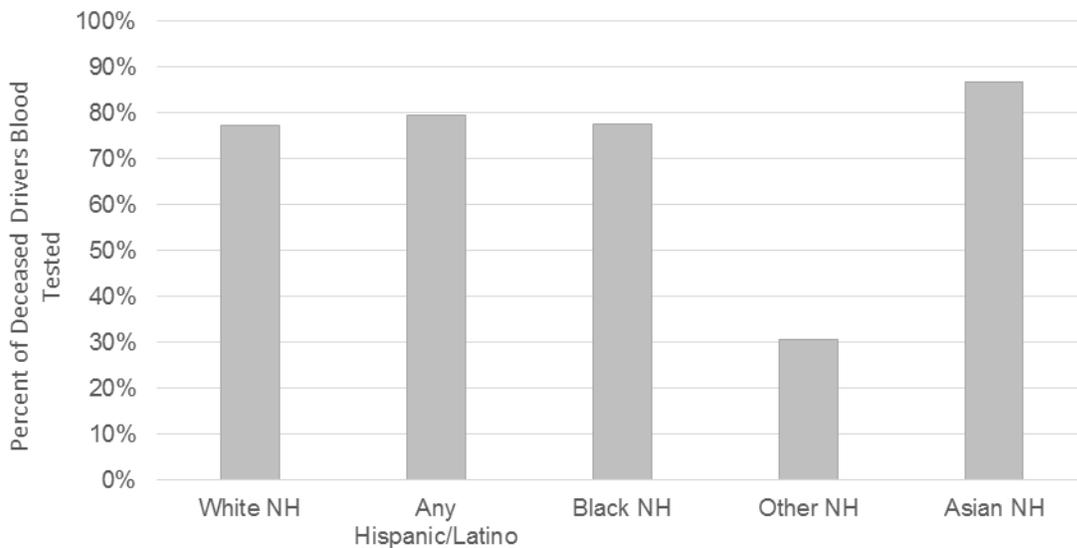

Figure 4. Percent of deceased drivers given a blood test for drugs, by race/ethnicity.

Marijuana Use

The prevalence of marijuana use among deceased drivers blood-tested for drugs was evaluated by examining how often they tested positive for any cannabinoid (Figure 5).

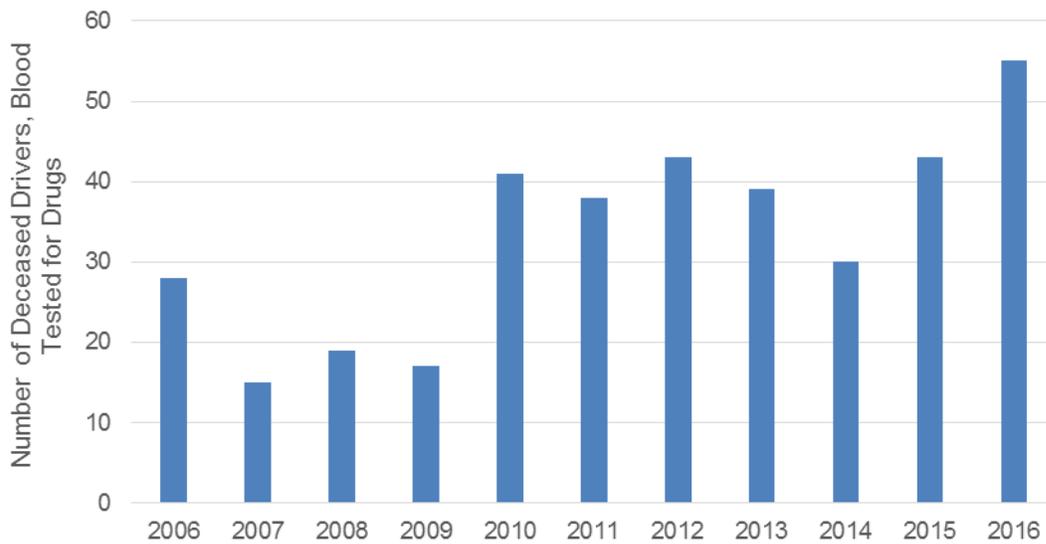

Figure 5. Number of deceased drivers given a blood test for drugs testing positive for any cannabinoid

When examining the frequency in which deceased drivers given a blood test for drugs tested positive for any cannabinoid, a noticeable increase was observed in 2010 (Figure 6).

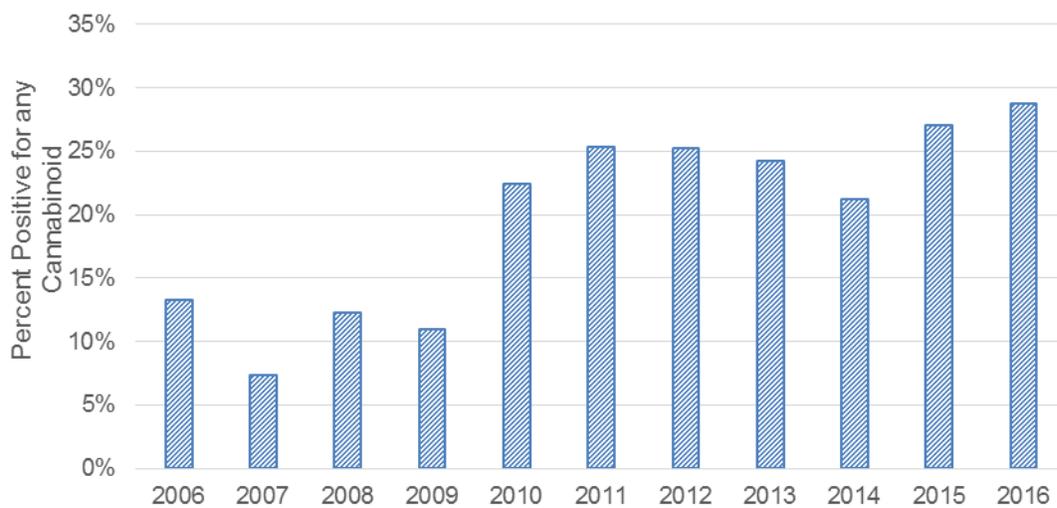

Figure 6. Percentage of deceased drivers given a blood test for drugs who tested positive for any cannabinoid

The data was further examined by driver sex, race, and age in order to identify potential differences in marijuana use in these demographic groups (Table 10).

Table 10. Number of deceased drivers given a blood test for drugs who tested positive for any cannabinoid by sex, race, and age

Demographic Category	Any Cannabinoid		No Cannabinoids		Total
	n	%	n	%	
Male	297	20.3%	1167	79.7%	1464
Female	71	17.1%	343	82.9%	414
White, non-Hispanic	275	17.8%	1272	82.2%	1547
Black, non-Hispanic	42	34.4%	80	65.6%	122
Asian, non-Hispanic	1	7.7%	12	92.3%	13
Other, non-Hispanic	12	18.8%	52	81.3%	64
Any Hispanic/Latino	38	28.8%	94	71.2%	132
<18 years	12	26.1%	34	73.9%	46
18-20 years	47	32.9%	96	67.1%	143
21-25 years	115	33.0%	233	67.0%	348
26-34 years	87	27.4%	231	72.6%	318
35-64 years	99	13.3%	644	86.7%	743
65+ years	8	2.9%	272	97.1%	280

Note: Rows percentages are reported. Any cannabinoid + no cannabinoid will sum to 100% within demographic groups.

When examining cannabinoid presence, there was no statistically significant difference between male and female drivers (Figure 7).

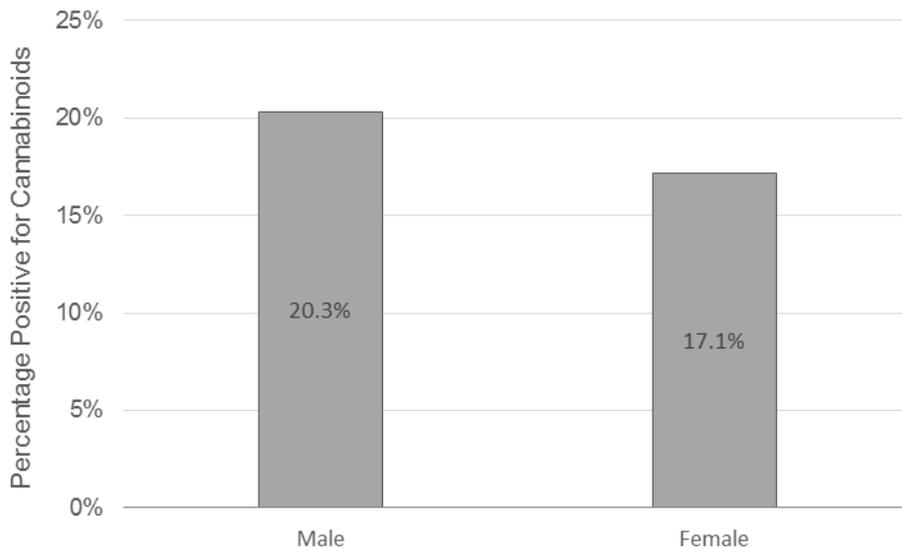

Figure 7. Percentage of deceased drivers given a blood test for drugs who tested positive for any cannabinoid, by driver sex

When examining race/ethnicity of deceased drivers given a blood test for drugs, the proportion of individuals of any Hispanic/Latino ethnicity and Black, non-Hispanic race/ethnicity who tested positive for cannabinoids was higher than for White, non-Hispanic drivers (Figure 8). There were very small samples of deceased Asian, non-Hispanic and Other, non-Hispanic drivers.

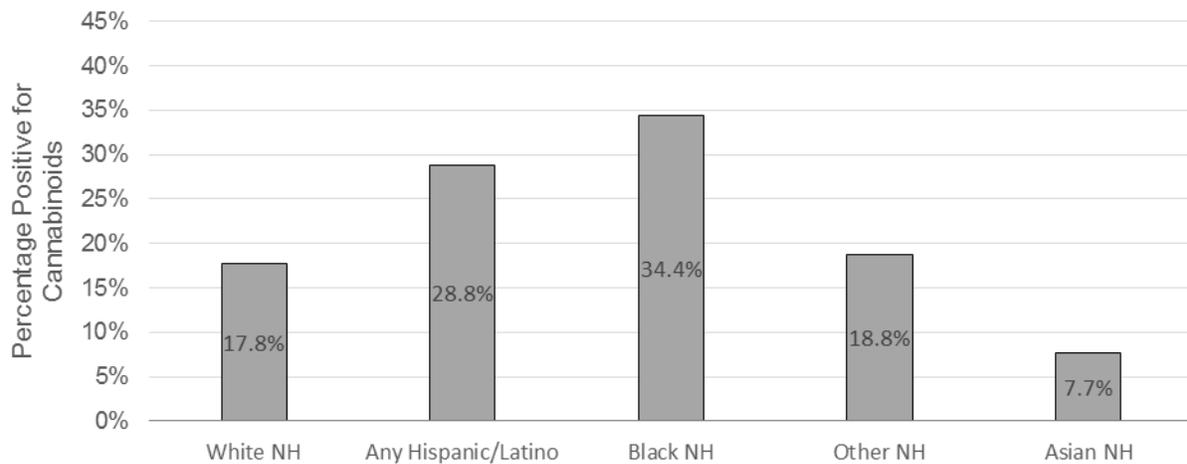

Figure 8. Percentage of all deceased drivers given a blood test for drugs who tested positive for any cannabinoid, by driver race/ethnicity

Figure note: NH=non-Hispanic

The presence of any cannabinoid in deceased drivers given a blood test for drugs was most common in young drivers and decreased precipitously from the 26-34 age group to the 35-64 age group, as shown in Figure 9.

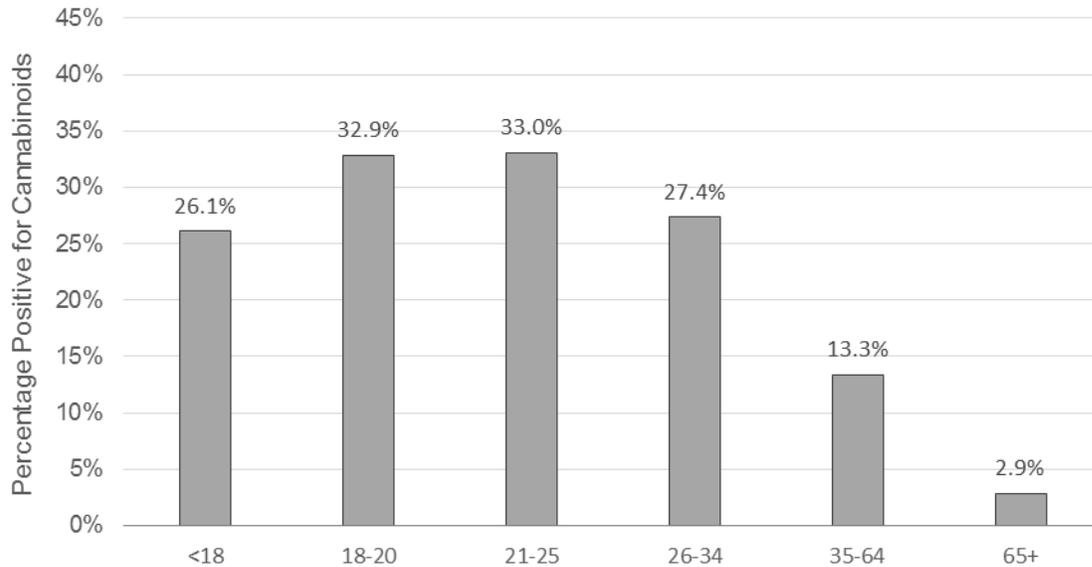

Figure 9. Percentage of deceased drivers given a blood for drugs who tested positive for any cannabinoid by driver age

Alcohol and Drug Use

Reducing the prevalence of drunk driving has long been a focal point for the public health community as a way to reduce motor vehicle crash injuries and deaths. As such, the presence of alcohol in fatal crashes was examined, both by itself and in conjunction with the presence of cannabinoids (Table 11). For all demographic categories, with the exception of Black, non-Hispanics there were more blood-tested, deceased drivers with a blood alcohol content greater than or equal to 0.08% than with cannabinoids in their system.

Cannabinoid results were examined in conjunction with alcohol use. Table 11 displays the number of deceased drivers given a blood test for drugs and alcohol who tested positive for any cannabinoid only, had a BAC \geq 0.08% only, had both a positive cannabinoid result and a BAC \geq 0.08% or tested negative for cannabinoids and had a BAC less than 0.08%.

Table 11. Number of deceased drivers given a blood test for alcohol and drugs who tested positive for any cannabinoid and/or had a blood alcohol content (BAC) \geq 0.08% by sex, race/ethnicity, and age.

Demographic Category	Any Cannabinoid, BAC \leq 0.08%		No Cannabinoid, BAC \geq 0.08%		Any Cannabinoid + BAC \geq 0.08%		No Cannabinoid, BAC \leq 0.08%		Total
	n	%	n	%	n	%	n	%

21-25 years	61	17.5%	103	29.6%	54	15.5%	126	36.2%	348
26-34 years	46	14.5%	104	32.7%	40	12.6%	119	37.4%	318
35-64 years	59	7.9%	206	27.7%	40	5.4%	418	56.3%	743
65+ years	6	2.1%	18	6.4%	2	0.7%	246	87.9%	280

Table Note: Other drugs could be present in any column. A small portion (2.4%) of all deceased drivers given a blood test for alcohol and drugs had an unknown alcohol result and are excluded from the table.

When examining alcohol and cannabis presence in fatal crash-involved drivers by age group, a trend emerges. The proportion of drivers that had only a BAC \geq 0.08% increased with age until peaking in the 26-34 years age category, whereas those with only a positive cannabinoid result peaked in the 18-20 years age group and then declined with age (Figure 10). As expected from these two trends, having both a positive cannabinoid result and a BAC \geq 0.08% peaked in the 21-25 years age group.

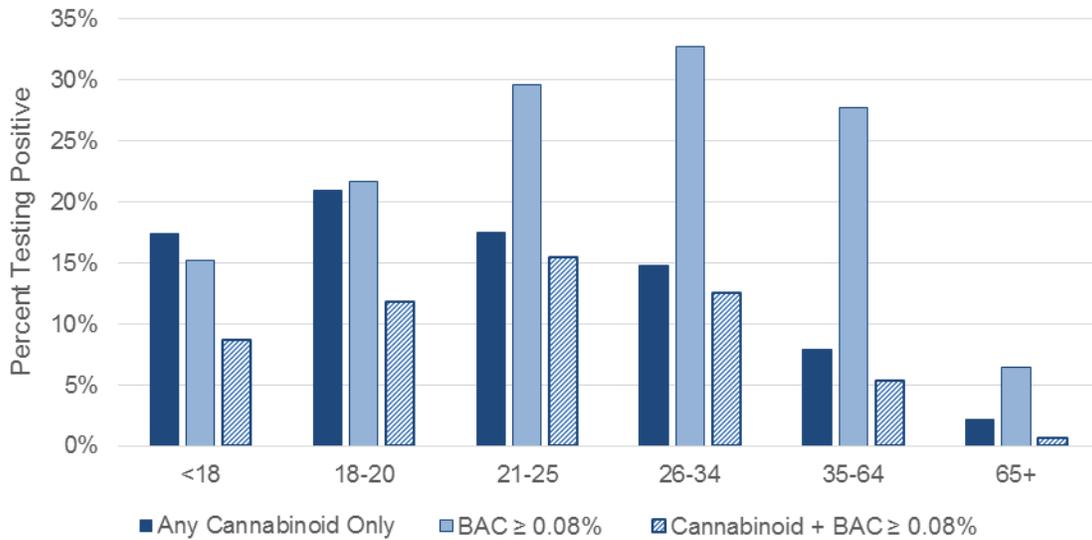

Figure 10. Percentage of all deceased drivers given a blood test for alcohol and drugs who tested positive for any cannabinoid and/or had a blood alcohol content (BAC) ≥ 0.08%, by driver age (years).

The trend in drivers with a BAC ≥ 0.08% and/or positive cannabinoid results was examined over time (Figure 11.) In 2007 and 2008, nearly 40% of all deceased drivers given a blood test for alcohol and drugs had a BAC ≥ 0.08%.

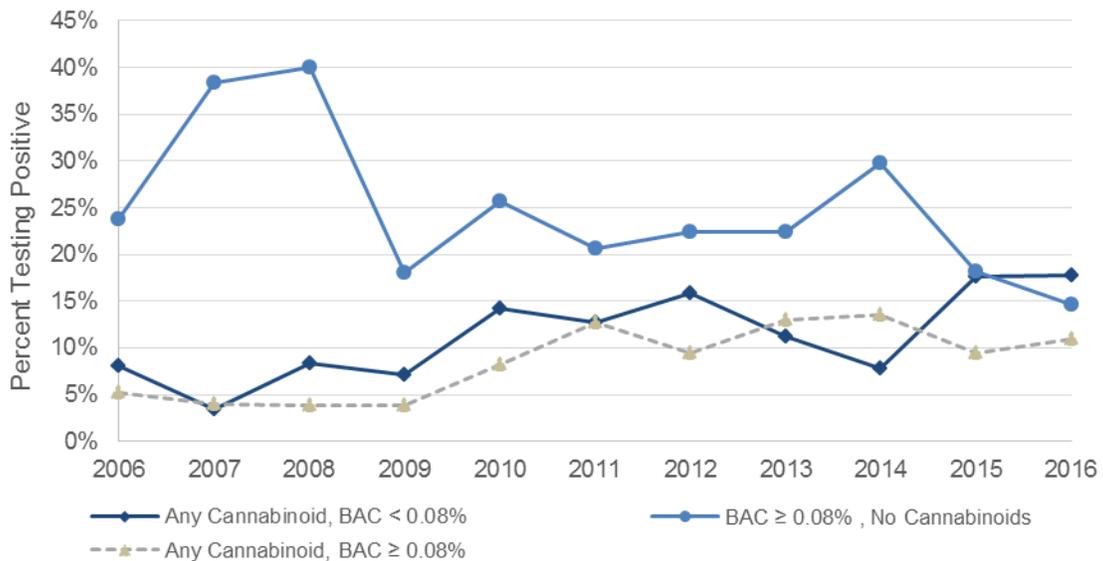

Figure 11. Percentage of all deceased drivers given a blood test for alcohol and drugs who tested positive for any cannabinoid and/or had a BAC ≥ 0.08% in Massachusetts from 2006 to 2016

The number of deaths resulting from these crashes has followed a similar trend (Figure 12). While the number of deaths from drivers with a BAC $\geq 0.08\%$ and no cannabinoids in their blood has steadily decreased since 2006, the number of deaths from drivers with cannabinoids and with a BAC below the legal limit of 0.08%, has steadily increased.

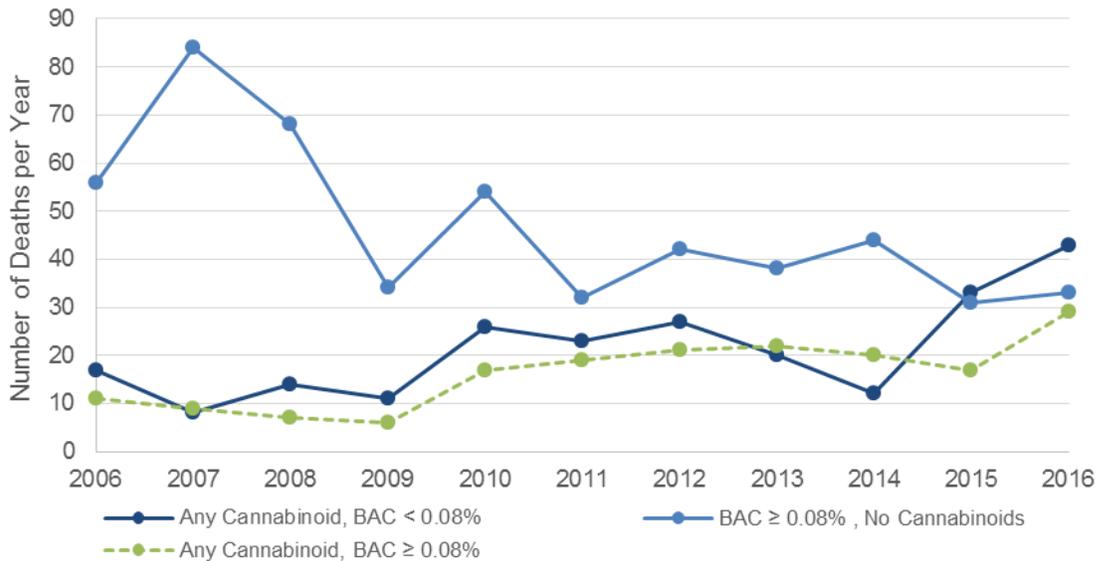

Figure 12. Number of deaths per year resulting from crashes with deceased drivers given a blood test for alcohol and drugs who tested positive for any cannabinoid and/or had a BAC $\geq 0.08\%$ in Massachusetts from 2006 to 2016.

The presence of other drugs was examined in addition to alcohol and cannabinoids. Figure 13 shows the frequency at which other drugs were present in blood-tested, deceased drivers. The drug categories were taken from the 2016 FARS/NASS GES Coding and Validation Manual (National Highway Traffic Safety Administration, 2016) with “Other” encompassing all drugs other than cannabinoids, narcotics, stimulants, depressants, and hallucinogens/PCP. Overall, all drug categories have generally trended upwards in the past 11 years.

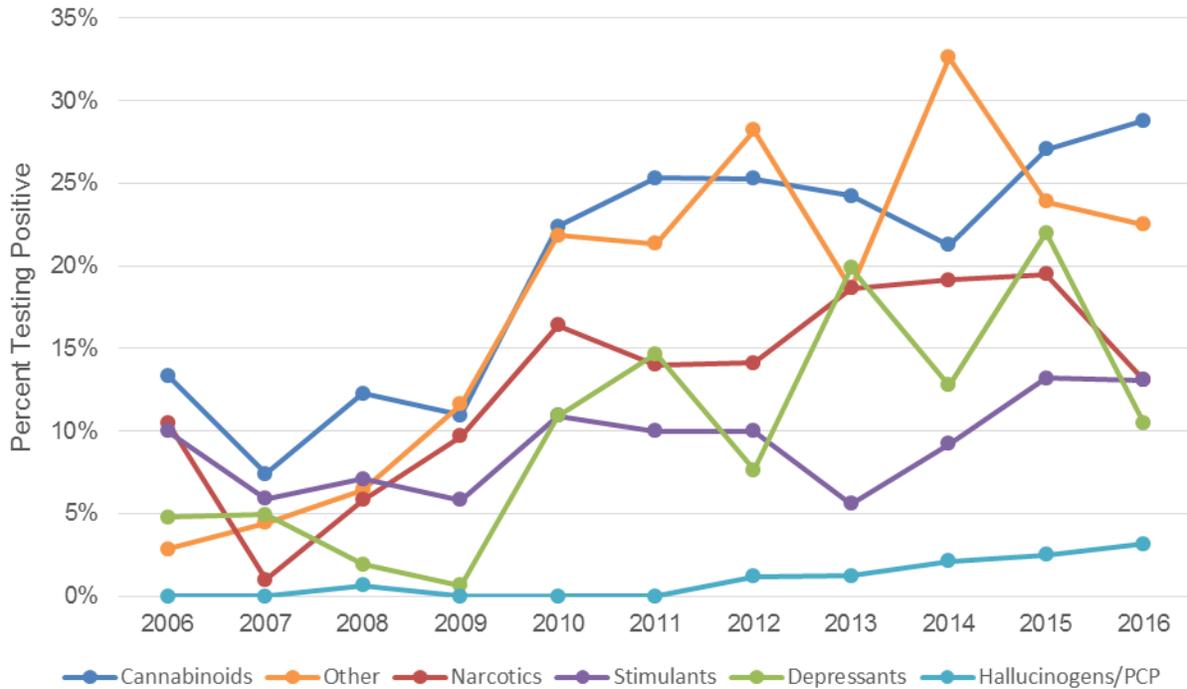

Figure 13. Percentage of all deceased, drivers given a blood test for drugs who tested positive for various drug categories in Massachusetts from 2006 to 2016.

Figure note: Totals will not sum to 100% as drivers could test positive in multiple categories. Cases with a positive test result but unknown drug type are excluded (0.2% of drivers given a blood test for drugs).

Drugs besides cannabinoids were analyzed in conjunction with alcohol (BAC ≥ 0.08) and any cannabinoids (Table 12). When examining racial/ethnic differences, White, non-Hispanic drivers were more likely to have only other drugs in their system than cannabinoids (Table 13). The same did not hold true for drivers with any Hispanic/Latino ethnicity and Black, non-Hispanic drivers. Those groups were equally or more likely to have cannabinoids only in their system than other drugs only. Sample sizes were too small for the other racial/ethnic categories to make similar comparisons.

Table 12, Table 13 and Table 14 show the number and frequency of deceased drivers by sex, race and age (respectively) testing positive for the seven combinations of cannabinoids, drugs and alcohol (defined as a BAC $\geq 0.08\%$) or none of those results.. Females were less likely than males to have a blood alcohol content above the legal limit or test positive for cannabinoids only, but were more likely than males to have a positive result for only other drugs (Table 12).

Table Note: NH= Non-Hispanic

Examining results for alcohol, marijuana, and other drugs by age, the percentage of deceased drivers within an age group testing positive for other drugs increases with age and is highest for the 65+ age bracket (Tables 14a and 14b). Deceased blood-tested drivers in this age range rarely tested positive for cannabinoids or had a BAC above 0.08%, but frequently tested positive for other drugs (Table 14b). This is likely due to the number of medications taken by older individuals that are reported in FARS drug results.

Crash Data System (CDS)

The results from our query of non-fatal crash data to identify officer-written crash narratives which contained the words “marijuana”, “weed”, and “cannabis” are shown in Figure 14. This figure displays the number of non-fatal crashes per year with a crash narrative containing one or more of these keywords. Data from 2017 was included because it was available from CDS. The number of crashes per year where the responding officer suspected marijuana-involvement has followed the same increasing trend as has fatal crashes (Figure 14).

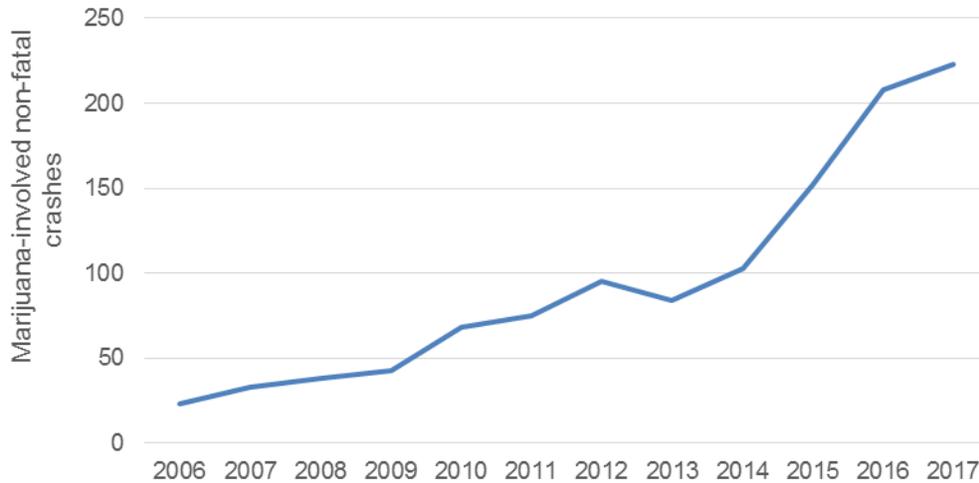

Figure 14. Non-fatal motor vehicle crashes which contain a crash narrative containing the keywords “marijuana”, “weed”, and/or “cannabis,” by year

Discussion

In 2017, 7.2% of Massachusetts adults drove under the influence of marijuana (DUI) and 11.7% rode with a driver who was under the influence of marijuana (RUI). Among marijuana users, nearly 4 in 10 reported DUI and or RUI-marijuana. When stratified by age, younger age groups appeared more likely to engage in both behaviors. We found that DUI-marijuana was reported by 25.6% of individuals age 18-20 years and 24.1% of those age 21-24 years. RUI-marijuana was reported by 36% of those age 18-20 years and 38% of those age 21-25 years. Prevalence was much lower for both DUI-marijuana and RUI-marijuana among adults age 25 years and older compared to those age 24 years and younger.

Compared to estimates from other states, the prevalence in Massachusetts of DUI- and RUI-marijuana appear higher, especially when stratified by age. However, some aspects of our results are consistent with prior work. For example, prior estimates from Colorado published in 2016 show that 6% of young adults age 18-25 years reported driving after using marijuana, while 4.8% 26-34 years old reported the behavior. Thus, our point estimates among Massachusetts adults are more than four times higher than estimates from Colorado (Department of Health and Environment). The results across states, however, are consistent in finding that prevalence of DUI-marijuana among older age groups is lower compared to younger age groups. Cross-state differences in results may be due to several factors, including regional beliefs, attitudes and policies related to DUI-marijuana.

Some prior studies have found that males are over-represented among those who drive under the influence of marijuana (Arria, Caldeira, Vincent, Garnier-Dykstra, & O'Grady, 2011; Whitehill et al., 2014). In the present study, this was not the case, with females

representing about 42% of marijuana users, and a similar proportion of those who DUI-marijuana.

About 4 out of 10 Massachusetts adults who drove under the influence of marijuana reported driving under the influence of alcohol and marijuana, simultaneously. This is concerning, since studies suggest that the crash risk from the combination of alcohol and marijuana may be higher than the risk from using either substance alone (Chihuri, Li, & Chen, 2017). Monitoring and preventing driving under the combination of alcohol and marijuana is an important consideration as legalization is implemented.

The analysis of data from fatal crashes in Massachusetts demonstrated that there were approximately 360 crashes in 2016 in which at least one person died, with a total of nearly 390 fatalities, of which 234 were drivers. Many of these crashes are preventable and reducing potentially-impairing alcohol and drug use by drivers should remain a priority as marijuana policies are changing within the state. Among the fatal crashes, approximately 36% of drivers received a blood drug test between 2002-2016. This included testing 73% of fatally injured drivers, and less than 1% of surviving drivers. To contextualize these numbers, prior studies seeking to establish national or cross-state comparisons using FARS data only include states in which testing rates are above 80% for deceased drivers. Thus, comparisons to other states may not be appropriate due to lower-than-ideal testing rates in Massachusetts.

We observed a trend that may indicate an increasing proportion of deceased drivers involved in fatal motor vehicle crashes testing positive for cannabinoids. This does not mean the drivers were impaired by marijuana at the time of the crash, and could merely indicate increasing population-level marijuana use, which would be consistent with the results from the adult survey. The analysis of FARS data showed a decrease over time in the number of deaths per year resulting from crashes with drivers who had a blood alcohol content above 0.08%, but an increase in the number of deaths with drivers testing positive for cannabinoids or a blood alcohol content above 0.08% plus cannabinoids. This trend is something that warrants future investigation in alternate data sources with regard to the possibility of either substitution (i.e. drivers using marijuana instead of alcohol) or combination (e.g. drivers using alcohol and marijuana) effects.

Limitations

As with all studies, these data are subject to several limitations. As reported in Task 1, Chapter 2, the survey response rate was 21.7%. Although this rate is in line with surveys of this kind, there is a possibility for response bias on a measure not accounted for by the weighting, which would impact generalizability. For example, if adults who did not use marijuana discarded the survey but those who used marijuana were more likely to return it, this could lead to overestimation of the prevalence of marijuana use, and related measures like driving under the influence. As marijuana legalization continues to be implemented in the Commonwealth, it will be important to replicate this survey as well as expand data collection to additional modalities that will provide a robust picture of marijuana use and related behaviors.

The cross-sectional survey design precludes determining the temporal sequencing of experiences and prevents drawing of causal inferences. Marijuana and other substance use were both self-reported, and not corroborated by testing of biological samples. Social desirability bias can lead to underestimates in survey research, however a unique contribution of this study is that it is the first to be conducted in Massachusetts after legalization of marijuana for adult recreational use. Data was collected in late 2017, nearly one year after marijuana became legal for recreational use by adults, and several years after legalization of medical marijuana in Massachusetts. This should reduce potential for social desirability bias that leads to under-reporting of marijuana use. Illegal behaviors (e.g. use of illicit drugs; driving under the influence of alcohol or drugs) may be underreported.

Small cell sizes for categories of some variables likely means that models including them are underpowered. For some variables, fewer than 5 respondents endorsed the items. Weighted estimates based on these few data should be interpreted carefully.

In conclusion, this study presents the first estimate of prevalence of DUI-marijuana and RUI-marijuana among Massachusetts adults after the legalization of marijuana for use by all adults over 21 years. Driving under the influence of marijuana is common among marijuana users, particularly among young adults. Riding as a passenger with a marijuana-using driver is even more common. Efforts to address social norms about driving under the influence of marijuana is one strategy that may reduce this behavior. In the meantime, more research to understand the true crash risk and methods for deterring impaired driving are needed.

Analysis of fatality data is also subject to limitations. In addition to a lower-than-ideal rate of testing, described above, prior studies have questioned the validity of drug data in FARS due to variability in drug testing practices, even within states (Berning & Smither, 2014). The data used for this study, which showed a dramatic dip to near-zero levels of recorded delta-9-THC results in 2011-2012 and precluded use of that data for this analysis likely reflects the type of testing and/or data coding problems that plague the FARS data.

Chapter 3: Marijuana-Related Health System Contacts in Massachusetts

Introduction

Problems related to marijuana use may lead users to require medical care. This care seeking includes incidents in which someone seeks treatment for a cannabis use disorder, or could be related to an acute injury (e.g. from a cannabis-involved motor vehicle crash) or episode of marijuana-related illness. For this study, we brought together three sources of data to document the current several aspects of the current picture of health system contacts related to marijuana. Specifically, we sought to document the number and prevalence of (1) substance use treatment admissions for a primary diagnosis of cannabis use disorder; (2) emergency room and urgent care services due to marijuana, and (3) marijuana-related exposure calls received by the regional poison control center (PCC).

Since historical data is not available on use of emergency room and urgent care services for marijuana, we sought to obtain a 2017 point estimate. For treatment admissions and cannabis exposures (including unintentional exposure among youth 0-9) through poison control calls will capture trends associated with regulations, legislation and cultural shifts. As marijuana legalization of marijuana for adult use is implemented, these are valuable indicator that can serve as a benchmark against which future policy changes change be compared.

Methods

Treatment Episode Data

The national Substance Use and Mental Health Services Administration (SAMHSA) collects and publishes annual data episodes of substance use treatment in each U.S. This data includes information on the raw number and population adjusted number of admissions to substance abuse treatment by primary substance of abuse and by year. We compiled the number of marijuana-related treatment episodes for 2004-2014, with 2014 being the most recent year of data available. We also extracted information on alcohol, opioid, cocaine, and methamphetamine/amphetamine admissions for comparison purposes. We graphed the trend over time in population-adjusted admissions for marijuana, and the proportion of all admissions due to marijuana.

Population Survey of Massachusetts Adults

We analyzed the survey conducted as part of the MBHS included questions on seeking emergency or urgent care related to marijuana use. Briefly, we conducted a population-based, mail and Internet survey of Massachusetts residents age 18 years and older. This study was approved by the Institutional Review Board at the Massachusetts Department of Public Health. The survey instrument can be found in Appendix A.

Details on the methods of survey design, data collection, measures, and statistical procedures, including survey weighting, can be found in Task 1, Chapter 2. In addition to the measures described therein, several questions were added to the survey for the

purpose of addressing use of emergency room or urgent care services related to substance use.

For individuals who reported yes to using a particular substance (alcohol, marijuana, or other substances) in the past 30 days, the survey asked if they had utilized emergency room or urgent care services in relation to that substance within the past year.

Poison Control Center Exposure Calls

It can be difficult to distinguish, from secondary data, the intentionality of an exposure. For example, if teenagers intentionally experiment with marijuana but have adverse reactions, they may call poison control claiming unintentional exposure. Therefore, prior studies have coded all exposures under the age of 9 years as unintentional.

As restricting cases to children 9 years old and under has been utilized in previous studies to ensure the analysis is accurately assessing unintentional exposures and exclude adolescents, this study looked at this age range separately as well as examined cases in different age groups. Other age groups of interest revolved around youth and adolescents. As adolescence varies by individual, sex and national differences, this analysis used age categories of 10-19 years, based on the World Health Organization identification as this time period as the general span of adolescents (World Health Organization, 2017). We also used a category for 20-24 years as this age span is described as late adolescence in the United States (Arnett & Tanner, 2004) and utilized in similar studies in Colorado (Wang et al., 2014).

Unknown age includes teen, unknown adult, unknown 20's and unknown. Adults 30 and over with decade specification but no specific age they were assigned the median of their decade, e.g. 50's was assigned 55. A listing of marijuana-involved exposure calls and aggregate numbers of all PCC exposure calls by age group and by year was provided by the PCC for calls originating from within Massachusetts. We excluded calls from Rhode Island.

We included the following product codes: 310124 Marijuana: Concentrated Extract (Including Oils and Tinctures); 083000 Marijuana: Dried Plant; 310121 Marijuana: Edible Preparation, 310122 Marijuana: Oral Capsule or Pill Preparation, 310126 Marijuana: Other or Unknown Preparation, 200618 Marijuana: Pharmaceutical Preparation, 310125 Marijuana: Topical Preparation, 310123 Marijuana: Undried Plant, 310096 eCigarettes: Marijuana Device Flavor Unknown, 310034 eCigarettes: Marijuana Device With Added Flavors, 310033 eCigarettes: Marijuana Device Without Added Flavors, 310097 eCigarettes: Marijuana Liquid Flavor Unknown, 310036 eCigarettes: Marijuana Liquid With Added Flavors, 310035 eCigarettes: Marijuana Liquid Without Added Flavors. There were five cases exposed to two marijuana codes: one exposure always being dried plant there was 1 synthetic, 2 edibles, 1 concentrate, and 1 other/unknown. These were recoded as 2 marijuana codes. No combination of marijuana preparations exceeded two preparations, for example dried plant and edible. For calls involving multiple substances, we did not have the information on what other substances were involved, for example acetometaphin.

To explore population fluctuations that could influence prevalence, we examined the percent change in the MA population in 2007, 2010, and 2016 within age categories, using census data. If the change was less than 10%, we used 2010 census data to calculate calls per 100,000 people. There was a greater than 10% change in 25-34, 35-44, 60-64, and 65-74 year age groups, but when collapsed into adults 25 and older, there was no significant change. We, therefore, used 2010 census data as the denominator for population prevalence rates.

We graphed trend lines for the percentage of all PCC calls due to marijuana exposure, and graphed the number of exposure calls due to various preparations of marijuana. Medical marijuana became legal in Massachusetts in late 2012, so we examined whether the proportion of all PCC calls due to marijuana was statistically significantly different before this change (2007-2012) versus after (2013-2016). Chi-squared tests or Fisher’s exact tests were used for those analyses. All analyses were stratified by age group.

Results

Episodes of Marijuana-Related Substance Use Treatment

As shown in Table 1, the number of admissions to substance use treatment for marijuana was 2652 in 2014. This represents an increase from 2012 and 2013 levels, but a decrease from the historic levels in the 2004-2010. The prevalence of marijuana-related admissions to treatment was 45 per 100,000 in 2014. This was consistent in the last few years, and a decline from peak levels in 2006-2005 (Figure 1).

Table 1. Number of Substance Abuse Treatment Admissions in Massachusetts by Primary Sub-Substance of Abuse, Age 12+, 2004-2014

Primary Substance	Year										
	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013	2014
marijuana	3144	3372	4957	4360	3362	3073	3157	2614	2501	2357	2652
alcohol	20421	20734	37337	36570	32435	32153	31299	28587	27678	26786	27619
opioids	29086	28509	41097	42014	39568	41700	40306	41723	46200	50482	50116
cocaine	3643	4223	7446	6597	4828	4066	3519	3036	2758	2461	2319
meth/amp	119	152	190	163	94	70	126	90	115	160	182
Total	53269	53618	86070	85344	76925	77989	75250	73436	76751	79889	80236

Note: other substances of abuse are not included in this table.

*meth/amp=methamphetamine/amphetamine.

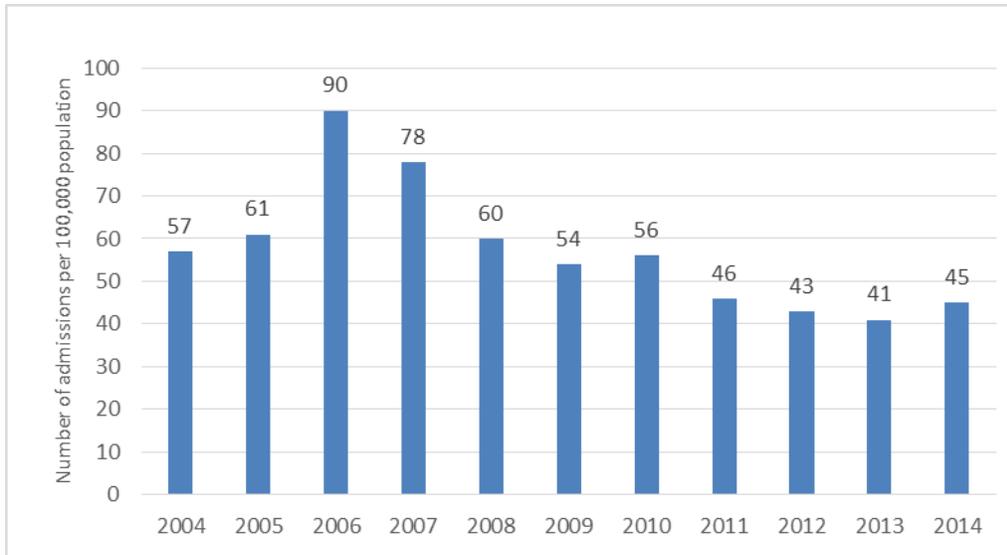

Figure 1. Massachusetts Admissions to Substance Use Treatment with Marijuana as Primary Substance of Abuse, Age 12+, 2004-2014

As shown in Figure 2, the proportion of substance abuse treatment admissions due to marijuana use has remained at less than 5% of all admissions. However, it is important to note that in the midst of the opioid epidemic, which has taxed the capacity of the treatment system, the proportion of admissions due to all other substances would inherently be reduced.

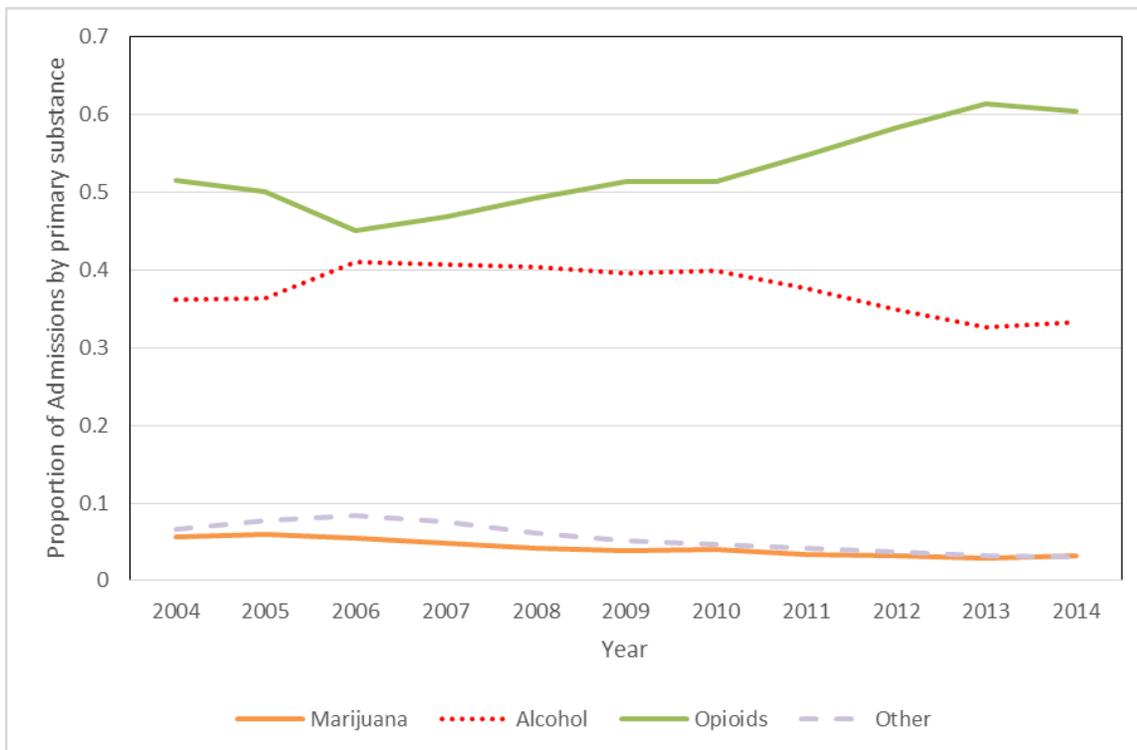

Figure 2. Proportion of Substance Abuse Treatment Admissions by Primary Substance of Abuse, 2004-2014

Substance Use-Related Emergency Care

Among those who used marijuana in the past 30 days, no respondents reported marijuana-related use of emergency room or urgent care services in the prior year. Nearly 70% of Massachusetts adults used alcohol in the past 30 days. Among this group, 1.7% reported use of emergency use of healthcare due to alcohol in the past year. Additionally, 4.1% of the population reported past 30-day use of other substances (e.g. cocaine, opioids, etc.); 4.7% of these individuals sought emergency care related to their substance use, although we note that this estimate is based on fewer than five individuals in the sample and should be interpreted with caution.

Marijuana-Related Exposure Calls to the Poison Control Center

During the 10-year study period (2007-2016) there were 641 calls to the PCC that included marijuana exposure (Table 2) with an upward trend over time (Figure 3). The overall period prevalence from 2007-2016 was 9.4 per 100,000 population. In 2016, there were 78 calls to the PCC with marijuana exposure. Six of these calls pertained to marijuana exposure in youth age 0-9 years, 33 among youth 10-19 years, 12 among young adults age 20-24 years, and 27 among individuals age 25 years and older. These numbers correspond to a prevalence of 0.79 per 100,000 among children age 0-9 years was; 3.8 among 10-19 year olds, 2.5 among 20-24, and 0.6 per 100,000 among those over age 25 years.

For youth under age 18, the proportion of all PCC calls that were due to marijuana, by age group, is shown in Figure 3. The proportion was highest for youth between 10-19 years. Although the magnitude is small, with the highest proportion being under 0.5% (among 10-17 year olds), this is concerning, since the youngest children 0-9 years are being impacted at increasingly levels, presumably through unintentional exposure (Figure 3). We also observed increasing proportions of calls due to marijuana for adults (Figure 4).

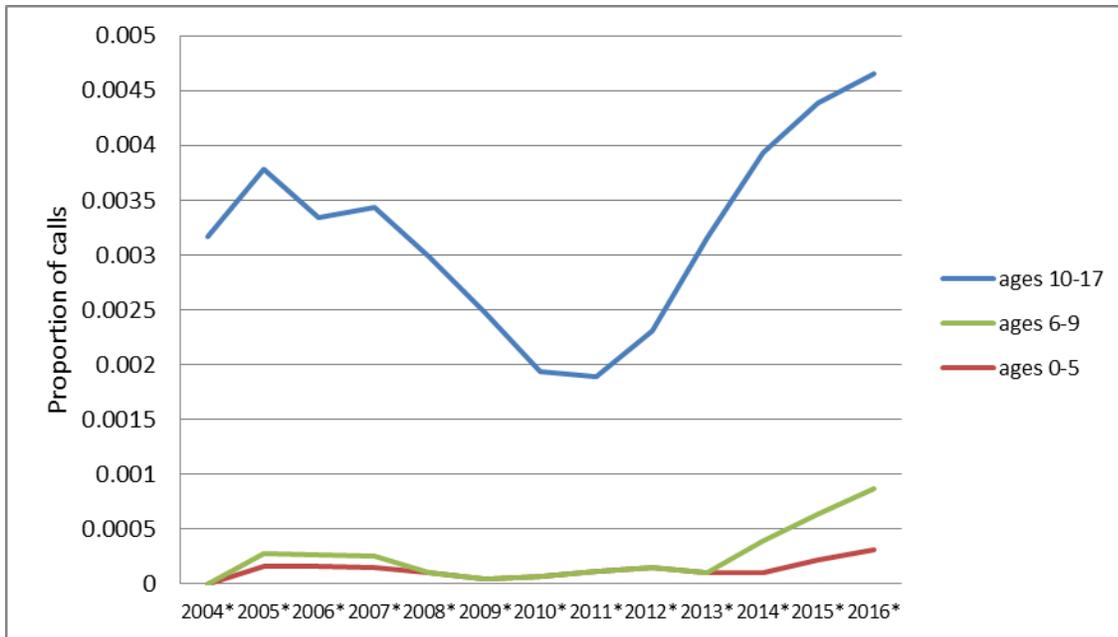

Figure 3. Proportion of MA Poison Control Calls due to Marijuana, Youth Age 0-17, 3-Year Moving Average, and 2004-2016

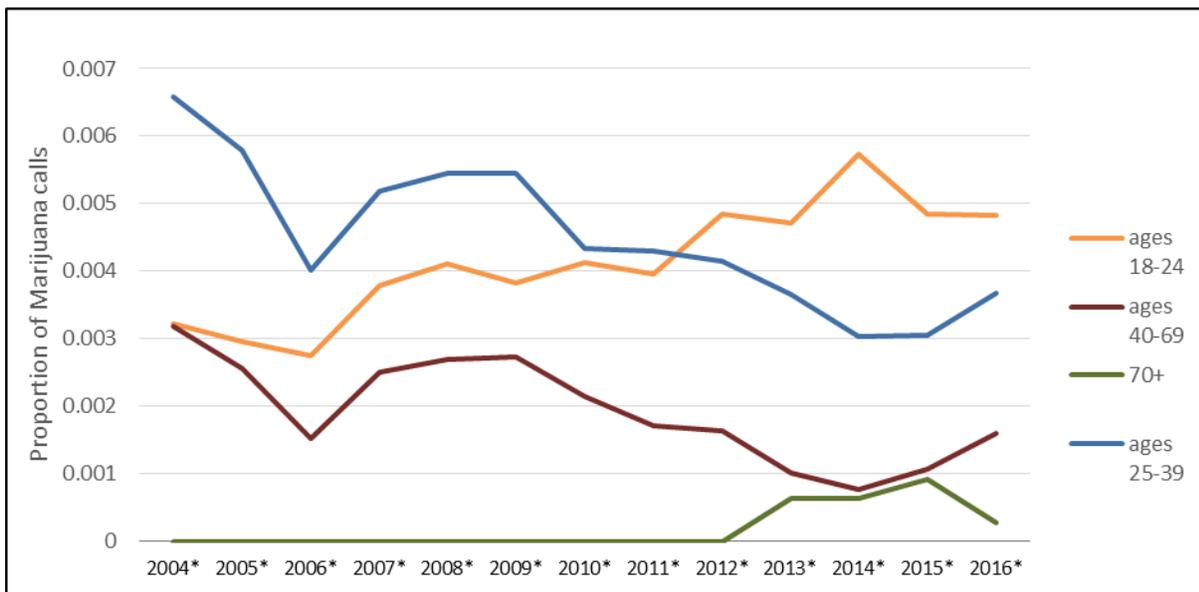

Figure 4. Proportion of MA Poison Control Calls Related to Marijuana Exposure, Adults 18+ Years, 3-Year Moving Average, 2004-2016

Table 2. Demographics and Medical Outcomes of Cannabis-Involved Exposure Calls to the Poison Control Center, Massachusetts, 2007-2016

	Frequency	Percent	
Sex

unrelated effect, exposure probably not responsible for effects	6	0.94	3(50%)
Total	641	100	

One substance was a non-synthetic preparation of Marijuana; Proportion in parentheses represents the proportion of all cannabis-involved calls within each medical outcome that were due to only one cannabis code.

Table 2 shows the medical outcomes reported by PCC professionals. Not surprisingly, there was a higher proportion of calls involving a death or major effect for calls involving multiple substances (as many as 14 involved) compared to calls involving only one cannabis code. The multi-substance calls included substances that were not marijuana. We examined whether there was an increase in the proportion of PCC calls due to marijuana after medical marijuana was legalized in Massachusetts versus before.

Results from chi-squared and Fisher's exact tests indicated that although the percentages are small, there was a higher proportion of PCC calls due to marijuana exposure in 2013-2016 compared to 2007-2012 for children age 0-5 years ($p=0.001$), children 6-9 years ($p=0.017$) and youth age 10-20 ($p=0.001$). See Table 3.

When examining the different marijuana product codes involved in calls to the PCC, we found that over time and across age groups, most calls involved dried marijuana plant. The next most common preparation involved was edible preparations, more frequently seen after 2012 (Figures 5-7).

Table 3. Differences in Proportions of Marijuana-Related Poison Control Center Calls, Pre- versus Post-2012

Ages 0-5

Discussion

In MA from 2005-2016, the period prevalence was 3.5 per 100,000 in children age 0-9 years. A study of Colorado between 2005 and 2011 found cases of children under the age of 9 who had Poison control calls for marijuana related exposures was 6.6 per 100,000; this was compared to generally less than 2 calls per 100,000 in states without similar marijuana legislation (Wang et al., 2014). That study raised discussions about whether the finding of increased prevalence in a state with medical marijuana at the time was due to increased exposure or less stigma among parents or caregivers calling to report such an exposure (Hoffman, 2016). Our data indicated that there was a statistically significant increase in the proportion of calls to the PCC that were related to marijuana after medical marijuana was legalized in Massachusetts.

Children age 0-9 years accounted for less than 5% of the calls to the PCC due to marijuana exposure during the study period, whereas youth aged 10-19 years accounted for 40% of marijuana-related calls.

Task 3: Economic and Fiscal Impacts

Chapter 1: From Medical to Retail Marijuana: Estimating Fiscal Effects of Legalization In Massachusetts

Abstract

Background

In 2016, Massachusetts voters approved a ballot measure to legalize broad adult use of marijuana. As part of the 2017-2018 Massachusetts Marijuana Baseline Health Study, we estimated fiscal impacts of legalization for state and local governments. We developed a model to estimate changes expected in four key domains within the first two years of retail sales: tax revenue from marijuana purchases (based on a 20% combined sales, excise, and local tax rate); regulatory oversight; law enforcement activities; and public health effects.

Methods

Estimates of revenue or savings and costs or losses were derived from the literature (restricted to impacts attributable to legalization); expert interviews; and secondary sources (on marijuana pricing, marijuana use prevalence, regulatory costs and revenue, public health and safety outcomes, and Massachusetts population size and demographics). For each measure, we defined a range of values, then used Monte Carlo simulation to randomly choose a value to calculate post-legalization estimate. We calculated post-legalization impacts by combining information on pre-legalization estimates with estimates of change due to legalization. We summed estimates across all measures and domains to obtain an overall impact estimate.

Results

In our main model, which included measures that were major drivers of budgetary impacts (sales and business tax revenue, regulatory costs and revenue, and savings due to reduced marijuana-related law enforcement), we projected a gain of \$215.8 million to the state budget. In a supplemental model that added in public health impacts thought to be less definitive or immediate, we projected an additional gain of \$65.3 million, yielding a total impact of \$281.1 million. Local tax revenue estimates (derived using local data on marijuana use prevalence and pricing, when available) ranged from a median of \$63,000 for suburban cities and towns to \$583,000 for urban cities.

Discussion

The primary driver of fiscal gains (accounting for 53% of the total impact) was sales and excise tax revenue collected on retail marijuana purchases. Other major contributors included new business tax revenue from marijuana dispensaries and increased individual income tax revenue due to worker productivity gains among older adults who are able to control debilitating medical conditions with marijuana.

Background

In November 2016, Massachusetts voters approved a ballot measure to legalize adult use of marijuana, joining a growing list of states approving and implementing similar measures in the past five years. The adult use of marijuana program will build on the medical marijuana program that has been operating in Massachusetts since 2013, serving nearly 50,000 active patients as of January 2018.¹ The program will also build on the experiences from other states that have legalized marijuana in recent years. However, given that retail sales of marijuana have only been legal in the United States for about four years, there is a sparse body of literature on the causal impacts of marijuana on a host of fiscal, health, public safety, and criminal justice outcomes. To better understand marijuana use in the state and to project fiscal impacts associated with retail sales, the state legislated that the Massachusetts Department of Public Health (MDPH) conduct the Marijuana Baseline Health Study (MBHS). The study examines the use, methods of consumption, and perceptions of marijuana; impaired driving and hospitalization related to marijuana use; and economic and fiscal impacts for state and local governments.² In this report, we address the third aim to estimate the fiscal impacts of moving from a medical marijuana program to broad adult use. We focus on four key domains: (1) tax revenue from marijuana sales, (2) regulatory oversight, (3) law enforcement activities, and (4) public health effects.

Retail sales of marijuana are planned to begin in July 2018, after legislation was passed in December 2016 to delay implementation of the program by six months.³ Whereas the original ballot measure included a 3.75% excise tax, 6.25% state sales tax, and an optional local tax up to 2%, for a maximum tax rate of 12%, the state legislature later passed a bill to increase the excise tax to 10.75% and the maximum local tax to 3%, yielding a total maximum tax rate of 20%.⁴ A share of the revenues collected by the state will be devoted to (1) public and behavioral health, (2) public safety, (3) municipal police training, (4) the Prevention and Wellness Trust Fund, and (5) a host of services for “economically-disadvantaged persons in communities disproportionately impacted by high rates of arrest and incarceration for marijuana offenses.”⁵

The existing medical marijuana program in Massachusetts registers nonprofit organizations to cultivate and dispense marijuana as well as patients and physicians.⁶ As of January 2018, the program had 227 registered certifying health care providers and nearly 50,000 active patients. The program has consistently added roughly 2,000 patients per month over its history. There are 22 registered marijuana dispensaries with final certification and approval to sell, 6 with final certification but not yet approved to

sell, and 99 with provisional certificates and in the inspection phase. In contrast to the adult use program, the medical program requires those selling medical marijuana to follow a seed-to-sale model—that is, the same entity is responsible for the product from cultivation to sale in licensed dispensaries. In addition, the marijuana is not subject to any taxes, and only nonprofit organizations can participate.

To implement and administer the adult use program and create a safely regulated industry, the state formed the Cannabis Control Commission (CCC) in 2017. The CCC will also take over regulatory activities for the medical marijuana program, currently administered by the MDPH Bureau of Health Care Safety and Quality.⁷ Massachusetts also created the Cannabis Advisory Board, a 25-member group charged with studying and making recommendations to the CCC on the regulation and taxation of marijuana in Massachusetts.

The adult use program in Massachusetts and the study presented here have the benefit of learning from experiences in several other states that have implemented similar programs in the past four years. Colorado and Washington approved ballot measures in 2013 to legalize marijuana for adult use and began retail sales in 2014. In 2014, Alaska, Oregon, and Washington, D.C. voted to legalize adult use, with retail sales beginning in 2015 in Oregon and in 2016 in Alaska; retail sales are not yet permitted in Washington, D.C. In 2016, California, Maine, Nevada, and Massachusetts approved ballot measures, with retail sales beginning in 2017 in Nevada and 2018 in California and Massachusetts; retail sales are not yet permitted in Maine. Finally, the state legislature in Vermont legalized adult use in 2018. Although the experiences with adult use of marijuana in these states have been brief, the states consistently saw substantial increases in revenue collected from retail sales after the first year. Revenue collected in the first year ranged from \$1.7 million in Alaska to \$67.6 million in Colorado.⁸ There were substantial increases in the second and third years of the programs; for example, the revenue collected by the Washington Liquor Cannabis Board (LCB) increased from \$64.9 million in the first year of the program to \$314.8 million in the third year (Washington State LCB, n.d.). In addition, the revenue collected was substantially above the amount projected by the states prior to implementation. Finally, there is some limited evidence suggesting that marijuana legalization could have positive impacts on public health and safety outcomes and criminal justice costs and outcomes (such as reduced incarcerations); however, the evidence is primarily for impacts from medical marijuana legalization, little evidence establishes causal links between legalization and the outcomes, and the timeline for observing impacts for legalization is brief (four years at most for the earliest implementers).

There are a handful of differences between the planned program in Massachusetts and other states that will likely affect the implementation and impact of legalization. First,

⁷ <https://mass-cannabis-control.com/about-us-2/>.

⁸ Alaska: <http://tax.alaska.gov/programs/programs/reports/monthly/Marijuana.aspx?ReportDate=8/1/2017>; Colorado: <https://www.colorado.gov/pacific/revenue/colorado-marijuana-tax-data>; for a summary of revenue collected, see <http://www.drugpolicy.org/legalization-status-report>.

other states have implemented substantially higher tax rates than the planned 17% tax rate in Massachusetts (excluding the local tax rate), which influences the price of marijuana in the licit market and thus how much demand is met by retail sales versus the black market. In high-tax Washington (44% point-of-sale tax, excluding the local tax rate), despite the fact that the licit price of marijuana has dropped over time and is only slightly above black market prices, licensed sales account for only about 30% of demand; the rest is met by the state's loosely regulated medical marijuana market and other black market sources.⁹ By contrast, in Colorado, where marijuana taxes were lower (27.9% combined tax rate through July 2017, excluding the local tax rate), an estimated 70% of demand is met by the licit market, with much of the remaining demand met by legal home-grown product. Differences in the structure of the medical marijuana programs will also influence the impact of legalization. The cultivation and sale of medical marijuana is strictly regulated and less accessible to Massachusetts residents compared to other states. Out of 27 states with medical marijuana programs, Massachusetts ranks 15th highest in terms of the number of medical marijuana patients per 1,000 state residents (Marijuana Policy Project, 2018); programs in California, Colorado, and Oregon include a much greater proportion of residents.¹⁰ On the other hand, other states apply taxes to medical marijuana sales to varying degrees; the fact that the Massachusetts medical marijuana program is untaxed could make it more attractive to marijuana consumers once retail sales begin.

In this study, we combine evidence from implementation in other states with the details and nuances of Massachusetts programs and residents to estimate fiscal impacts of legalizing adult use of marijuana on state and local budgets. We estimate impacts separately for key domains of interest: (1) sales and business tax revenue from retail marijuana sales, (2) law enforcement costs, (3) the costs of regulatory oversight, and (4) estimated impacts on state public health expenditures and individual income tax revenue as a result of changes in worker productivity (both of which were included in a supplemental model). Our estimates reflect impacts expected only within the first two years after retail sales are allowed but also include start-up costs and revenue. Given the uncertainty of many of the inputs used to estimate impacts in some of these domains (for example, the projected price of marijuana in the retail market or the percentage of current users that will purchase their marijuana in the licit market), we conducted a number of sensitivity analyses to test the robustness of the results to our inputs. The results generated in the study will help the state and municipalities plan for the impacts of legalization while also providing a point of comparison for early impacts once the program is implemented. Furthermore, the study will provide valuable information to other states considering legalization on the complex public health, public safety, and economic impacts of legalizing marijuana.

Methods

Data Sources

We developed a model to estimate changes expected in four key domains within the first two years of retail sales. Each domain (for example, marijuana sales tax revenue) included individual measures (for example, marijuana use prevalence and the price of marijuana) that we estimated using three main sources of information: existing literature, interviews with academic and government experts, and secondary data sources. For each measure that fed into the model, we defined a range of plausible values as follows:

- If multiple (high quality, rigorous) studies or sources estimated the same metric, we defined the range based on the point estimates from these sources.
- If only a single study was used to estimate a metric, we defined the range based on the confidence interval around the point estimate from that paper.
- If there was no credible study or source for a given metric, we estimated a range using information from other states with legalized adult use or from expert stakeholder input.

Literature Review

To inform estimates of the impact of legalization in Massachusetts, we first reviewed the literature on the impacts of marijuana laws or policies on consumption of marijuana, alcohol, and tobacco; public health; public safety; and worker productivity. We also used the literature to identify major sources of direct costs and revenue stemming from marijuana legalization, plus demographic subgroups that are affected differentially by legalization. As a starting point, we first searched peer-reviewed publications based on key search terms (such as “marijuana” and “legalization”) applied to the MEDLINE®, Scopus, and EconLit databases. To avoid excluding potentially relevant search results, we used a broad set of search terms related to marijuana legalization rather than searching by specific terms related to consumption, public health, public safety, and labor productivity. We then searched the gray literature to identify working papers from the National Bureau of Economic Research, research briefs, and other reports published from policy institutes and state governments. After excluding papers based on a review of titles, we reviewed the abstracts to ascertain relevance. We identified 57 candidate papers, to which we uniformly applied a set of causal evidence criteria, as described below, to determine inclusion.

Because the literature has focused mostly on medical marijuana legalization, and there is limited literature on adult use legalization, many of the model impacts derived from the literature are based on the experiences of medical marijuana programs. To account for the possibility that these impacts will not accurately reflect the experience of legalization in Massachusetts, we incorporate ranges for estimates derived from this literature, along with a sensitivity analysis that removes all impacts taken from the medical marijuana literature.

Causal Criteria

To ensure that our model estimates are based only on papers that demonstrate strong causal evidence that links outcomes directly to marijuana policies, we developed a set of guidelines to determine inclusion of impacts in our model estimates.¹¹ We rated each paper based on the strength of evidence as high, moderate, or low causal evidence for marijuana-attributable impacts. A high rating indicates that the analysis meets high methodological standards (for example, with a control group included in the analysis) and the impacts estimated are credible; it does not mean that the study found positive impacts. A moderate causal evidence rating means that we are somewhat confident that the estimated impacts are attributable to the intervention studied, but other factors that were not included in the analysis could have contributed to the impacts observed. Research not meeting the criteria for a high or moderate causal evidence rating received a low causal evidence rating, indicating that we could not be certain that the impacts observed were attributable to the marijuana law or policy being studied. To derive estimates for our model measures, we relied only on studies with a high causal rating. Of the 57 candidate papers reviewed, 16 met the criteria for high causal evidence. As our research progressed, we identified an additional 3 papers published in 2017 that had high causal evidence, resulting in a total of 19 (out of 60) that met our criteria for high quality evidence of impacts attributed to marijuana.

An implication of applying these strict causal guidelines to our inclusion criteria is that we ultimately excluded some studies and state government reports that used longitudinal data to examine how public health and safety outcomes (such as emergency room visits, suicides, and non-fatal crashes) changed after adult use of marijuana was legalized because these analyses lacked valid comparison groups. Our exclusion of these studies does not imply that the results are not valid or useful for certain purposes, but rather that we cannot be confident that the pre-post changes are attributable to legalization.

Stakeholder Interviews

For certain domains of interest, there was insufficient rigorous evidence from the literature on causal impacts of legalization to inform our model estimates. Instead, we gathered information from interviews with expert stakeholders in Massachusetts and other states with legalized marijuana retail sales as well as from researchers studying marijuana legalization. We also used these interviews to gain insight into contextual differences between Massachusetts and other states with legalized adult use that may affect our modeling approach or interpretation of estimates. We interviewed experts in the following knowledge areas: (1) regulatory costs to state and local governments, (2) regulation of the current Massachusetts medical marijuana program, (3) the degree of shift from illicit to legal consumption, (4) current law enforcement practices in Massachusetts, and (5) public health experiences and budget expenditures in Colorado. For each interview, we developed separate protocols with tailored questions that we

¹¹ These guidelines follow the Clearinghouse for Labor Evaluation and Research (CLEAR). CLEAR was established by the Department of Labor to promote informed decision making and policy development by providing a central and trusted source of research evidence.

asked in person, by phone, or through email correspondences. Our notes from these interviews informed the model estimates for measures and domains of interest, as detailed in Table 1.

Table 1. Model Measures Informed by Stakeholder Interviews

Domain	Interviewee's institution	Model measure informed by interview
Tax revenue	Harvard University	Percentage shift from illicit to legal market for current adult users Percentage change over time in current prices of marijuana
Regulatory oversight	Washington State Institute for Public Policy (WSIPP) MDPH	State regulation costs State regulation revenue Number of infractions per RMD per year
Law enforcement	Massachusetts Executive Office of Public Safety and Security (EOPSS)	Number of misdemeanor arrests Number of misdemeanor convictions Number of incarcerations Number of inmates on supervised release (parolees/probationers) Percentage change in misdemeanor arrests Percentage change in misdemeanor convictions Percentage change in incarcerations Percentage change in supervised release Costs of employee training on cannabis impaired driving

MDPH = Massachusetts Department of Public Health; RMD = registered marijuana dispensary.

Secondary Data Sources

We augmented information from the literature and key informant interviews with analyses of a number of secondary data sources. To estimate taxable sales from marijuana, we required information on marijuana pricing. We extracted this information from three websites that aggregate crowd-sourced information on marijuana pricing (as of December 2017): Budzu and PriceofWeed (which enables users to submit information on the location where they purchased marijuana and on the price, amount, and quality of the marijuana purchased) and a document hosted on Google Sheets called Dispensary Sheet (which displays information about the price of marijuana for each amount sold at Massachusetts dispensaries). Because retail marijuana sales are not yet legal, information on the current price per gram of dried flower marijuana from these sites may contain a combination of prices in the illicit market and those in the medical market. We also used data supplied by MDPH to identify the median price of medical marijuana sold in registered marijuana dispensaries (RMDs) in Massachusetts (see Appendix D).

We obtained data on the prevalence of current marijuana use from a combination of the MBHS Task 1 survey of the general population in Massachusetts; the 2015 National Survey on Drug Use and Health (NSDUH, based on national estimates because Massachusetts-specific detailed data were unavailable at the time of the analysis¹²); and the 2015 Behavioral Risk Factor Surveillance System (BRFSS) of Massachusetts residents.^{13,14} For adolescent marijuana use prevalence, we obtained estimates from the 2015 Massachusetts Youth Risk Behavior Surveillance System (YRBSS) survey of 9th through 12th grade students,¹⁵ the 2015 Massachusetts Youth Health Survey (YHS) of middle and high school students,¹⁶ and 2015–2016 NSDUH estimates.¹⁷

We gathered estimates of changes in regulatory costs and revenue attributable to retail legalization from CCC, MDPH, Washington, and Colorado budgets. Given that the CCC is expected to take over regulatory oversight of the medical marijuana program from MDPH, the increase in start-up costs for Massachusetts fiscal year (FY) 2018 were based on the difference between the CCC budget estimate¹⁸ and projected FY 2017 costs from the MDPH’s Medical Marijuana Trust Fund Annual Report.¹⁹ Thereafter, for FY 2019 and FY 2020, we inflated CCC and MDPH projections of costs to account for the expected growth in the number of RMDs in operation (estimated to be 26 by the end of FY 2018, 40 by the end of FY 2019, and 123 by the end of FY 2020, based on data posted by MDPH on the current status of all registered marijuana dispensaries and applications through January 12, 2018²⁰). We also translated recurring marijuana-related law enforcement costs incurred in Washington (based on the I-502 Fiscal Impact Statement²¹) and public safety costs incurred in Colorado²² to Massachusetts’ projected costs on a per capita basis.

Sources of regulatory revenue within the first two years of legalization include marijuana dispensary application fees and fines collected for infractions or deficiencies. To

estimate regulatory revenue, we inflated FY 2017 projections from MDPH's Medical Marijuana Trust Fund Annual Report, as described above for the start-up costs, to reflect the growth in RMDs. We also included estimated fines that the CCC will collect for infractions in FY 2019 and FY 2020. Though CCC fines can be as high as \$25,000 per deficiency, we assumed an average fine of \$1,000 (in line with Group 2 regulatory marijuana fines in Washington²³) and assumed five deficiencies per RMD per year (based on conversations with MDPH). We did not factor in additional licensing revenue because, based on our analysis of data from MDPH on the current status of all registered marijuana dispensaries and applications through January 12, 2018, we do not expect to see a substantial increase in the number of RMD applications in the two-year study period compared to current application rates.

Finally, several secondary data sources informed our estimates of public health effects of adult use legalization: treatment admission data from the 2011 and 2016 Massachusetts Treatment Episode Data Set (TEDS)²⁴ and the Massachusetts Budget and Policy Center, data on suicides from the 2015 Centers for Disease Control and Prevention National Vital Statistics System statistics on Massachusetts, traffic fatality statistics from the 2015 Fatality Analysis Reporting System (which were compiled by the MBHS Task 2 team), and 2016 data on the number of opioid-related deaths from MDPH.

To translate estimates from other states to Massachusetts, we used data from the U.S. Census microdata (Ruggles, Genadek, Goeken, Grover, & Sobek, 2017) and the 2015 American Community Survey 5-Year Estimates (United States Census Bureau, 2015) on Massachusetts population size and demographics.

MBHS Task 1 Survey

We analyzed data from the Massachusetts general population adult survey, administered as part of MBHS Task 1 by the University of Massachusetts' Donahue Institute, to obtain estimates of the prevalence of marijuana use, the number of regular versus heavy users of marijuana, and use by mode of consumption. All estimates were based on weighted frequencies that were generated using SAS PROC SURVEYSELECT (SAS version 9.4).

Our estimate of prevalence of current marijuana use came from a question on use of marijuana or hashish at least once within the past 30 days. We calculated the prevalence of use statewide (based on all individuals surveyed) and combined this information with data on the prevalence of use obtained from the NSDUH and BRFSS surveys to obtain a range of plausible values that fed into our models. We also estimated the number of regular versus heavy users of marijuana in Massachusetts based on definitions in the literature that rely on the number of days of marijuana use in

²³ <http://apps.leg.wa.gov/wac/default.aspx?cite=314-55-525>.

²⁴

https://www.samhsa.gov/data/sites/default/files/TEDS2011St_Web/TEDS2011St_Web/TEDS2011St_Web.pdf (Tables 2.1 and 2.2) and <https://www.dasis.samhsa.gov/webt/quicklink/MA16.htm>.

the past month (Kilmer et al., 2013). We calculated the number of individuals surveyed who used marijuana between 1 and 20 days in the past month (defined as regular users) and how many used marijuana 21 days or more in the past month (defined as heavy users). Finally, we examined modes of consumption and found that the clear majority of users (95%) consume marijuana as a dried flower product (by smoking or vaporization)—either alone or in combination with other modes of consumption (such as by eating it, dabbing it, or applying it topically or sublingually). We therefore based our pricing of marijuana on price per gram of dried flower product.

In addition, we estimated prevalence of marijuana use at the city or town level using data collected in the MBHS Task 1 survey by respondents' five-digit ZIP code. Because ZIP codes tend to span multiple cities, we used a two-part approach to allocate respondents to a single city or town, based on MassGIS data on city and town boundaries.²⁵ (1) we associated each ZIP code to the city or town that contained the majority of the ZIP code boundary, and (2) if no city contained the majority of the ZIP code boundary, we used the town or city that contained the geographic center of the ZIP code. We then calculated the prevalence of current marijuana use in each city or town for cities and towns with at least 15 MBHS Task 1 survey respondents (to ensure we had sufficient data to produce a valid estimate); for the remaining municipalities, we estimated the prevalence by averaging the current marijuana use prevalence estimates from the national NSDUH and Massachusetts-specific BRFSS surveys.

Statistical Modeling

Our model estimates the fiscal impacts of shifting from a medical marijuana to a broader adult use program within the first two years after retail sales begin. We also include start-up costs and revenue. Our modeling consists of three models:

- (1) A *main* model, which includes primary measures that we hypothesize are major drivers of economic impacts to the state and for which there is strong evidence to inform estimates: sales tax revenue, regulatory oversight costs and revenue, and reductions in marijuana-related law enforcement activities
- (2) A *supplemental* model, which adds secondary impacts on public health, public safety, and income tax revenue for which the evidence is less definitive or immediate than those domains included in the main model
- (3) A *local* model, which estimates local tax revenue for each city or town in Massachusetts (assuming the maximum local tax rate of 3%)

We first calculated measure-specific revenue or savings and measure-specific costs or losses by multiplying various input estimates (for example, to calculate marijuana sales revenue, we multiplied the estimated number of marijuana users by the average grams of marijuana used per day by the average price per gram of marijuana). To do so, we combined information on pre-legalization baseline measures (such as the number of marijuana users) with estimates of the post-legalization change (such as the percentage

²⁵ <https://docs.digital.mass.gov/dataset/massgis-data/zip-codes-5-digit-here0navteq-0>.

change in the number of marijuana users). We next estimated the precision of our post-legalization estimates, and finally tested the sensitivity of the findings to key assumptions. To calculate the post-legalization fiscal impact of marijuana legalization for metrics in our model, we defined a range of plausible values using information from the literature, stakeholder interviews, secondary data sources, and the MBHS Task 1 survey. We then used Monte Carlo simulation—a method that is useful when there is inherent uncertainty about model inputs—to randomly draw a value from the range for each metric and then use that value to calculate the overall impact estimate. This process of randomly drawing values from the range was repeated 1,000 times, each time resulting in a different value, to generate a probability distribution of values for the impact metric. This simulated distribution was then used to calculate a 95% confidence interval—a low and high range that indicates precision—around the impact estimate. To obtain an overall impact estimate of adult use legalization, we summed together measure-specific (for example, sales tax revenue from marijuana purchases by adults considered heavy users, adults considered regular users, and adolescents) for each domain included in the model.²⁶ In Table 2, we summarize baseline and projected values for each input in our models (see Appendix C Table C.1 for detailed information on the variables and data sources used to construct each measure). In the Limitations section, we indicate the measures we excluded from our model because we lacked sufficient data or causal evidence for their inclusion.

²⁶ Because we produce a distribution of outcome values for each level of impact (measure, domain, and model), the average value for a summed outcome will not exactly equal the sum of the average components that fed into it (for example, the sum of the individual measures used to calculate sales tax revenue does not exactly equal the total impact of the sales tax revenue domain); however, the differences are small.

Table 2. Main and Supplemental Model Input Values

Measure	Baseline	Projected	Difference	(%)
Main model				
Domain: Sales and business tax revenue				
Sales tax revenue from marijuana purchases				
Number of adolescent users age 17 or younger	158,892	158,616	-276	(-0.2%)
Number of regular users age 18 or older ^a	318,797	394,896	76,099	(23.9%)
Number of heavy users age 18 or older ^a	150,436	150,436	0	(0%)
Sales tax revenue from beer	\$72,830,435	\$69,271,226	-\$3,559,209	(-4.9%)
Business income tax revenue from dispensaries	0	\$40,501,857	\$40,501,85	(n.a.)
			7	
Domain: Regulatory oversight				
Costs over two years	\$41,927,099	\$43,706,042	\$1,778,944	(4.2%)
Revenue over two years	\$112,728,59	\$114,914,00		
	9	6	\$2,185,407	(1.9%)
Domain: Law enforcement				
Marijuana related				
Arrests	240	84	-156	(-65%)
Convictions	159	57	-102	(-63.9%)
Incarcerations	40	14	-26	(-65%)
Parolees and probationers	122	43	-79	(-64.8%)
Averted mortality due to traffic fatalities ^b	306	274	-32	(-10.6%)
Employee training on cannabis impaired driving	\$0	\$655,000	\$655,000	(n.a.)
Supplemental model				
Domain: Public health				
MassHealth prescription drug expenditures	\$459,769,13	\$452,684,07		
	5	3	-\$7,085,063	(-1.5%)
Substance abuse treatment admissions				
Cannabis	2,840	3,387	547	(19.2%)
Opioid	3,956	3,498	-458	(-11.6%)
Averted mortality ^b				
Opioid-related deaths	1,990	1,633	-357	(-17.9%)
Suicides, males age 20-29	76	67	-9	(-11.2%)
Suicides, males age 30-39	77	68	-9	(-11.2%)
Worker productivity				
Full-time equivalent dispensary jobs	110	617	507	(461.0%)
Hourly earnings, males age 20-29	\$15.60	\$15.21	0	(-2.5%)
Females age 50+ with a qualifying medical marijuana condition, employed full time	90,584	99,093	8,509	(9.4%)
Males age 50+ with a qualifying medical marijuana condition, hours worked/week	41.7	43.8	2	(5%)

Sources: Mathematica's analysis of impacts of legalized adult use of marijuana in Massachusetts using estimates from the literature, key stakeholder interviews, and primary and secondary data sources. See Appendix C Table C.1 for data sources used to inform these estimates.

Note: Baseline values are for Massachusetts fiscal year 2018 (before retail sales begin), while projected value are for fiscal year 2020 (the second year of retail sales).

^a Regular users are those who consume marijuana between 1 and 20 days per month; heavy users are those who consume marijuana 21 or more days per month (Kilmer et al., 2013).

^b These numbers are also used to estimate income tax revenue from averted mortality in the supplemental model.

n.a. = not applicable.

Sensitivity Analyses for State-Level Models

We conducted two analyses to examine the sensitivity of our results. The first involves the number of current marijuana users in Massachusetts. In our primary analysis, we used the NSDUH and BRFSS population surveys to establish a range (8.6% to 12.1%) for the prevalence of current marijuana use in Massachusetts. In a sensitivity analysis, we expanded the high end of the range to 20.1%, based on the MBHS Task 1 survey estimate. It is unclear why the estimate of use prevalence was substantially higher in the MBHS Task 1 survey than in existing population surveys. On the one hand, because the NSDUH and BRFSS surveys were conducted prior to adult use legalization, they may have underreported marijuana use, which is a recognized problem in surveys targeting illegal substance use (Harrison, Martin, Enev, & Harrington, 2007). Because the MBHS Task 1 survey was conducted after the referendum to legalize retail marijuana was passed in Massachusetts, it may have captured more honest reporting that captures true Massachusetts-specific consumption patterns. However, it should be noted that the rate of consumption reported in Colorado in the 2014–2015 NSDUH—which was conducted after legalization—was still only 17%. On the other hand, because the MBHS Task 1 survey response rate was low (roughly 20% of individuals who were mailed a survey completed the survey), it is not clear how representative MBHS Task 1 survey estimates are of the general adult population in Massachusetts and whether self-reporting bias affected the estimates obtained. In our sensitivity check, we examined what effect using the MBHS Task 1 survey consumption estimate as the high end of the range had on our overall impact estimate.

In our second sensitivity analysis, we set all impacts based on the medical marijuana literature to zero, given the possibility that these impacts might have already been realized when Massachusetts implemented the medical marijuana program. In our primary analysis, we assume that the expansion from the medical marijuana to the adult use of marijuana regime will generate similar impacts as the expansion from no legalization to the medical marijuana regime. However, while far from conclusive, the limited evidence of the impacts from the expansion from medical to retail legalization are small or statistically insignificant (Dills, Goffard, & Miron, 2016, 2017). In this sensitivity analysis, we take the conservative view that there are no behavioral impacts generated from the shift from the medical to adult use regimes beyond consumers switching from the black market to legal retail market. In other words, we do not anticipate any impacts of adult use legalization on the likelihood or frequency of marijuana consumption, nor do we anticipate any impacts on public health outcomes explored in the supplemental model, such as alcohol or opioid consumption, or economic impacts from increased labor force participation of older adults. The results from this sensitivity analysis can therefore serve as a lower bound of the expected fiscal impact of marijuana legalization in Massachusetts.

Local Analyses

To estimate fiscal impacts to local governments, we projected the revenue that cities and towns would collect from local taxes imposed on retail marijuana sales during the

first two years of adult use legalization. Unlike our main model, the local model does not factor in costs associated with adult use legalization (such as increased training and law enforcement costs that are anticipated at the local level) because of the high level of uncertainty associated with these costs, coupled with a lack of local-level data to inform such estimates. To estimate revenue, we assumed a local tax rate of 3% (the maximum local tax) in all cities and towns with an RMD expected to open within the first two years of retail marijuana sales. We applied this rate to the projected number of marijuana purchases, calculated using the prevalence of current marijuana use assumed in our state-level models (defined to range from 8.6% to 12.1%, based on the NSDUH and BRFSS surveys), which was assumed to be consistent across all cities and towns. In a sensitivity analysis, we used local-level prevalence estimates that were informed by the MBHS Task 1 survey for cities and towns with at least 15 individuals surveyed. We assumed that marijuana users in cities and towns without a projected RMD would purchase marijuana from the nearest city or town with an RMD. Based on the locations of RMDs expected to open within the two-year study period, we expect that individuals in the majority of cities and towns (n = 337) will reside within 10 miles of an open RMD and that all individuals in Massachusetts will reside within 20 miles of an RMD. Finally, in the primary local analysis, we assumed that 50% to 80% of marijuana users would shift from purchasing their marijuana in the illicit market to purchasing from RMDs, based on information from the Washington State Institute of Public Policy (WSIPP) and a stakeholder interview. In a sensitivity analyses, we set the shift to 50% and 80% to examine the effect on the results.

Results

Main Model Impacts

Our main model included changes in the following primary measures: sales tax revenue (from marijuana purchases among adults with regular and heavy use and among adolescents using marijuana purchased from RMDs); business income tax revenue from RMDs (which we estimated by applying an 8% business tax rate to our estimate of gross revenue, excluding business-related expenses); regulatory costs and revenue; and marijuana-related law enforcement activities (related to decreases in arrests, convictions, incarcerations, and parolees/probationers). Based on our main model, we estimate that marijuana legalization will result in a net two-year fiscal contribution of \$215.8 million (Figure 1 and Table 3). The majority of this gain (70%, amounting to \$150.3 million) will come from sales tax revenue, followed by RMD business tax revenue (28%, amounting to \$60.1 million); about 2% will come from savings due to reduced law enforcement needs to police illegal marijuana use; and less than 1% will come from regulatory revenue—largely because we estimate that Massachusetts will spend about the same amount to regulate marijuana sales and production (\$1.8 million) as it will receive in application fees and violation fines from marijuana dispensaries (\$2.2 million). Based on the probability distribution generate from the Monte Carlo simulation, we estimate a 95% confidence interval of \$95.7 to \$405.9 million around our main model impact estimate.

Sales tax revenue was driven largely by marijuana purchases anticipated by adults categorized as heavy users (we estimate these consumers are responsible for \$89.8 million of the \$150.3 million expected in new sales tax revenue). Additional sales tax revenue comes from: adults categorized as regular marijuana users (\$23.3 million); adolescents who consume marijuana that was purchased by adults from RMDs (\$14.6 million); tourist purchases (\$14.4 million), which we assumed would comprise between 7% and 12% of total tax revenue, based on estimates from Light et al. (2016) and Cooper et al. (2016); and new adult users (\$7.7 million), whose use of marijuana begins after the commencement of retail sales. As a result of retail marijuana sales, we also forecast a \$3.6 million reduction in sales tax revenue from beer sales over the study period. The majority of law enforcement savings are realized through reductions in law enforcement costs related to vehicular crashes that result in fatalities (\$3.8 million) and in the number of marijuana-related incarcerations (\$1.4 million).

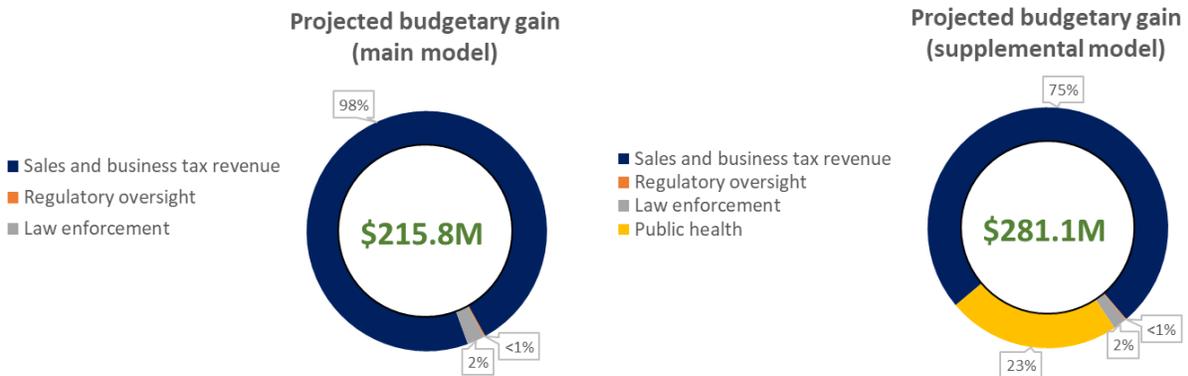

Supplemental Model Impacts

Our supplemental model included changes in the following health-related measures estimated with less certainty: income tax revenue (mainly as a result of increases in worker productivity among adults age 50 or over, coupled with extra years of life due to averted mortality), decreased MassHealth spending on prescription drugs replaced with marijuana, decreased spending on opioid addiction treatment, increased spending on cannabis addiction treatment, and state-level savings due to averted deaths. With respect to averted deaths, the evidence from the medical marijuana literature suggests a decrease in traffic fatalities (Anderson, Hansen, & Rees, 2013; Santaella-Tenorio, Mauro, Wall, Kim, & Martins, 2017), which would decrease legal costs to the state, along with a decrease in suicides among males ages 20 to 39 (Anderson, Rees, & Sabia, 2014), which would decrease state spending on related medical costs. Adding these measures to our main model increased our projected budgetary gain by \$65.3 million, and yielded a total impact estimate of \$281.1 million (Table 3). Across all domains, estimated changes in sales and business tax revenue represent approximately 75% of all economic and fiscal impacts, while revenue and savings as a result of public health effects account for an additional 23%; regulatory oversight and law enforcement fiscal impacts together constitute less than 5% of estimated impacts. The 95% confidence interval around the secondary model impact estimate was \$98.4 million to \$528.3 million.

When we examine projected revenue or savings (without factoring in projected costs or losses), the single largest contributor is sales tax revenue for marijuana purchases at RMDs by heavy adult users, followed by marijuana-related business income tax revenue (Appendix C Figure C.1). We also estimate substantial income tax revenue from gains in worker productivity (\$54.4 million). In particular, we project growth in hours worked among men over age 50 (\$46.7 million) and in full-time employment among women over age 50 (\$20.9 million) who have a debilitating medical condition (such as chronic back pain or depression) that is well-controlled with marijuana. Retail marijuana legalization is estimated to reduce mortality from suicides, vehicular crashes, and opioid-related deaths; together, these could increase income tax revenue by \$1.1 million and reduce state public health spending by \$0.7 million.

When we look at costs or losses (data not shown), we project that a reduction in average hourly earnings as a result of marijuana addiction or dependence will reduce state income tax revenue by \$12.5 million. We also estimate a loss of \$3.6 million in alcohol sales taxes because of substitution effects (whereby individuals purchase marijuana in lieu of alcohol). The estimated impact on state spending for substance abuse treatment is minimal, composed of reduced spending on opioid addiction treatment (\$1.0 million) that is offset by increased spending on cannabis addiction treatment (\$1.1 million).

Figure 1. Estimated Two-Year Impacts of Legalizing Adult Use of Marijuana

Sources: Mathematica’s analysis of impacts of legalized adult use of marijuana in Massachusetts using estimates from the literature, key stakeholder interviews, and primary and secondary data sources. See Appendix C Table C.1 for data sources used to inform these estimates.

Note: Each model sums the estimated changes in revenue or savings and the estimated costs or losses associated with the domains in the legend. Changes were projected within the first two years of retail sales, and include start-up costs associated with migrating from a medical marijuana program to a broader adult use marijuana program. Percentages sum to more than 100% due to rounding.

Table 3. Estimated Two-Year Impacts by Model and Domain

Model	Estimated net gain in revenue	Range (95% confidence interval)
Main model	\$215,750,686	\$95,740,066 –
Sales and business tax	\$210,431,454	
Sales tax revenue	\$150,308,182	
Business income tax	\$60,123,273	
Law enforcement	\$5,055,969	
Regulatory oversight	\$406,463	
Supplemental model	\$281,054,592	\$98,400,908 –
Public health	\$65,303,906	\$2,660,843 – \$122,382,655
Individual income tax	\$57,400,988	
State spending on	\$7,764,492	

Sources: Mathematica’s analysis of impacts of legalized adult use of marijuana in Massachusetts using estimates from the literature, key stakeholder interviews, and primary and secondary data sources. See Appendix C Table C.1 for data sources used to inform these estimates.

Note: The sum across domains may not equal the overall estimate because of random variation in the simulations. The range is based on the 95% confidence interval around the model estimate.

Sensitivity of Impacts

In our first sensitivity analysis, in which we increased the upper end of the range of plausible values for prevalence of current marijuana use to include the MBHS Task 1 survey estimate, our main model impact estimate increased by 38% (from \$215.8 million to \$298.8 million), and our supplemental model estimate increased by 29% (from \$281.1 million to \$364.1 million). In our second sensitivity analysis, in which we adjusted all impacts derived from the medical marijuana literature to zero, our main model estimate decreased by only 8% (to \$143.9 million), but our supplemental model estimate (which included a number of public health measures informed by the medical marijuana literature) decreased by 28% (to \$201.4 million).

Local Impacts

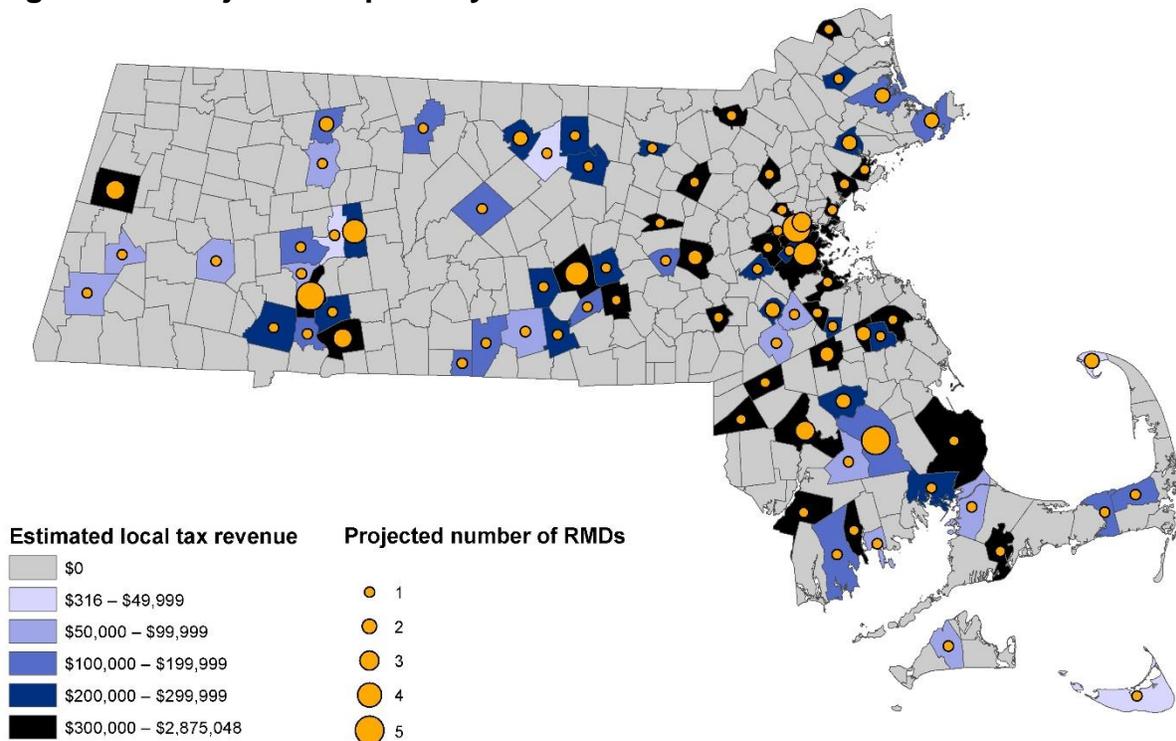

In Figure 2, we show our estimated two-year local tax revenue, assuming a 3% local tax rate, along with information on the projected number of RMDs expected per city or town. With some exceptions, local tax revenue is generally higher on the coast and lower in the western part of the state. In Table 4, we summarize estimated local tax revenue by city or town density, defined using the methodology of Pozzi and Small (2005) as rural (≤ 100 people/km²); suburban low, medium, and high density (100–500 people/km², 500–1,000 people/km², and 1,000–10,000 people/km², respectively); and urban ($> 10,000$ people/km²). As expected, revenue is highest in dense regions, though there is considerable fluctuation in tax revenue projections among the 51 high-density suburban cities and towns (see Appendix C Table C.3 for detailed results). Both sets of results are

restricted to the 83 cities and towns in which an RMD is expected to be open within the first two years of retail marijuana sales.

In Appendix C Figure C.2, Table C.2, and Table C.3, we show how local revenue estimates would change if RMDs were open in all cities and towns across Massachusetts, such that marijuana users would no longer travel to nearby cities or towns to purchase marijuana. For some of the 83 cities and towns included in the primary analysis—particularly those that will be more isolated from other RMDs in the state—local tax revenue estimates dropped dramatically (for example, from about \$992,000 in Burlington to about \$108,000).

In the sensitivity analysis in which we used local-level marijuana use prevalence estimates that were informed by the MBHS Task 1 survey (which were available mostly for urban and high-density suburban cities and towns), our estimate of local tax revenue increased by 215% for urban cities (to almost \$1.3 million) and by 20% for high-density suburban cities (to about \$288,000). And in the sensitivity analysis in which we specified that the percentage shift in marijuana purchases from the illicit market to RMDs would be exactly 50% or 80% (instead of 65%, which we derived for the primary analysis based on the range of 50% to 80%), our median revenue estimates decreased and increased, respectively, by 18% for all density categories.

Figure 2. Estimated Two-Year Local Tax Revenue by City or Town with a Registered Marijuana Dispensary

Sources: Mathematica’s analysis of impacts of legalized adult use of marijuana in Massachusetts using estimates from the literature, key stakeholder interviews, and primary and secondary data sources. See Appendix C Table C.1 for data sources used to inform these estimates.

Note: The figure includes estimates only for cities and towns in which a marijuana dispensary is projected to be open within the first two years of marijuana retail sales; no rural areas (< 100 people/km²) are expected to have open dispensaries. Appendix C Table C.2 provides estimates assuming RMDs are open in all Massachusetts cities and towns within the first two years of legalization. See Appendix C Table C.3 for estimates by city or town.

Table 4. Estimated Two-Year Local Tax Revenue by Density Category

City or Town Type	Number of Cities or Towns	Two-Year Local Tax Revenue		
		Median	Minimum	Maximum
Suburban, low density (100–500	6	\$72,835	\$60,801	\$144,385
Suburban, medium density (501–	10	\$63,272	\$20,872	\$170,209
Suburban, high density (1,001–10,000	51	\$243,144	\$68,139	\$991,873

Sources: Mathematica’s analysis of impacts of legalized adult use of marijuana in Massachusetts using estimates from the literature, key stakeholder interviews, and primary and secondary data sources. See Appendix C Table C.1 for data sources used to inform these estimates.

Note: The table includes only cities and towns in which a marijuana dispensary is projected to be open within the first two years of marijuana retail sales; no rural areas (< 100 people/km²) are expected to have open dispensaries. Appendix C Table C.2 provides estimates assuming RMDs are open in all Massachusetts cities and towns within the first two years of legalization. See Appendix C Table C.3 for estimates by city or town.

Discussion

We estimate that the legalization of adult use of marijuana will result in an increase of approximately \$215.8 million to the Massachusetts state budget over the first two years of retail sales, largely as a result of sales and excise taxes collected on retail marijuana purchases. Although our model includes fiscal impacts of legalization due to a number of domains, most are miniscule compared to increases expected from sales and business tax revenue. The increase will largely be a result of retail purchases made by adults with heavy use—defined as consuming marijuana an average of 21 days or more each month. New business income tax revenue from marijuana dispensaries will also be a major contributor, as will increases in income tax revenue (primarily due to increased worker productivity among adults over age 50 who are able to control debilitating medical ailments with marijuana). When we included measures calculated with less certainty (because of either a lack of data or an uncertain time frame within which impacts could occur), we estimate that the state may see an additional \$65.3 million added to its budget. This increase would mainly come from added individual income tax revenue from worker productivity gains in older adults able to control serious ailments with marijuana.

Our estimate of tax revenue is heavily influenced by assumptions about the number of current marijuana users in Massachusetts. Because previous population surveys (used to inform our main model estimates) yielded a lower estimate of prevalence of use than the MBHS Task 1 survey, our main model estimate may be conservative. However, because we assumed that changes seen when moving from medical marijuana sales to retail marijuana sales could be as high as moving from no legal marijuana sales to medical marijuana sales, our fiscal estimates could also be somewhat higher than may be realized.

A strength of our analytic approach is that the Monte Carlo simulation factors the uncertainty of inputs into the model estimates; that is, we were able to incorporate plausible ranges of values for inputs to not overstate their certainty. The combination of uncertain inputs leads to substantial uncertainty in the estimated impact of adult use legalization on the state budget, as indicated by the wide confidence interval around the estimate. As more studies are published on the impacts of adult use legalization, the ranges of estimates from the literature will be better defined and our impact estimates will become more precise.

The results of our model should be interpreted in the context of Massachusetts-specific information, such as the proposed regulatory framework, tax regime, and existing medical marijuana program. Below, we provide additional details on the assumptions and implications of our approach with respect to the four domains included in our analysis: sales tax revenue, regulatory oversight, law enforcement, and public health. We also compare how our estimate of the fiscal impact of adult use of marijuana legalization compares with previous impact estimates (generated from the Massachusetts Department of Revenue [DOR] and in other states with legalized use) and discuss limitations of our approach.

Sales Tax Revenue

We project fiscal impacts within a two-year window starting at the commencement of retail marijuana sales, but it is important to note that the revenue generated is heavily weighted toward the tail end of the two-year period. Indeed, in other states that have implemented retail marijuana sales for at least two years (Colorado, Washington, and Oregon), 66% to 77% of sales tax revenue collected within the first two years was generated in the second year (Colorado DOR, 2018; Oregon DOR, n.d.; Washington State LCB, n.d.), and the data suggest that sales tax revenues are likely to increase substantially after consumers, suppliers, and regulators adjust to the new regime.²⁷ Based on data from these states, we assumed that about 70% of the two-year estimate of sales tax revenue would be collected from Massachusetts RMDs in the second year of sales. This translates to an estimated \$61.6 million collected in the first year and

²⁷ Alaska collected less tax revenue from legal marijuana in its second year of sales than in its first. However, Alaska differs from other states that have legalized marijuana—including Massachusetts—in many respects, including the fact that they tax marijuana by plant weight, rather than through a tax rate applied to retail sales (<http://tax.alaska.gov/programs/programs/reports/Annual.aspx?60000&Year=2017>). Therefore, we excluded Alaska when reviewing the experiences of states that allow marijuana sales.

\$154.2 million in the second year of retail sales. It is important to note we cannot claim with certainty that spending on marijuana represents new spending rather than a shift from other recreational options like spending on alcohol. Similarly, income tax revenue from new dispensary jobs may represent transfers from other industries. As a result, it is possible that some amount of tax revenue generated by legalization may be offset by a reduction in tax revenue elsewhere.

Our methodology for estimating change in tax revenue attributable to marijuana legalization differs from other models in two major respects. First, we did not factor in changes in the price of marijuana over time because it is particularly difficult to know the rate at which prices will change within the first two years of legalization (Hunt & Pacula, 2017). Instead, we estimated a single, average price of marijuana during the study period based on crowd-sourced data and data from RMDs. We also did not link marijuana prices to sales volumes—that is, examine the price elasticity of demand—because doing so compounds this uncertainty.²⁸ Instead, we estimated changes in demand using marijuana use quantities derived from the literature and MBHS Task 1 survey results, coupled with changes in use behavior derived from the growing body of evidence from states that have legalized marijuana use.

Second, we did not account for expected increases in revenue related to the establishment and growth of the broader marijuana industry. Several previous studies attempted to quantify these macroeconomic impacts, with mixed results; one study concluded that previous analyses underestimate or overestimate impacts by up to 300% (Light, Orens, Rowberry, & Saloga, 2016). However, it is likely that the development of a novel industry will generate some amount of tax revenues from businesses that grow, manufacture, or test marijuana and stimulate growth among traditional businesses that supply or interact with this new market.

Our model also assumed a steady growth rate in medical marijuana patients (based on current growth trajectories) that would be unchanged after retail sales begin. Because medical marijuana is untaxed in Massachusetts, it may be more attractive to new marijuana consumers once retail sales begin. Accordingly, it is possible that the initiation of retail sales could actually increase the rate of growth in medical marijuana use. However, we did not model this scenario.

Whenever possible, we benchmarked our estimates against other sources. For example, we found that the median price per gram of dried flower marijuana (\$13.70) based on crowdsourced data for Massachusetts was nearly identical to the median price per gram sold by RMDs for medical use (\$13.30). Also, based on stakeholder interviews, we estimated that the price of marijuana during the two-year study period will be roughly 75% of the current price. The prices also align with data from other sources, which suggest that post-legalization prices in other states have fallen roughly 20% per year (Committee on Foreign Affairs and International Trade, 2018). Finally, data on

²⁸ This approach is similar to the one used by Cooper, Johnston, & Segal (2016) to model the economic impact of marijuana sales in California.

marijuana use frequency from the MBHS Task 1 survey align with data from the 2015–2016 NSDUH survey of Massachusetts residents in that both suggest that approximately two-thirds of current marijuana users are “regular” users based on their use frequency being between 1 and 20 days per month, and the remaining one-third are “heavy” users based on a use frequency of 21 or more days per month. The sources also indicate that regular users average 7 use days per month, and heavy users average approximately 29 use days per month.

Estimates of the average amount of marijuana consumed per day of use among current marijuana users were inconsistent between the MBHS Task 1 survey and the literature. To estimate dollars spent per day of marijuana use, we derived dollars spent in the past month on the average number of days marijuana was used in the past month—both of which were estimated using the MBHS Task 1 survey. We then divided this by the average price per gram of marijuana to estimate the average number of grams used per day. Our calculations yielded an average daily use of: 0.17 grams consumed by regular users and 0.32 grams consumed by heavy users. By contrast, estimates from Kilmer et al. (2013) were much higher: 0.67 grams and 1.6 grams, respectively. One explanation for the difference is that marijuana potency may have increased between 2013 and 2017, such that consuming fewer grams now achieves the same effect as in 2013. Another possibility is that our estimate of the price per gram of marijuana was inaccurate. Our estimate combines information on black market and RMD pricing. If MBHS Task 1 survey respondents paid less per gram than we estimated, this would then result in higher estimates that may be more in line with Kilmer et al. (2013). To account for the uncertainty in average marijuana grams consumed each day of use, we varied the model estimate for use between the MBHS Task 1 survey estimate and the estimate from Kilmer et al. (2013).

Regulatory Oversight

Our model suggests that within the first two years of retail sales, the cost of regulatory oversight will be offset by revenue generated from application fees and fines collected by the CCC. However, our analyses of regulatory costs incurred by other states that have legalized retail sales show a great deal of variability in the cost of regulating marijuana, even after accounting for differences in population size and number of RMDs. In Washington (which has approximately 100 marijuana dispensaries²⁹), we estimated total regulatory costs to be \$52,638 per dispensary per year, whereas in Colorado (which has approximately 371 marijuana dispensaries³⁰), the corresponding estimate was \$31,945. There are, however, notable differences in regulatory operations between states. For example, following legalization of adult use of marijuana in Washington in 2012, the state did not create a new regulatory agency but rather incorporated cannabis regulation under the state’s LCB. Given that Massachusetts will have a separate regulatory body—the CCC—rather than incorporating cannabis regulation under the state’s LCB, Massachusetts may incur additional costs not included

²⁹ Based on data from <https://www.marijuanadoctors.com/medical-marijuana-dispensaries/WA>.

³⁰ Based on data from <https://www.colorado.gov/pacific/enforcement/med-licensed-facilities>.

in the estimates from Washington. Additionally, at the time of legalizing retail marijuana, Washington did not have a robust medical marijuana law or medical dispensaries prior to the legalization of adult use of marijuana (even though medical marijuana had been legal in Washington since 1998).³¹ Medical marijuana became more formally regulated in Washington in 2015, requiring a second wave of regulatory work to incorporate medical use under the LCB.

Data from Washington show that 55% of regulatory costs incurred within the first two years of legalization were associated with rulemaking, licensure, and enforcement; spending on health and social service programs accounting for another 38% of costs. In Washington, these costs totaled \$105,250 per year after start-up, whereas in Colorado, the cost ranged from \$164,634 to \$172,031 per year. In our model, we considered as regulatory costs any recurring law enforcement activities at the state and local level, including employee blood testing for individuals suspected of driving under the influence as well as administrative, legal, and judicial costs associated with suspended or revoked licenses. We estimated these costs by translating the range of estimates from Washington and Colorado to Massachusetts on a per capita basis.

Because of a lack of data, we did not attempt to factor regulatory costs at the local level into our model. We learned through a stakeholder interview that local governments in Washington struggled to keep up with ongoing regulatory changes, which required several staff dedicated to monitoring these changes. Although local governments initially absorbed start-up costs required to regulate businesses locally, eventually the fees they collected on licenses ended up covering the costs of regulating businesses locally. Based on information from the CCC,³² we anticipate that the Marijuana Regulation Fund that the CCC establishes could cover much of the costs of education and prevention as well as municipal police training. The expert we interviewed also indicated that the main factor differentiating local regulatory costs in Washington, from one city to another, is whether the city focuses on marijuana production or on retail sales. For producers (which are largely located in rural areas), primary costs involve odor and environmental issues surrounding waste disposal and wastewater. For retailers (which are more concentrated in urban areas), age compliance and traceability have been major sources of concern that have added costs. Also, rural towns—which were more likely to ban marijuana retail sales—incurred costs associated with lawsuits by businesses wanting to open an RMD.

Law Enforcement

Our modest projected reductions of law enforcement costs reflect a two-thirds decrease in marijuana arrests in the years preceding legalization of retail sales.³³ Because few

³¹ <https://www.doh.wa.gov/YouandYourFamily/Marijuana/MedicalMarijuana/LawsandRules/HistoryinWashington>.

³² <https://malegislature.gov/Laws/GeneralLaws/PartI/TitleXV/Chapter94G/Section14>.

³³ According to data supplied to the authors by the Massachusetts Department of Corrections, the number of cases charged with a marijuana governing offense declined from 975 in 2010 to 336 in 2014.

people currently enter the criminal justice system for marijuana offenses, further decreases in incarcerations will have little effect on statewide expenditures. However, this estimate is subject to a few limitations. First, it is difficult to obtain reliable data on individuals charged with marijuana offenses who are also charged with other, more serious crimes. It is possible that sentence lengths assigned to this group will be reduced when marijuana sales are legally permitted, further reducing costs. Second, some law enforcement officials in Massachusetts and elsewhere are skeptical of findings that marijuana legalization reduces vehicular crashes and express concern about increases in the incidence of driving under the influence of marijuana (Migoya, 2017; stakeholder interview). If these concerns are borne out, traffic fatalities will represent an increase rather than a decrease in expenditures. Also, there may be other benefits that manifest from reducing the proportion of the population incarcerated for marijuana-related crimes. However, such benefits are challenging to quantify, given a lack of evidence, and they may take longer than two years to be realized.

With respect to impaired driving, our model included an estimated decrease in motor vehicle fatalities attributed to adult use of marijuana legalization. There is some evidence of increases in THC blood concentrations among drivers after adult use legalization that could also contribute to increases in non-fatal motor vehicle crashes. For example, a report from Washington that analyzed trends over time before and after adult use of marijuana legalization found that the proportion of drivers testing positive for THC was fairly constant before and immediately after adult use legalization took effect, but that beginning approximately 9 months after adult use legalization took effect, the proportion began to increase substantially at a rate of 9.7% per year (Tefft, Arnold, & Grabowski, 2016). In addition, the law enforcement communities in Colorado and Washington have expressed anecdotal concerns that marijuana is increasing both fatal- and non-fatal motor vehicle crashes (Migoya, 2017). Because these studies did not meet our causal evidence guidelines, we did not include estimates from them in our model.

Finally, although our model factored in a start-up cost of \$655,000 in Massachusetts (based on stakeholder input) for Drug Recognition Expert and Advanced Roadside Impaired Driving Enforcement officer training, data from Washington indicate that the costs could be much higher. The Washington State Patrol spent \$2.1 million on employee training on cannabis impaired driving, which accounts for 77% of the increase in law enforcement costs attributed to marijuana legalization within the first five years. Additional costs may be incurred for driving campaigns and other public safety messaging.

Public Health

Our supplemental model added projected fiscal impacts due to public health impacts of legalizing adult use of marijuana. We estimate that revenue and savings related to public health impacts will account for about 23% of the total budgetary gains projected because of legalization, based on our supplemental model. The added budgetary gain in our supplemental model mainly comes from projected increases in worker

productivity (which would generate increases in individual income tax revenue) among older adults with debilitating medical conditions that are well controlled with marijuana (Nicholas & Maclean, 2016). We assumed that these productivity gains would be fully realized within the first two years of retail sales; if they span longer than two years, model estimates would need to be proportionally reduced. We also suspect that some of the productivity gains projected may have already been realized by the medical marijuana population. However, when we adjusted the population to which we applied the impact estimate (by subtracting out older medical marijuana patients, based on data from MDPH), our impact estimate decreased by only 8% for older women and 4% for older men.

Other public health savings (for example, due to reduced spending by the state on the MassHealth program to cover prescription drugs for fee-for-service beneficiaries) are expected to account for only 3% of the supplemental model estimate. Decreases in Medicaid prescription drug spending, estimated by Bradford and Bradford (2017), were based on treatment for medical conditions that medical marijuana is used to treat, including depression and psychosis. That is, we project that some individuals will use marijuana in lieu of prescription medications to treat these conditions. Because of a lack of information on how spending might change because of marijuana legalization, our model did not account for changes in spending associated with inpatient, outpatient, or emergency treatment—it was limited to prescription spending alone. It is also important to note that our model projects impacts only out to two years, and that the health effects associated with marijuana use could have a much longer latency, possibly taking decades before the full extent of benefits or harms would be seen.

Projected savings of roughly \$980,000 due to decreases in opioid addiction treatment were offset by projected spending amounting to \$1.1 million due to increases in cannabis addiction treatment. For both sets of costs, we focused only on the costs of treatment admissions incurred by the state. However, many individuals with drug addiction or dependence do not seek treatment; instead, costs incurred by the state government for these individuals may be related to costs associated with overdoses and emergency room visits. Because of a lack of data, we did not incorporate non-treatment costs related to addiction/dependence in our model. Likewise, when we factored in the measure related to reductions in opioid-related deaths into our model, we only accounted for increases in income tax revenue. We did not account for reductions in other costs that may be incurred for opioid-related deaths, such as the cost of ambulatory treatment (which is covered by MassHealth) or mortuary costs (which are expected to be relatively small, given a \$1,500 cap on MassHealth coverage for these costs).

In our model, expected decreases in suicides among males age 20 to 39 accounted for less than 1% of expected public health savings. Although there have been anecdotal concerns that legalization of adult use of marijuana has led to an increase in suicides in Colorado and Washington, neither the literature nor state-level data we examined reflect this measure. For example, the most recent Colorado Violent Death Reporting System report noted an increase in the suicide rate in 2014 and 2015, although there were no

statistically significant changes observed during this time period (Jamison, Mintz, Herndon, & Bol, 2017). Using data from this report, we calculated the change in suicide rate from the three-year period before legalization (2011–2013) to the two year-period after legalization (2014–2015) and noted a 6.25% increase in suicides over this time period. However, given that the report itself found that these changes were not statistically significant, we did not include them in our model.

Comparison with Previous Estimates

Our model included estimates of sales tax revenue as well as revenues and costs realized in other domains. Although there are no comparable estimates of projected revenues and costs related to business and income tax revenue, public health, and criminal justice costs, we discuss below the differences between our estimates of projected sales tax revenue and estimates from other states and from the DOR for Massachusetts.

Our estimate of taxable retail marijuana sales was \$748.7 million (\$224.6 million in the first year and \$524.1 million in the second). The second year estimate amounts to \$745 per adult user, which is similar to second year estimates from Oregon (\$675) and Washington (\$818) but is substantially lower than the second year estimate for Colorado (\$1,128).³⁴ Differences across the states could be attributed to any or all of the following:

- *Differences in the speed at which the programs are fully implemented.* Because it takes new dispensaries one to two years to be fully operational in Massachusetts, retail marijuana sales may be limited at first, particularly in areas without RMDs. However, the fact that Massachusetts has a well-established medical marijuana program (unlike Washington at the time of retail marijuana legalization) and can learn from the experiences of other states with legalized use could hasten implementation of the adult use program.
- *Differences in tourist sales volumes.* Marijuana purchases by tourists to Colorado may have been substantially higher in the first two years of legalized adult use than they will be in Massachusetts. Colorado was the first state to implement an adult use program, and even now most of its bordering states do not have medical marijuana programs. By contrast, Massachusetts borders two other states that have legalized adult marijuana use (Vermont and Maine), and all its bordering states have medical marijuana programs.

³⁴ For comparability with retail sales estimates in Massachusetts and in Oregon (calculated by dividing revenue estimates from <http://www.oregon.gov/DOR/programs/gov-research/Pages/research-marijuana.aspx> by the 17% tax rate), we converted total sales revenue (which included medical plus retail sales) in Colorado (<https://www.colorado.gov/pacific/revenue/colorado-marijuana-sales-reports>) and Washington (Washington State LCB dashboard, n.d.) to retail sales revenue by subtracting the percentage of revenue due to medical sales, which we assumed would be equal to the percentage of total marijuana users (<https://www.samhsa.gov/data/sites/default/files/NSDUHsaeSpecificStates2016A/NSDUHsaeSpecificStates2016.htm>) that are medical users (<https://www.mpp.org/issues/medical-marijuana/state-by-state-medical-marijuana-laws/medical-marijuana-patient-numbers/>).

- *Differences in tax rates.* The 17% sales plus excise tax rate in Massachusetts is lower than the rate of almost 30% in Colorado, and much lower than the rate of 44% in Washington. As a result, more of the total demand in Massachusetts could be met by RMDs, as opposed to the illicit market, resulting in higher sales volumes per user compared with other states.

Our estimate of projected revenue collected through the maximum 20% tax rate in Massachusetts (assuming a maximum local tax of 3%) is substantially lower than estimates produced by the Massachusetts DOR. We estimate that the state will collect almost \$105 million in tax revenue from \$524 million in sales; the DOR report projects roughly \$205 million in revenue from \$1.1 billion in sales, after adjusting to the increase from a 12% to a 20% tax rate (Joint Committee on Marijuana Policy, 2017).^{35,36} However, the difference is reduced by roughly one-third when we compare the DOR estimate to the estimate from our sensitivity analysis that uses the Task 1 survey's estimate of prevalence of current marijuana use.

The difference between our estimate and the DOR estimate is primarily due to the DOR applying per capita sales estimates from the third year of legalized use in Colorado and Washington (which saw nearly 50% and 70% increases between years two and three, respectively) to the second year of legalization in Massachusetts, believing that Massachusetts will have a shorter implementation period because the state has the benefit of learning from the experiences in Colorado and Washington. If Massachusetts second-year sales approach third-year levels from those other states, our model may underestimate this component of the fiscal impacts of legalization. However, as noted above, the speed at which dispensaries are approved to begin retail sales across the state could limit the extent to which the state is able to ramp up sales. In Massachusetts, we project that the revenue in the second year will more than double the first year's revenue. For comparison, the second year's revenue nearly doubled in Colorado and nearly tripled in Washington compared to the first year.

Limitations

Our models exclude a number of potential impacts of adult use of marijuana legalization that do not have supporting casual evidence to link the impact to marijuana laws and policies. For example, we do not have sufficient information on the impacts of legalization on a number of public health outcomes, including spending related to

³⁵ The Massachusetts DOR estimates \$128 million of tax revenue collected on \$1.07 billion in taxable sales based on a 12% total tax rate (including sales, excise, and local taxes). In a sensitivity analysis, they estimate \$237 million of tax revenue collected on \$1.018 billion in sales assuming a total tax rate of 23.25%. Based on these estimates, we calculate that the DOR estimate would be roughly \$205 million in tax revenue with a total tax rate of 20%.

³⁶ The Massachusetts DOR report cites two reports with estimates that were lower than its own – a Tax Foundation Report (estimating \$747 million in taxable sales based on a 15% tax rate) and a study by the Massachusetts Special Senate Committee on Marijuana (estimating \$500 million in taxable sales) – and a third report with an estimate that was similar to their own (a study by ArcView Market Research estimating \$1.07 billion in taxable sales in 2020).

emergency room or urgent care visits and the prevalence of low birth weight, obesity, tobacco use or nicotine dependence, and non-fatal vehicular crashes. We also did not include changes in spending related to poison control center costs because the changes were estimated to be quite small. It is possible that adult use of marijuana legalization could lead to changes in marijuana consumption that would in turn affect these and other public health outcomes. Finally, we did not factor in potential spending related to increases in energy or water use related to marijuana growth and production. Second, because literature on adult use of marijuana is sparse, our model estimates rely mainly on the medical marijuana literature. That is, we assumed that changes observed when migrating from no legal marijuana to medical marijuana would be similar to changes observed when migrating from medical marijuana to adult use of marijuana. Ideally, causal impacts taken from the literature would reflect the impacts of shifting from a medical marijuana market to a market that includes medical and broader adult use of marijuana. The limited studies on adult use of marijuana legalization have not found statistically significant impacts from the expansion of medical marijuana to broader adult use. However, a recently published study provides additional evidence that supports our strategy to use medical marijuana impact estimates. Powell, Pacula, & Jacobson (2015) found that the relationship between medical marijuana laws and the reduction in opioid deaths is influenced by the type of medical marijuana laws that states implemented. They found that opioid deaths decreased only in states in which marijuana dispensaries were easily available to patients. In Massachusetts, the medical marijuana program is more tightly regulated than in other states, and the state has fewer legal medical marijuana patients per 1,000 people than many other states that have legalized medical marijuana. Moreover, the number of qualifying conditions for medical marijuana use in Massachusetts is fewer than those in other states and does not include chronic pain, which is a qualifying condition in 13 of the states that have legalized medical marijuana (ProcCon, 2017). Therefore, the impact of marijuana legalization in Massachusetts may not be fully realized prior to adult use legalization, and the impact of medical marijuana policies in states with more liberal guidelines may provide insight into the expected impact of adult use legalization in Massachusetts. A third potential limitation of our model is that we assumed that each input metric acts independently of other metrics; therefore, we did not account for the correlations between metrics in our model. It is analytically feasible to incorporate relationships between metrics into the impact estimates, for example, by factoring in the price elasticity of demand to see how marijuana use changes as pricing changes.

Finally, it is not clear whether the impacts projected from our model will sustain beyond the two-year time frame. Most of the impacts in our model can be considered one-time (but not necessarily immediate) shifts as a result of legalization. For example, we may not expect marijuana-related arrests to further decrease beyond the two-year time frame, nor do we expect the start-up costs of establishing the regulatory framework to persist. However, impacts on consumption and associated public health outcomes may take longer to realize because they depend on market prices, the accessibility of dispensaries, and other factors that are associated with a high degree of uncertainty.

Directions for Future Research

The MBHS provides a valuable baseline understanding of the impacts of legalization in Massachusetts and serves as a benchmark to improve the implementation of marijuana legalization in other states. In this report, we synthesize information from a number of sources to provide projections that serve as a reference to compare to the actual experience in Massachusetts as the program unfolds. Such a comparison can be used to better understand the factors driving the fiscal impacts of adult use of marijuana and to project future impacts beyond the first two years of legalization. Our analysis should also help the state and localities anticipate what resources may be needed to roll out the adult use program.

DPH Statewide Survey Tool

Massachusetts Survey of Health and Social Behavior: Marijuana Baseline Health Study

Please have the adult in your household (18 years or older) who is a Massachusetts resident and had the most recent birthday complete this survey. We do not mean the oldest person. We mean the person who had a birthday last. While every question is important to our study, this survey is completely voluntary and you can skip any question.

If you would prefer to complete this survey online, please go to:

<http://TinyURL.com/HealthSurveyMA>

Instructions for Completing the Booklet

This booklet contains several types of questions. Each question should be answered only about yourself, not anyone else in your household.

- For some questions, you answer the question by marking a box, like this (please mark only one box, unless directed otherwise):

Yes
 No

- For some questions, you answer the question by filling in one number per box, like this:

0 9

- You will sometimes be instructed to skip one or more questions. In this example, if your choice is 'No', you skip to question 10; otherwise, you continue to the next question.

Yes
 No → *Go To Question 10*

Thank you for taking the survey. Please check one box for each question unless the directions ask you to do otherwise.

Household Demographics

1. How many adults age 18 years or older live in your household? (Please fill in the number.)

Number of adults

2. How many children under 18 years old live in your household?

Number of children

3. Many people only live in Massachusetts for part of the year. Do you live in Massachusetts for 6 or more months out of the year?

Yes
 No

4. In what year were you born?

Year

5. What is your gender?

Male
 Female
 Other

6. Are you Hispanic or Latino?

Yes
 No

7. Which one or more of the following would you say is your race? (Check all that apply.)

White or Caucasian
 Black or African American
 Asian
 Native Hawaiian or Other Pacific Islander
 Native American or Alaskan Native
 Some other race

Draft

8. What is the highest degree or level of school you have completed?

- Never attended school or only attended kindergarten
- Grades 1 through 8
- Grades 9 through 11
- Regular high school diploma or GED
- Some college credit, but less than one year of college credit
- One or more years of college credit, no degree
- Associate degree
- Bachelor's degree
- Master's degree
- Professional degree beyond a bachelor's degree
- Doctorate degree

9. What is your annual household income from all sources?

- Less than \$15,000
- \$15,000 – \$29,999
- \$30,000 – \$49,999
- \$50,000 – \$99,999
- \$100,000 – \$149,999
- \$150,000 or more

10. What is the zip code where you currently live?

--	--	--	--	--

Zip Code

11. What type of healthcare coverage do you have?

(Check all that apply.)

- Private commercial or group plan (for example, an HMO or PPO through an employer)
- Medicare
- Medicaid
- Commonwealth Care Program (Health Connector)
- Indian Health Services
- Veterans Affairs (VA)
- No Health Insurance
- Other plan

12. Do you own the place where you currently live, pay rent, or something else?

- Own
- Rent
- Something else

Opinion

In 2016, Massachusetts voters legalized marijuana for recreational use. We are trying to understand how this change may affect the attitudes and behaviors of Massachusetts residents.

13. Do you believe that marijuana should be legal for recreational use in Massachusetts?

- Yes
- No

14. How much do you think people risk harming themselves (physically or in other ways) if they use marijuana regularly?

- No risk
- Slight risk
- Moderate risk
- Great risk

Social Behaviors

Now we will ask about some of your social behaviors. Please remember that this survey is private and confidential. Each question should be answered only about you, not anyone else in the household.

Alcohol Consumption

The next set of questions is about alcohol. One drink of alcohol is equal to a 12-ounce beer, a 5-ounce glass of wine, or a drink with one shot of liquor.

15. During the past 30 days, did you have at least one drink of any alcoholic beverage such as beer, wine, a malt beverage, or liquor?

- Yes
- No → Go To Question 20

--	--	--	--	--

16. During the past 30 days, how many days per week did you have at least one drink of any alcoholic beverage?

Days per week

17. During the past 30 days, about how much money did you spend on alcohol in total? (Only include alcohol that you consumed. Do not include alcohol that you purchased for other purposes, such as gifts or storage.)

\$, Dollars

18. During the past 12 months, how many times were you treated in an emergency room or urgent care facility for any reason related to alcohol use?

- 0 times
- 1 time
- 2–3 times
- 4–5 times
- 6 or more times

19. During the past 30 days, how many times have you driven a car or other motor vehicle while you were under the influence of alcohol?

- 0 times
- 1 time
- 2–3 times
- 4–5 times
- 6 or more times

20. During the past 30 days, how many times did you ride as a passenger in a car or other motor vehicle when the driver was under the influence of alcohol?

- 0 times
- 1 time
- 2–3 times
- 4–5 times
- 6 or more times

Marijuana

The next set of questions is about marijuana. People sometimes call this cannabis, weed, pot, grass, ganje, hashish, hash, or other terms. Please remember that this survey is private and confidential. Each question should be answered only about you, not anyone else in the household.

21. During the past 30 days, did you use marijuana or hashish at least once?

- Yes
- No → Go To Question 28

22. During the past 30 days, on how many days did you use marijuana or hashish?

Days

23. During the past 30 days, which of the following purposes did you use marijuana for? (Check all that apply.)

- Recreational use (Non-medical)
- Medical use (Prescribed by a qualified physician)
- Medical use (Not prescribed by a qualified physician)

24. During the past 30 days, how did you use marijuana? (Check all that apply.) Did you:

- Smoke it (in a joint, bong, pipe, or blunt)
- Eat it (in brownies, cakes, cookies, or candy)
- Drink it (in tea, cola, alcohol)
- Vaporize it (in an e-cigarette-like vaporizer)
- Dab it (using butane hash oil, wax, or concentrates)
- Apply it topically on the skin (using cannabis oil, cannabis ointment/lotion, or topical cannabis salve)
- Use rectal cannabis suppositories
- Use sublingual (under-the-tongue) uptake products (dissolvable strips, sublingual sprays, or medicated lozenges)

25. During the past 30 days, about how much money did you spend on marijuana in total? (Only include marijuana that you consumed. Do not include marijuana that you purchased for other purposes, such as gifts or storage.)

\$, Dollars

26. During the past 12 months, how many times were you treated in an emergency room or urgent care facility for any reason related to marijuana use?

- 0 times
- 1 time
- 2-3 times
- 4-5 times
- 6 or more times

27. During the past 30 days, how many times did you drive a car or other motor vehicle when you were under the influence of marijuana or hashish?

- 0 times
- 1 time
- 2-3 times
- 4-5 times
- 6 or more times

28. During the past 30 days, how many times did you ride as a passenger in a car or other motor vehicle when the driver was under the influence of marijuana or hashish?

- 0 times
- 1 time
- 2-3 times
- 4-5 times
- 6 or more times

Other Substances

The next set of questions is about substance use other than alcohol or marijuana, both prescription drugs used for non-medical purposes and other substances. Please remember that this survey is private and confidential. Each question should be answered only about you, not anyone else in the household.

"Non-medical" prescription drug use means using it to get high or experience pleasurable effects, see what the effects are like, or use with friends.

29. During the past 30 days, did you use any of the following drugs? (Check all that apply.) Did you use . . .

- Cocaine or Crack
- Heroin
- Non-medical use of anti-anxiety drugs such as Sedatives/Tranquilizers/Anxiolytics or sleeping drugs such as Benzodiazepines/Barbituates
- Non-medical use of prescription opioids such as Oxycodone/OxyContin, Hydrocodone/Vicodin, Morphine, Methadone, Fentanyl
- Other (Please write in your answer):

None → Go To Question 34

30. During the past 30 days, on how many days did you use the drug or drugs that you indicated in the previous question?

Days

31. During the past 30 days, about how much money did you spend on drugs, either prescription drugs or other substances, in total? (Only include drugs that you consumed. Do not include drugs that you purchased for other purposes, such as gifts or storage.)

\$, Dollars

Appendix B

DPH Patient Survey Tool

**MASSACHUSETTS DEPARTMENT
OF PUBLIC HEALTH**

MARIJUANA BASELINE HEALTH STUDY

MEDICAL USE OF MARIJUANA PATIENT SURVEY

Dear Participant,

Thank you for taking the time to complete this survey on medical use of marijuana.

The purpose of this survey is to better understand the patterns of use and perceptions among medical use of marijuana patients in Massachusetts. The information you provide will help to inform the safe use and implementation of marijuana legalization in Massachusetts. This survey will ask questions about your use of marijuana and other substances. There is a small risk that some of the questions may make you feel uncomfortable.

Filling out this survey is completely voluntary. You do not have to answer any question you do not want to. You can stop this survey at any time. Choosing to not participate in this survey will not affect your access to marijuana or any other related service.

All information that you provide is confidential. You will be asked to provide your unique Registration Number that is visible on your Program ID card to complete the survey. You will not be asked to provide your name or any other identifying information. Your responses will not be tied back to you in a way that can be identified. Your name or any other identifying information will not be tied to your responses.

This research study has been reviewed by the Massachusetts Department of Public Health (MDPH) Institutional Review Board (IRB). The Commissioner of the Massachusetts Department of Public Health has approved this study in accordance with Massachusetts General Law c. 111 s. 24A. This law protects the confidentiality of all information collected for this study. This law states that the information we collect is not available as a public record. It may not be used as evidence in any legal proceedings. This means that individually identifying information about you will not be shared with anyone outside the study team. It will not be used for any purpose other than for this study.

This survey will include questions on the following topics:

Basic information about you (your age, your racial identity, and what county you live in)
Your current and past experiences regarding the use of marijuana for medical purposes
Your current and past experiences using other drugs

This survey should take between 20-30 minutes to complete.

There are no direct benefits to all participants as a result of participating in this survey. However, as an incentive for your participation, you will be asked at the end of this survey if you would like to be entered into a drawing to win a gift card worth \$100, \$250, or \$500. If you would like to participate, your identifier will be entered into a pool with other participants for the chance to win a gift card. If your identifier is chosen as a winner you will be contacted through email to receive your gift.

If you have any questions about this survey, please contact [REDACTED] or at MBHS@state.ma.us.

For more information about your rights as a research participant, please contact the MDPH IRB at (617) 624-5621.

Thank you again for your time today.

Demographics

1. What is your age?

18 to 25

26 to 35

36 to 50

51 to 64

65+

2. What is your gender?

Male

Female

Other, please specify: _____ *

Refuse to answer

3. Are you currently pregnant?

Yes

No

Don't Know/Not sure

Refuse to Answer

4. Are you currently breastfeeding?

Yes

No

Don't know/Not sure

Refuse to answer

5. Are you Hispanic or Latino?

Yes

No

Don't know/Not sure

Refuse to answer

6. What is your race? Please select all that apply.

White or Caucasian

Black or African American

Asian

Native Hawaiian or Other Pacific Islander

American Indian or Alaska Native

Other, please specify: _____ *

Don't know/Not sure

Refuse to answer

7. What is the highest grade or year of school you have completed?

Never attended school or only attended kindergarten
Grades 1-8
Grades 9-11
Regular high school diploma or GED
Trade school certificate/diploma
Some college credit, but less than one year of college credit
One or more years of college credit, no degree
Associate degree
Bachelor's degree
Master's degree
Professional degree beyond a Bachelor's degree
Professional degree beyond a Master's degree
Doctoral degree

8. What is your annual household income from all sources?

Less than \$15,000
\$15,000 to \$24,999
\$25,000 to \$39,999
\$40,000 to \$59,999
\$60,000 to \$74,999
\$75,000 to \$99,999
\$100,000 to \$149,999
\$150,000 to \$199,999
\$200,000 or more
Don't know/Not sure
Refuse to answer

9. What is the county where you currently live?

Barnstable
Berkshire
Bristol
Dukes
Essex
Franklin
Hampden
Hampshire
Middlesex
Nantucket
Norfolk
Plymouth
Suffolk
Worcester
Don't know/Not sure
Refuse to answer

10. Do you currently identify as having an ambulatory disability that limits your ability to be mobile?*

- Yes, I have an ambulatory disability
- No, I do not have an ambulatory disability
- Don't know/Not sure
- Refuse to answer

Marijuana and Marijuana Product Use

11. During the past 30 days, on how many days did you use marijuana or marijuana products?

- Number of days (1-30): _____ *
- None (0 days) – Skip to Q53
- Don't know/Not sure
- Refuse to answer

12. During the past 30 days, which of the following purpose(s) did you use marijuana or marijuana products for and on how many days? *Please select all that apply.*

- Recreational use (Non-medical, e.g., to get high). Number of days (1-30): _____
- Medical use certified by a qualified practitioner. Number of days (1-30): _____
- Medical use NOT certified by a qualified practitioner. Number of days (1-30): _____
- Don't know/Not sure
- Refuse to answer

If you do not use marijuana or marijuana products for medical use (certified or not certified), then skip to Q15.

If you are not taking this survey with a computer or tablet, then skip to Q14.

13. If you use marijuana for medical purposes, please indicate which medical condition(s) you use marijuana or marijuana products for. *Please select all that apply.*

- ADHD
- Alcohol Dependency
- Anxiety
- Arthritis
- Asthma
- Bipolar Disorder
- Bowel Distress
- Cancer
- Carpal Tunnel
- Chronic Pain
- Crohn's Disease
- Depression
- Diabetes
- Fibromyalgia

Glaucoma
Headaches/Migraines
Hepatitis C
HIV/AIDS
Huntington's Disease
Hypertension
Insomnia
Loss of Appetite
Multiple Sclerosis
Muscle Spasms
Muscular Dystrophy
Nausea
Neuropathy
OCD
Opioid Use
Osteoarthritis
PTSD
Schizophrenia
Seizures
Skin Conditions
Sleep Apnea
Stress
Tourette's Syndrome
Tremors
Vomiting
Wasting
Weight Loss
Other, please specify: _____ *
Don't know/Not sure
Refuse to answer

If you are not taking this survey with a smartphone, then skip to Q15.

14. If you use marijuana for medical purposes, please indicate which medical condition(s) you use marijuana or marijuana products for. *Please select all that apply.*

ADHD
Alcohol Dependency
Anxiety
Arthritis
Asthma
Bipolar Disorder
Bowel Distress
Cancer
Carpal Tunnel
Chronic Pain
Crohn's Disease

Depression
Diabetes
Fibromyalgia
Glaucoma
Headaches/Migraines
Hepatitis C
HIV/AIDS
Huntington's Disease
Hypertension
Insomnia
Loss of Appetite
Multiple Sclerosis
Muscle Spasms
Muscular Dystrophy
Nausea
Neuropathy
OCD
Opioid Use
Osteoarthritis
PTSD
Schizophrenia
Seizures
Skin Conditions
Sleep Apnea
Stress
Tourette's Syndrome
Tremors
Vomiting
Wasting
Weight Loss
Other, please specify: _____ *
Don't know/Not sure
Refuse to answer

15. Do you typically use marijuana or marijuana products that are higher in THC (delta-9-tetrahydrocannabinol), higher in CBD (cannabidiol), or that contain somewhat equal amounts of THC and CBD?

Higher in THC
Higher in CBD
Contain somewhat equal amounts of THC and CBD
Don't know/Not sure
Refuse to answer

If you are not taking this survey with a computer or tablet, then skip to Q17.

16. What method(s) of marijuana administration have you used (one time or more) in the past 30 days? *Please select all that apply.*

Smoked dried flower

Vaporized dried flower

Vaporized concentrate (cartridge/vape oil)

Dabbed marijuana products (butane hash oil, wax, shatter, etc.)

Ate marijuana products (brownies, cakes, cookies, etc.)

Drank marijuana infused products (tea, cola, alcohol, etc.)

Used sublingual (under the tongue) or orally administered uptake products (dissolvable strips, sublingual sprays, oils, tinctures, medicated lozenges, etc.)

Used oral capsules/tablets

Applied topical cannabis oil, ointment, lotion, cream, salve, etc. to your skin

Used rectal/vaginal cannabis suppositories

Other

If you are not taking this survey with a smartphone, then skip to Q18.

17. What method(s) of marijuana administration have you used (one time or more) in the past 30 days? *Please select all that apply.*

Smoked dried flower

Vaporized dried flower

Vaporized concentrate (cartridge/vape oil)

Dabbed marijuana products (butane hash oil, wax, shatter, etc.)

Ate marijuana products (brownies, cakes, cookies, etc.)

Drank marijuana infused products (tea, cola, alcohol, etc.)

Used sublingual (under the tongue) or orally administered uptake products (dissolvable strips, sublingual sprays, oils, tinctures, medicated lozenges, etc.)

Used oral capsules/tablets

Applied topical cannabis oil, ointment, lotion, cream, salve, etc. to your skin

Used rectal/vaginal cannabis suppositories

Other

If you do not administer marijuana or marijuana products in and “Other” way, skip to Q19.

18. Please specify the "Other" form marijuana administration you have used (one time or more) in the past 30 days.

Marijuana and Marijuana Product Use

If you have not “Smoked dried flower” in the past 30 days, skip to Q22.

19. How frequently did you smoke dried flower in a joint, bong, pipe, blunt, etc. in the past 30 days?

Once in the past 30 days

2-3 times in the past 30 days

Once per week

2-3 times per week

4-6 times per week

Once per day

Several times per day

Don't know/Not sure

Refuse to answer

If you are not taking this survey with a computer or tablet, then skip to Q21.

20. How much **dried flower** did you smoke in the past 30 days? *Below is a visual guide for dried flower quantities.*

Less than 1 gram

1 to 3 grams

1/8 ounce (or about 3.5 grams)

1/4 ounce (or about 7.0 grams)

1/2 ounce (or about 14.2 grams)

3/4 ounce (or about 21.3 grams)

1 ounce (or about 28.4 grams)

More than 1 ounce (more than 28.4 grams), please specify: _____*

Don't know/Not sure

Refuse to answer

If you are not taking this survey with a smartphone, then skip to Q22.

21. How much **dried flower** did you smoke in the past 30 days? *Below is a visual guide for dried flower quantities.*

Less than 1 gram

1 to 3 grams

1/8 ounce (or about 3.5 grams)

- 1/4 ounce (or about 7.0 grams)
- 1/2 ounce (or about 14.2 grams)
- 3/4 ounce (or about 21.3 grams)
- 1 ounce (or about 28.4 grams)
- More than 1 ounce (more than 28.4 grams), please specify: _____*
- Don't know/Not sure
- Refuse to answer

Marijuana and Marijuana Product Use

If you have not “Vaporized dried flower” in the past 30 days, skip to Q25.

22. How frequently did you vaporize dried flower in an e-cigarette-like vaporizer in the past 30 days?

- Once in the past 30 days
- 2-3 times in the past 30 days
- Once per week
- 2-3 times per week
- 4-6 times per week
- Once per day
- Several times per day
- Don't know/Not sure
- Refuse to answer

If you are not taking this survey with a computer or tablet, then skip to Q24.

23. How much dried flower did you vaporize in the past 30 days? *Below is a visual guide for dried flower quantities.*

- Less than 1 gram
- 1 to 3 grams
- 1/8 ounce (or about 3.5 grams)
- 1/4 ounce (or about 7.0 grams)
- 1/2 ounce (or about 14.2 grams)
- 3/4 ounce (or about 21.3 grams)
- 1 ounce (or about 28.4 grams)

You have reached the end of this survey. Thank you for your participation! If you have any questions about this survey, please call [REDACTED]

Appendix C
Economic and Fiscal Model Inputs

Table C.1. Model Inputs and Data Sources

Input Metric	Estimate or Range	Data Source
Domain: Sales and Business Tax Revenue		
Marijuana Consumption by MA Residents		
Number of residents in MA		
Adolescent	970,444	2015 ACS
Adult	4,991,000	2015 ACS
Percentage of MA residents with current marijuana use		
Adolescent	8.7–24.0	2015 YHS, 2015 YRBSS, 2015–2016 NSDUH
Post-legalization percentage change	(5)–4.5	Anderson, Hansen, & Rees (2015); Choo et al. (2014); Hasin et al. (2015); Wen, Hockenberry, & Cummings (2015); Dills et al. (2017)
Percentage purchasing from RMDs	0–60	Friese, Grube, & Moore (2013), authors' assumption
Adult	8.6–12.1	2015 BRFS, 2015 NSDUH
Post-legalization percentage change	15.9–16.6	Hasin et al. (2017); Wen et al. (2015)
Percentage shift from illicit to legal market	50–80	Stakeholder interview
Number of use days in past month, among users		
Regular users (1-20 use days per month)	7.26	Task 1 survey
Heavy users (21+ use days per month)	29.16	Task 1 survey
Percentage change in marijuana use days	12–17	Wen, Hockenberry, & Cummings (2014)
Percentage of users		
Regular users (1–20 use days per month)	67.94	Task 1 survey
Heavy users (21+ use days per month)	32.06	Task 1 survey
Grams of marijuana consumed each day of use		
Regular users (1-20 use days per month)	0.17–0.67	MBHS Task 1 survey, Kilmer et al. (2013)
Heavy users (21+ use days per month)	0.32–1.6	MBHS Task 1 survey, Kilmer et al. (2013)
Number of medical marijuana users	53872	
Current price of marijuana	\$13.3–\$13.7	RMD, Price of Weed, Budzu, Dispensary Sheets
Post-legalization percentage change	(50)–0	Stakeholder interview, WA State LCB (n.d.)
Tax rate	6.25% sales 10.75% excise 0-3% local	
Marijuana Consumption by Tourists		
Percentage of tax revenue generated from tourists	7–12	Light et al. (2016); Cooper et al. (2016)
Business tax rate on gross revenue	0.08	MA DOR
Beer Consumption		
Tax revenue from beer	72,830,435	Russell et al. (2017), Wide Open Eats (2017)

Input Metric	Estimate or Range	Data Source
Post-legalization percentage change in sales	(9.21–0.59)	Anderson, Hansen, & Rees (2013)
Domain: Regulatory Oversight		
State Regulatory and Law Enforcement		
Costs	\$1,778,944	WSIPP, CCC
Revenue	\$2,185,407	WSIPP, CCC
Domain: Law Enforcement		
Misdemeanor Arrests		
Unit cost	\$1,188	Aos, Phipps, Barnoski, & Lieb (2001)
Number ^a	240	Stakeholder interview
Post-legalization percentage change	(50–80)	WSIPP, stakeholder interview
Misdemeanor Convictions		
Unit cost	\$522	Aos et al. (2001)
Number ^a	159	Stakeholder interview
Post-legalization percentage change	(50–80)	WSIPP, stakeholder interview
Incarcerations		
Average annual cost of incarceration	\$53,041	Aos et al. (2011)
Number ^a	40	Stakeholder interview
Post-legalization percentage change	(50–80)	WSIPP, stakeholder interview
Supervised Release (Parolees/Probationers)		
Average annual cost of parole	\$4,180	Aos et al. (2011)
Number ^a	122	Stakeholder interview
Post-legalization percentage change	(50–80)	WSIPP, stakeholder interview
Traffic Fatalities		
Cost of cannabis impaired training	\$655,000	Stakeholder interview
Legal cost per crash involving fatalities	\$115,989	Blincoe, Miller, Zaloshnja, & Lawrence (2015)
Number	306	2015 FARS
Post-legalization percentage change	(11.4–9.8)	Anderson, Hansen, & Rees (2013); Santaella-Tenorio et al. (2017)
Domain: Public Health		
Medicaid prescription drug spending	\$459,769,135	Bradford and Bradford (2017)
Post-legalization percentage change	(1.09–1.99)	Bradford and Bradford (2017)
Cannabis abuse or dependence		
Cost of treatment to the state	\$2,086	Stakeholder interview
Treatment admissions	2,840	2016 TEDS
Post-legalization percentage change	10–27.2	Chu (2015); Wen et al. (2015); Hasin et al. (2017); Darnell & Bitney (2017)
Opioid abuse or dependence		
Cost of treatment to the state	\$1,039– \$4,221	Stakeholder interview, Birnbaum et al. (2011), 2011 TEDS
Treatment admissions	3,956	2016 TEDS
Post-legalization percentage change	(45.81)–22.47	Powell et al. (2015)
Averted Mortality		
Opioid-related mortality		
Number of overdose deaths	1,990	MPDH
Post-legalization percentage change	(18.00)– (17.90)	Powell et al. (2015); Bachhuber, Saloner, Cunningham, & Barry (2014)
Average income	\$60,840	2015 ACS

Input Metric	Estimate or Range	Data Source
Suicides		
Cost of a suicide to the state	\$39,887	Shepard, Gurewich, Lwin, Reed, & Silverman (2015)
Number of suicides, males age 20–29	76	2015 CDC Vital Statistics
Post-legalization percentage change	(18.8)–(3.8)	Anderson, Rees, & Sabia (2014)
Average income, males age 20–29	\$24,228	2015 ACS
Number of suicides, males age 30–39	77	2015 CDC Vital Statistics
Post-legalization percentage change	(17.5)–(2.4)	Anderson, Rees, & Sabia (2014)
Average income, males age 30–39	\$56,913	2015 ACS
Traffic fatalities	<i>see Law Enforcement section above</i>	
Average income	<i>see Opioid-related mortality above</i>	
Worker Productivity		
Number of recreational dispensaries	123	MDPH estimate
Average salary for minimum wage full-time employees ^{a,b}	\$22,000	\$11/hr, 40 hrs/wk, 50 wks/yr
Income tax rate	0.05	MA DOR
Number of FTEs at minimum wage per dispensary previously unemployed or working in illicit market ^b	0-10	Authors' assumption
Hourly earnings, employed males age 20–29		
Population total	340,203	2015 ACS
Average hourly earnings	\$15.6	2015 ACS
Post-legalization absolute change	(\$4.85)–(\$0.42)	Sabia and Nguyen (2016)
Average hours worked per week	37.4	2015 ACS
Average weeks worked per year	51	2015 ACS
Full-time employment, females age 50+ ^b		
Population total	532,394	2015 ACS
Average earnings per year	\$49,175	2015 ACS
Percentage employed full time ^b	28.5	2015 ACS
Post-legalization percentage change	1.34–17.48	Nicholas and Maclean (2016)
Hours worked per week, employed males age 50+		
Population total	539,526	Census
Average hourly earnings	\$34.1	ACS
Average hours worked per week	41.7	ACS
Average weeks worked per year	50	ACS
Post-legalization percentage change	(0.98)–10.78	Nicholas and Maclean (2016)

Sources: Mathematica's synthesis of estimates from the literature, key stakeholder interviews, and primary and secondary data sources on the impact of legalized adult use of marijuana in Massachusetts.

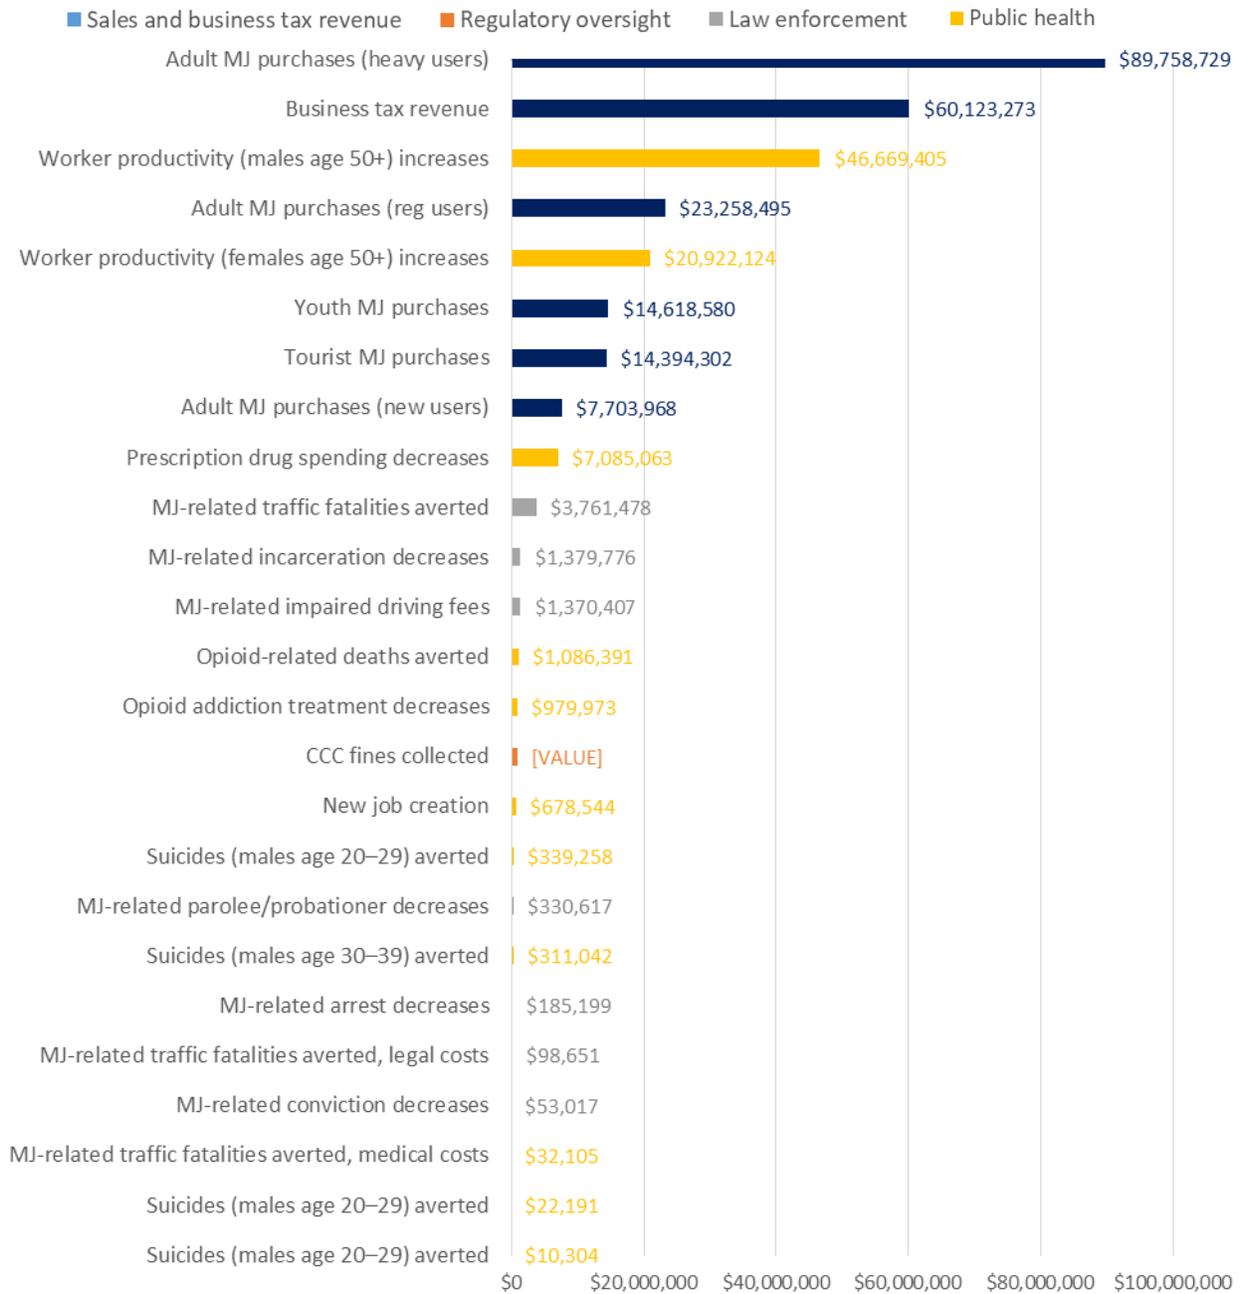

Note: Values in parentheses reflect negative values.

^a Values were calculated by the authors based on the data.

^b FTE = full-time employee, with full-time defined as working more than 35 hours per week.

ACS = American Community Survey; BRFSS = Behavioral Risk Factor Surveillance System; CCC = Cannabis Control Commission; CDC = Centers for Disease Control and Prevention; FARS = Fatality Analysis Reporting System; LCB = Liquor Cannabis Board; MA DOR = Massachusetts Department of Revenue.; MBHS = Marijuana Baseline Health Study; MDOC = Massachusetts Department of Corrections; MDPH = Massachusetts Department of Public Health; NSDUH = National Survey on Drug Use and Health; RMD = registered marijuana dispensary; TEDS = Treatment Episode Data Set; WSIPP = Washington State Institute for Public Policy; YHS = Massachusetts Youth Health Survey; YRBSS = Youth Risk Behavior Surveillance System.

Figure C.1. New Revenue or Savings Estimated Post-Legalization, by Source

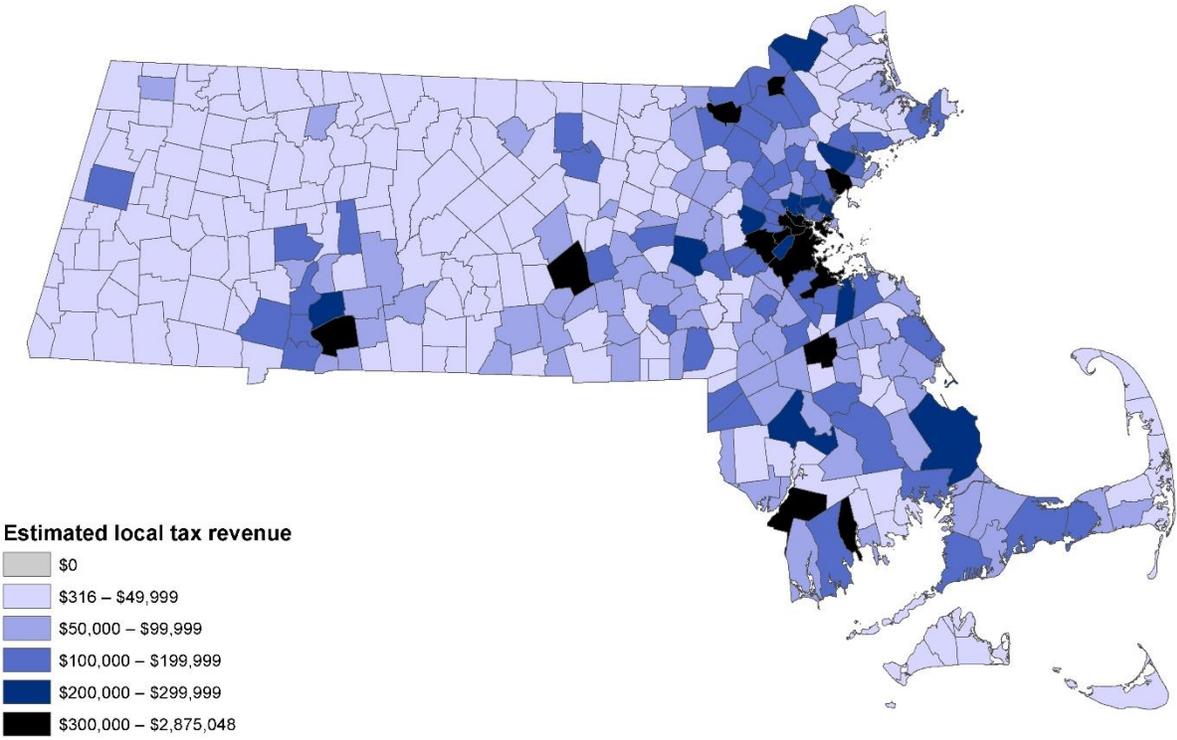

Sources: Mathematica’s analysis of impacts of legalized adult use of marijuana in Massachusetts using estimates from the literature, key stakeholder interviews, and primary and secondary data sources. See Appendix C Table C.1 for data sources used to inform these estimates.

Note: The table displays sources of revenue or savings and excludes measures associated with costs or losses.

CCC = Cannabis Control Commission; MJ = marijuana.

Figure C.2. Estimated Two-Year Local Tax Revenue if Registered Marijuana in all Cities/Towns

Sources: Mathematica’s analysis of impacts of legalized adult use of marijuana in Massachusetts using estimates from the literature, key stakeholder interviews, and primary and secondary data sources. See Appendix C Table C.1 for data sources used to inform these estimates.

Table C.2. Estimated Two-Year Local Tax Revenue if Registered Marijuana Dispensaries in all Cities/Towns

City or town type	Number of cities or towns	Estimated two-year local tax revenue		
		Median	Minimum	Maximum
Rural (< 100 people/km ²)	29	\$3,077	\$316	\$7,476
Suburban, low density (100–500 people/km ²)	60	\$7,713	\$1,926	\$32,340
Suburban, medium density (501–1,000 people/km ²)	64	\$29,375	\$9,242	\$110,963
Suburban, high density (1,001–10,000 people/km ²)	171	\$70,090	\$13,076	\$369,822
Urban (> 10,000 people/km ²)	27	\$258,946	\$56,766	\$2,875,048

Sources: Mathematica’s analysis of impacts of legalized adult use of marijuana in Massachusetts using estimates from the literature, key stakeholder interviews, and primary and secondary data sources. See Appendix C Table C.1 for data sources used to inform these estimate

Table C.3. Estimated Two Year Local Tax Revenue for each City or Town

City or town	Cities/towns with an RMD		With RMDs in all towns
	State-level # MJ users	Localized # MJ users

Sources: Mathematica’s analysis of impacts of legalized adult use of marijuana in Massachusetts using estimates from the literature, key stakeholder interviews, and primary and secondary data sources. See Appendix C Table C.1 for data sources used to inform these estimates.
 MJ = marijuana; RMD = registered marijuana dispensary.

Appendix D

Marijuana Product and Price Characterization

Introduction

Medical marijuana products that are sold in Massachusetts are required to be evaluated according to established laboratory testing protocols (DPH, 2016). Briefly, these protocols describe evaluating dispensed products for contaminants and cannabinoid content, inclusive of evaluating finished (dried) plant material, cannabis resin, and cannabis concentrates. As some of these products (e.g., oils and resins) are tested and later incorporated into marijuana-infused products (MIPs) intended for use as edibles (e.g., capsules, brownies, candy, etc.), or various personal care products (e.g., tinctures, lotions, suppositories, etc.), a marijuana-containing product may undergo multiple rounds of product testing before it is dispensed.

Marijuana products of a similar variety are generally priced according to the cannabinoid content. In August 2017 Registered Marijuana Dispensaries in Massachusetts were asked to complete a voluntary survey of retail marijuana prices to inform the economic and fiscal analyses being conducted as part of the MBHS.

This appendix describes an overview of the cannabinoid content and price of medical marijuana products that were available through the DPH Medical Use of Marijuana Program. As these medical marijuana products were likely to be very similar in composition to the types of products available in adult-use marketplace, an earlier draft of the information provided in this Appendix was used to inform various analyses in the MBHS. As such, a summary of the cannabinoid content and price of retail medical marijuana products available in Massachusetts over the period of May 14, 2015 through December 31, 2018 is included here as Appendix D.

Cannabinoid Content Summary

Marijuana products that are dispensed for medical use in Massachusetts must bear a label that identifies the percentage (by dry weight) of Δ^9 -tetrahydrocannabinol (Δ^9 -THC), cannabidiol (CBD), tetrahydrocannabinolic acid (THCa), and cannabidiolic acid (CBDa). Of these cannabinoids, Δ^9 -THC is the primary psychoactive component and cannabidiol (CBD) is the primary non-psychoactive component of cannabis.

While regulating the sale and use of medical marijuana in Massachusetts, DPH has evaluated over 15,000 laboratory reports, describing over 14,500 medical marijuana products, from thirteen different medical marijuana facilities. These reports have been voluntarily submitted to DPH and describe the laboratory testing of flower products (44.6%), MIPs (27.0%), and concentrates, such as resin (3.7%), oils (19.5%), shatter (3.0%), or wax (2.2%). Of these laboratory reports, a total of 12,375 describe an evaluation of cannabinoid profile testing that describes levels of: Δ^9 -tetrahydrocannabinol (Δ^9 -THC), cannabidiol (CBD), tetrahydrocannabinolic acid (THCa), and/or cannabidiolic acid (CBDa).

The types of products tested for cannabinoids include flower products (37.2%), concentrates (29.4%), and MIPs (33.3%; see Figure 1). Table 1 describes the

cannabinoid testing results for flower, concentrates and MIPs. The cannabinoid Delta (Δ)9-THC was detected in 93.3% of flower products, 98.6% of concentrate, and 95.2% of MIPs. The cannabinoid THCa was detected in 99.6% of flower products, 67.2% of concentrates, and 17.0% of MIPs. The cannabinoid CBD was detected in 27.9% of flower products, 56.6% of concentrates, and 33.1% of MIPs. The cannabinoid CBDA was detected in 50.3% of flower products, 53.2% of concentrates, and 7.1% of MIPs.

The cannabinoid content of the available products is shown in Table 2. Of the 4,605 flower samples tested, THCa concentrations were most often between 14-28%. Approximately 5% of flower samples had THCa concentrations greater than 28%. CBDA was rarely detected in flower samples, and never at a concentration greater than 28%. The majority of flower samples (43.6%), had THCa levels between 14 and 21%. Of the 3642 concentrate samples tested, the majority (38.2%) had THC concentrations between 60 and 80%. Approximately, 15.4% of concentrate samples had THC concentrations greater than 80%, while only 0.6% had CBD concentrations greater than 80%.

Retail Price Summary

A summary of the price of retail marijuana products available at 11 of the 12 open and operating RMD locations in August of 2017 is shown in Table 4. Similar products across various RMDs were combined to provide an overview and summary (e.g., same product types) using the RMD retail price survey found in Figure 2. The product's dose of THC (in milligrams) was calculated for any product with a dose presented as a percentage, using the product net weight (i.e., dose percentage multiplied by product net weight).

Flower	0.1	0.2	0.3	0.6	3.4
Concentrate	0.5	1.0	4.7	49.0	99.0
MIPs	0.1	0.1	0.5	5.8	92.0
Flower	0.1	0.1	0.2	12.5	28.3
Concentrate	0.1	0.2	0.4	12.1	64.2
MIPs	0.0	0.0	0.1	0.6	3.3

Table 4: Summary of Retail Product Prices Provided in RMD Survey

	Product Group	Type	Description	Product Weight	THC Dose	Retail Price
Concentrates	Resin	Rosin	Concentrate for vaporization	0.5-1g	50-85%	\$25-\$45
	Resin	Keif	Cold pressed bar for vaporization	7g	38%	\$100
	Vape Oil	Cartridge	Concentrate oil for vaporization	0.9mL	200-1000mg	\$25 - \$100
	Wax	Wax	Concentrate for vaporization	1g	900mg	\$50
	Vape Oil	Cartridge	Concentrate oil for vaporization	0.25-0.5g	30-90%	\$60 - \$75
	Shatter	Shatter	Solid concentrate for vaporization	1g	85%	\$60
	Oil	Extract or distillate	Extract or distillate for infusion	1g	65-87%	\$65-\$80
Dried Flower	Pre-roll	Joint/cigar/cigarette	Intended for smoking	1g	15-35%	\$15-\$20
	Flower	Finished flower	Various strains	1g	15-35%	\$15
	Flower	Finished flower	Various strains	3.5g	15-35%	\$50
	Flower	Finished flower	Strain blend	28g	15-30%	\$250
	Flower	Finished flower	Various strains	28.4g	15-35%	\$250-\$350
Edible MIPs	Capsule	Capsule	Infused for ingestion	1-2g	10-25mg	\$2.50-\$5
	Lozenge	Flavored hard confection	Infused for ingestion	6.5g	10mg	\$4-\$5
	Chocolate	Chocolate bar/nugget	Infused for ingestion	9-68g	10mg	\$4-\$10
	Beverage	Lemonade	Infused for ingestion	--	20mg	\$10
	Baked Good	Cookie/muffin	Infused for ingestion	--	10-85mg	\$10-\$40
	Gummy	Flavored gummy confection	Infused for ingestion	5g	25-50mg	\$12-\$23
	Chocolate	Chocolate bar/nugget	Infused for ingestion	9-68g	100mg	\$25-\$30
	Lozenge	Flavored hard confection	Infused for ingestion	6.5g	100mg	\$25-\$35
	Gummy	Gummy confection	Infused for ingestion	50-100g	100-500mg	\$30-\$80
	Cooking oil	Grapeseed oil	Infused for ingestion	188g	840mg	\$100
Non-Edible MIPs	Suppository	suppository	Rectal/vaginal use	2g	10mg	\$4
	Topical	Lip Balm	Stick for lip application	--	10.15mg	\$5
	Suppository	suppository	Rectal/vaginal use	2g	25mg	\$7-\$12
	Topical	Salve	Cream for dermal application	28.4g	8-25%	\$30-\$45
	Topical	Lotion	Cannabis infused topical lotion	112.5g	350-375mg	\$30-\$60
	Topical	Transdermal patch	Skin application	--	125mg	\$40
	Tincture	Tincture	Infused for sublingual application	30mL	500mg	\$60-\$75

Figure 1. Cannabinoid Testing Results of Retail Marijuana Products for Δ 9-THC, THCa, CBD, CBDa through December 31, 2018

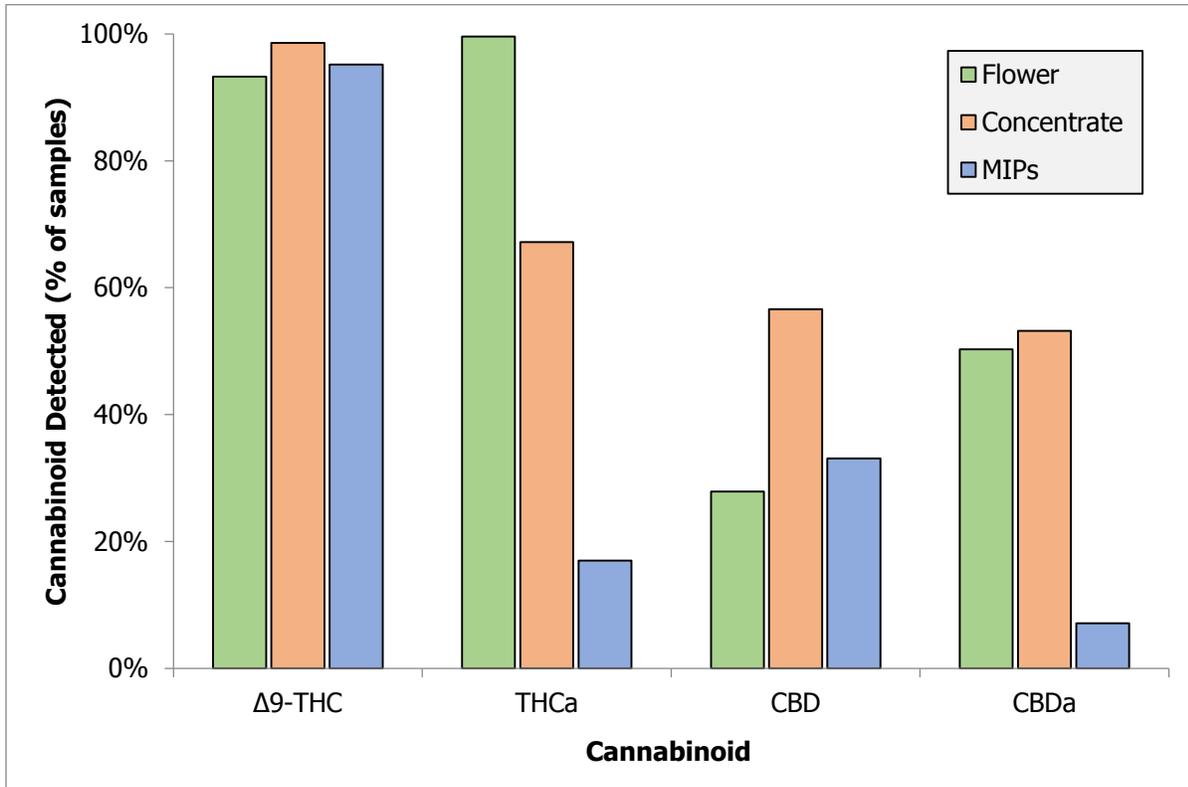

Figure 2: RMD Retail Price Survey*

RMD Name:

Category	Examples	Type	Description	Product Weight	Dose (Potency)	Retail Price
Dried Flower	Finished flower, pre-rolls, "Mini"-Pre-rolls					
Concentrates	Vape pen cartridge, oil, shatter, wax, resins, bubble hash, rosin					
Edible MIPs	Beverage, capsule, lozenge, gummy candy, brownie, cookie, honey, sauces/jams					
Non-Edible MIPs	Tincture, suppository, lotion/salve, massage oil, lip balm, patch, bath oils/salts					

****Instructions provided for filling out the above survey:***

Category: This column identifies the product-type category (i.e., dried flower, concentrate, edible MIPs, and non-edible MIPs).

Dried Flower: dried leaves and flowers of the female marijuana plant that have been trimmed and dried and include most importantly the inflorescences (i.e., “buds”) that may be used directly (e.g., smoked) as a medical product without further processing.

Concentrate: marijuana product derived by using solvents to extract and concentrate cannabinoid compounds (e.g., oils, pastes, waxes, or solids) or a solid medical marijuana product produced by gathering and compressing the cannabinoid-rich trichomes (i.e., keif) of the marijuana plant (e.g., cannabis resin, “hashish,” “hash,” or “bubble hash”).

Edible Marijuana-Infused Products (edible MIPs): a marijuana-infused product that is to be consumed by eating or drinking.

Non-edible Marijuana-Infused Products (non-edible MIPs): a marijuana-infused product that is to be used through routes other than eating or drinking (i.e., all other uses).

Examples: This column identifies common product-type examples and is not considered an exhaustive list.

Type: This column provides fields to describe further product-type classification. Examples of Types by Category are provided in the Examples column (e.g., finished flower, pre-rolls, "mini"-pre-rolls, etc.).

Description: This column provides fields to include a product description describing characteristics such as appearance, intended route of use, and instructions for use (e.g., suggested serving size).

Product Weight: This column provides fields to include the product weight (e.g., net weight) by unit of sale (e.g., a single serving edible MIP: 100 grams)

Dose/Potency: This column provides fields to include the product cannabinoid dose for each advertised cannabinoid in amounts, expressed as the dry-weight percentages or milligrams of Δ^9 - tetrahydrocannabinol (Δ^9 -THC), cannabidiol (CBD), tetrahydrocannabinolic acid (THCa) and cannabidiolic acid (CBDa) in a medical marijuana product. Amounts of other cannabinoids may be reported, but are not required.

Retail Price: This column provides fields to include the estimated retail price (US dollars) for the specific product described. Itemized prices are most useful but a price range may additionally be provided to capture market variability and other closely related products.

Appendix C: 2015-2016 Cohort Patient-Reported Negative Effects

Note: Word choice and spellings have been retained as written by respondent to avoid inadvertent mischaracterization of intent. Brackets have been used to explain words redacted to prevent individual identification or for other reasons. Negative effects are broken down negative effect type, and by negative effect score rating.

Access-Related Issues

No Score

- Can use cannabis as in a group home
- Travel to get the product

1: No Negative Effects

- none, other than difficulty/inconvenience in accessing medical cannabis
- I have to ride 3 to 3 1/2 hours one way for my medicine because there are none in southwest Minnesota.
- The only issue is the distance I need to travel to get it if I don't take into account the cost
- I have to ride 3 to 3 1/2 hours one way for my medicine because there are none in southwest Minnesota.
- the only negative effect i have experienced is when i had to find a Doctor that would certify me. All my health care providers were told not to participate in the cannabis program. Finally my Doctor was able to certify me. Also the self exam questions when getting the medical cannabis from the dispensary are useless.
- Locations of dispensaries. We have to drive from [CITY] to the cities.

2

- Travel to pick up my prescription.
- Difficulty accessing medical cannabis
- Time consuming to order, drive and pick up medicine.
- unable to use outside of the state of MN.

3

- Physically having to pick up medication by myself

4

- The fact that my son's home care nursing staff is not permitted to administer PRN or scheduled Medical Cannabis is a difficult component at times.
- Driving so far away to get meds. And [CANNABIS PATIENT CENTER] not being open as much!!!

7: Great Deal of Negative Effects

- Distance.... DISTANCE.

Physical Negative Effects

No Score

- tired
- Did not like inhaling the cannabis. Irritated my lungs.
- a moderate dry mouth.
- seizures worsened but unsure if completely related to medical cannabis

1: No Negative Effects

- Dry mouth , and too many trips to the fridge
- some nausea after capsule form.
- I experience fatigue but that is a plus because I had problems sleeping at night because of pain. it seems to help with that
- sleep
- Cotton mouth!
- Stomach upset only when not taken with food.
- slight fatigue
- Mild drowsiness
- Do you feel a little tired at times .
- Sometimes my mouth can become dry, but it's fine if I'm hydrated.

2

- Had a bad reaction to oil suspension, this was corrected by adjusting dosage
- Initial increase in seizures
- We noticed the combination of CBD/THC worsened seizures for [PATIENT]. CBD also seems to be upsetting on her stomach with changes/increases in dosing.
- Getting chest colds from vape pen.
- e-cig- too much inhaled caused excessive coughing and vomiting.
- more small seizures
- sore throat
- fatigue
- Yes ~ In the morning I have to be careful with my blood pressure. It does lower it a bit. I have to watch my fluid intake because of my cathing schedule. Plus I already have low blood pressure in the morning. This lowers it a bit. I'm finding I need to drink Gatorade and get up a bit slower and then I'm fine. But out all the benefits this side effect is so minor and manageable. I could go into the crazy cost, the monthly travel time from [CITY] and having others pick it up for you without having to pay for another background

check when the company they work for through you already did one. I shouldn't have to pay for another PCA criminal background study for a current PCA that works for me. That is redundant request. Suggestions: Could there be a 3 month supply given instead of a 30 day supply? This would eliminate some winter driving months, gas money and for people who are suffering in pain (dying of cancer or children having seizures) it's so hard for them to travel. Some days even hard for them to get out of bed or eat. I wish people understood. I wish people would be more compassionate. People hurting ~ suffering are willing to pay for this with in reason, travel within reason and doctors are willing to come on board but without fear (so I don't blame them). I do not feel it's fair to ask a question on negative effects of a drug without asking the positive and negative effects of the process too! I am only one voice but today please allow me to be the voice of many...

- Increased appetite- causing weight gain
- Some head shaking as side effect.
- bad aftertaste with vaped oil
- Dry mouth
- Increased appetite.
- Dry mouth, and the need to carefully plan when I'm going to take the Cannabis so it doesn't interfere with daily life
- dry mouth
- seems to sleep more. Can not respond to other examples given as [PATIENT] does not have a form of communication that pertains to pain or depression, confusion, etc...
- Tired
- Coughing. Headache
- heaviness in legs
- Sometimes the pills make me too tired and I sleep more than I would like.
- Munchies : (
- with the vapor only, bad taste
- I really dislike the taste from the vape pen.
- We have experienced the occurrence of night terrors which we have not seen prior to starting medical cannabis. We are uncertain if this is related to the medication or a normal developmental step.
- speed of effects and lasting time.
- He just gets a little tired, he ever it doesn't both either of us and I love that it's 1pp% natural!
- slight dizziness and mental cloud
- Some stomach upset.
- Tired
- Smell from vapor pen can cause nausea.
- Tiredness
- 1. Sleepiness/tiredness

2. Hard to regulate dosage on vapor pen, can become paranoid if too much inhaled
3. Can hurt lungs and cause coughing if inhaled too hard, after learning how hard to inhale it has been much better.

- Sometimes the cannabis in oral liquid makes me a little queasy.
- I have gastroparesis with a stomach implant. I found when taking the heather solution it caused constipation.
- Like to rest a moment after vaping a dose.... but just time my day accordingly.
- The vaping can cause congestion, and you already have that going on because of the Chemo.

Some fatigue, but it's once you have been up and moving, so it's not so bad that it causes you to rest from time to time.

It's hard to know if mental clouding is caused from the chemo or the cannabis. However it's not enough to be alarmed.

- Very sleepy if I don't go to bed in a timely matter after my evening dose.
- Fatigue

I have some mental clouding but partly from the effects of chemo

- 1. Increased Heart Rate
2. Sweating and Heat Flashes
 - Dry mouth the cost is very high
 - Feel sleepy so I have to time taking the medications (vape or tincture). It is expensive also so I can't get a refill as easily as I would like since money is tight because of my conditions anyways.
 - Sluggish next morning
 - To strong
 - When on [HIGH CBD PRODUCT], loss of coordination and had increased weakness.
 - Fatigue was an initial issue, but medication adjustments have brought it under control. I don't like having to complete the survey every time I refill, it should be mandatory a couple of times a year and self elective if great improvements or noticeable worsening of issues.
 - Only side effect is diarrhea at times
 - Dry mouth
 - Lethargy
 - Stomach rumbles after taking the pill
 - Maybe increased the appetite
 - tired
 - Occasional tired, that could also be attributed to the chemotherapy
 - dry mouth and dizziness
 - While taking the tincture product I got a headache.
 - sluggish/drowsy, occasionally
 - I haven't been able to tell if from the vapor or pill but I've noticed increased drowsiness.

3

- initially makes me worse.
- possible drug to drug interaction
- Saw great results with Violet, but when we added Indigo at night, [PATIENT]'s sleep/wake cycles were disrupted. 3 weeks in a row after adding [HIGH CBD PRODUCT] he would stay awake for 24 hours, then sleep for 24, & it would take a few days before he could get back on track. That was the only change we made so I think the very small amount of THC in it had adverse effects for him. Went back to [HIGH CBD PRODUCT] only.
- A little off balance if taken when awake
- Nondry mouth
- coughing and dry throat upon taking. [MANUFACTURER] inhalers worse than [MANUFACTURER] spray but still have bit from spray.
- May be contributing to frequent loose stools
- It takes 1-2 hours for the oral medical cannabis to kick in. My throat sometimes gets sore after using the vaporizer.
- Mostly positive. Maybe a bit tired sometimes.
- Tiredness But that's in combination with other seizure medications that he takes
- I just notice that I cough more using the vape pens vs the oil
- [PATIENT] is dead. I can't answer this question in detail. He was not able to communicate much at the end. But I remember him expressing that he did not like the taste.
- cotton mouth
- upset stomach
- seem to be more tired
- Regulating the correct amount and type correct which takes time and experience. Much easier to do with the pills it seems for me personally as smoking it made my lungs worse and often times would be hard for me to control the dosage.
- I would like more edible options

4

- Interaction with other five seizures medications is hard to identify.
- while the cannabis helps with the muscle spasms, it seems to make my nerve damage worse.
- Drowsiness
- Makes me sleepy if I take during the day.
- I have experienced occasional diarrhea from using the oral suspension product.
- speaking quite loudly at home since starting the product
- fatigue
- Reduction in morning energy levels.
- Unsteadiness

- I don't like the side effect that gives me the munchies, I have a weight issue and it makes it hard for me to use it often.
- the oil in higher doses seem to cause me some small belly issues >but I do need it to calm pain/ spasms at night so I can sleep.
- dizziness
- Nausea
- symptoms seem to go up and down as the body adjusts to the cannabis and can be frustrating. still adjusting dose to find what will work best so still having symptoms/tics. can cause both hyperness and sleepiness
- Weight gain
- Sleepiness
- I tend to sleep a longer some days, but the days I am awake I have more energy and I feel better than I have in a long time. I have also lost about 8 lbs. since I started in the program.
- Little tired
- It gives me a sore throat and it tastes really bad
- Fatigue
- increased appetite
- Blurred vision
- Dizziness
- some headache
- I'm a little more tired and eat more
- Constant hunger

5

- increased seizure activity
- possible allergic reaction; i.e., hayfever - type symptoms
- Has interacted with my other seizure meds
- The oil made me sick
- Lightheadedness
- Vaping really hurts my throat. And since there is no raw flower available to purchase, I'm stuck with a sore throat. The oral options don't take effect for an hour or two, and even then, they don't relieve my symptoms effectively like vaped or smoked. I hope raw flower is available soon. I bet it's even safer than vaping.
- visual impairment
- Terrible headaches
- Dry mouth
- Notice I tend to eat more which leads to weight gain, sleepiness

6

- More seizures

- Sublingual tincture seems to be very caustic to the soft tissue under the tongue
- My son's seizures got worse when we moved from CBD only to [HIGH CBD PRODUCT]. It could be a coincidence, but even after I stopped the oil, I could not get his seizures under control and we had to be admitted to the hospital
- stomach pains
- sleeping
- Shakiness, balanced worsened
- I have stopped the cannabis. While the cannabis helped, I have had two spells of light-headedness and almost passing out. It would appear they are caused by the cannabis
- Dizziness and once passed out

7: Great Deal of Negative Effects

- Caused pain on left side of body
- Tried several times to restart with just one kind then the other
- still pain
- Found that I am allergic to cannabis - I broke out in hives approx. 6 weeks after starting to use it. Now, after 9 weeks off of it, the hives are almost gone.
- Severe, uncontrollable diarrhea. Severe, rapid weight loss. Increased seizure activity due to extra stress on body caused by severe, uncontrollable diarrhea and weight loss.

Mental Negative Effects

No Score

- b in the question below

1: No Negative Effects

- Anxiety increases on occasion.
- None-just cloudiness sometimes
- felt buzzed twice

2

- The most irritating part of the program is we have to do oil. I have never liked oil because it makes my short term memory a little worse and gives me mental clouding. It's not that big of a problem but I get annoyed if I forget something or I'm not thinking at my full ability. I had never had any negative side effects when I smoked the plants buds. In my experience oils good if you want to get high. But for treating crohns smoking the plants buds are better. This is because bud contains other chemicals than just thc or cbd that help with crohns while oil doesn't. This rule makes absolutely no sense. I understand that this was made law because someone who was ignorant in regards to cannabis thought ""vaping oil"" sounded better than ""smoking bud""
- But please please please fix this stupid law and let me treat my crohns with no negative side effects again.

- The fact that the oil makes me too high, mellows me out too much; regular cannabis lets me function on a normal level
- I need to time my dosage at night so I don't feel groggy in morning.
- Some decrease in motivation.
- Generally makes me feel lousy. I couldn't function even with a small dose.
- Slight memory loss (short-term memory)
- Very rarely happens, but losing train of thought when making a point. Now practicing my own "tickler techniques" to get my thought pattern quickly back on track.
- The high, it's not bad but I only use at night
- just a couple of times feeling high.
- At first, I had to try the different cbd/thc formulas. There were some times when I felt confused or lightheaded. Now, I know what blend to take to address my symptoms and I've figured out which delivery method works best for me. Now I have almost no negative effects.
- Would prefer not feeling altered and sometimes vapor pen doesn't seem to be releasing and I take in more than planned - very short term impact.
- At first it made my head feel a little funny, but very quickly that has gone away and having less pain has been a huge improvement. I have many more good days.
- nothing significant noticed. maybe some slight ""mental cloudiness"" but not every time and very mild
- Getting stupid.
- Short term memory loss.
- Forgetfulness/Losing train of thought
- Some confusion
- using the cbd oil, at times I have felt out of it.

3

- Makes me lazy.
- I cannot take any cannabis with THC in it. Must take only pure cannabis. With the THC I get anxiety. With out is everything is good
- depression
- Loss of judgment.
- In the beginning he seemed very lethargic, now that is better but [PATIENT] still has lack of appetite often
- Makes me feel rather lazy - I try to use that to my advantage and catch up on some sleep or to relax.
- unmotivated, subdued, weak and tired if too much THC - still trying to find that right balance
- Unable to drive for four hours after taking.
- Not being able to drive when using the cannabis
- Some mental clouding for about 2 hours

- mental clouding
- mental fog
- Some cognition fog that seems to decrease with time.
- Gotten almost lazy

4

- Increased anxiety, but I could still be detoxing from clonazepam. Today has been better.
- Hyper and Impulsiveness
- Disorientation
- Getting high
- Struggle with memory, focus, comprehension, weight gain, staying on task, lose track of time & easily distracted. Which affects my work....however it helps with my intense pain & migraines, which is why I wanted to take it..
- It has added to my cognitive confusion/fibro brain symptoms at times. It does a really good job of masking the pain I get from physical exertion which has been a downside because then I've over-done at times which then has added to my fatigue and exhaustion and pain. Prior to the MM, my pain was my greatest problem. Now that the pain has been managed to a better extent, I now am dealing with overwhelming fatigue and exhaustion a lot of the time.
- Balancing previous existing mental health issues.
- If I use enough to better "control" pain, I can get paranoid. It can also cause urinary retention, but other times, it helps me to go.
- I do not feel like myself
- Anxiety, chills, sometimes fatigue and/or confusion, sore throat/coughing from vaporizer
- High feeling
- increased sedation, lightheadedness
- social anxiety not wanting to be around people when I'm on the medicine
- makes me loopy
- Small amount of paranoia
- High feeling
- Uncooperative
- I've felt depressed and sad and wanting to be in the dark liking it to be very silent and also not wanting to be around others.
- I'm not effective or efficient when I'm using cannabis. I'm awake, but impaired. When I've had to use different things in the past like opioids, I'm ineffective, but I'm usually asleep the whole time. Being awake and impaired, I spend a lot of time confused and unable to follow conversations, read or watch TV. Cannabis doesn't make me sleepy.

5

- anxiety
- it's difficult to take it during my work hours, because it makes me feel less attentive, NO pain or pain.
- When taking it sometimes, maybe a little paranoia set in. That is something I can't have.

6

- Crying and irritability non stop once we increase the dose from 1 ml to 1.2 ml.

7: Great Deal of Negative Effects

- change in behavior and mood, digestive/pancreas?/liver? upset
- not aware of day/time, not remembering what I was saying mid-sentence, increased anxiety

Cost-Related Negative Effects

No Score

- the hardest part for me is the cost. I wish it was covered by insurance. Our insurance premiums are so high and then the additional cost for this just puts us up over the edge in costs...which depresses me.
- Was only on med. cannabis for 4 days and had to quit due to other medical issues and cost!

1: No Negative Effects

- Cost
- The cost! !!!!!
- I'm not allowed to list financial cost
- cost
- The cost is outrageous
- cost
- cost
- Cost price availability
- None beside cost
- Cost
- The cost is so much that i think in time people will search out other otions
- The cost is very high ! Have to find a way to lower it ???
- expensive
- Cost and accessibility I live in northern mn
- The price and not available in leaf form.
- None, except expensive
- Cost is unreasonable
- None..just the cost

- Cost..., way too much.
- Just cost and lack of ability for [PATIENT]'s MA Tefra to help us with the out of pocket expense.
- can't afford to try a more therapeutic dose have to drive 180 miles round trip to the dispensary
- Cost of Medicine
- Cost and way of consuming. THC oil is 70%. Plant matter is 20-25%. Hundreds of other elements in the cannabis plant besides THC, CBD that is useful consumption. Some want the cannabis glowered bud to consume in smoking or edibles extracted from the cannabis buds.
- The price.
- cost
- The cost of the medicine. The extract version of the cannabis plant is definitely more potent than loose leaf cannabis. However, the introduction of lower cost leaf cannabis would help patients afford the medicine.
- The cost of the cannabis and it NOT at all whatsoever being covered by insurance it is medicine just as any other medicine.
- none just cost
- The cost
- Cost
- cost!
- None beyond funding.
- the cost of medication is high for someone out of pocket with out insurance paying for it
- None, no negative effects ., only the cost has been a factor as it is not covered by medical insurance and it is too much money and is hard to afford.
- cost
- Besides cost, nothing is negative.

2

- The cost for a young person. Insurance does not cover it.
- cost, or lengthy road trip to dispensary
- Price
- The cost is high and month to month I do not know if I will be able to afford a monthly supply.
- cost

3

- cost
- The cost of the product is crazy high and not in line with the market. The same product in WA, CA, or CO costs about half of what things cost in MN.

4

- Cost (2 reports)
- Financial. It is very expensive. That is the only negative.

5

- Cost

6

- Way too expensive where I can't afford it!
- money that is charged

7: Great Deal of Negative Effects

- I'm broke and still need medicines that other states get at a much lower price. I lied and borrowed just for my first time. It's hard buying not know for sure that's what I want or need. Purchased unless items.having a choice between strain IE sour diesel, headband,kush and etc.
- would rather suffer than go to mn med solution again, thy are worse thieves than the drug dealer down the street. leafline lab was ok.

Negative Attitudes Toward Medical Cannabis Use

1: No Negative Effects

- the only negative effect i have experienced is when i had to find a Doctor that would certify me. All my health care providers were told not to participate in the cannabis program. Finally my Doctor was able to certify me. Also the self exam questions when getting the medical cannabis from the dispensary are useless.
- what other people would think if they know- so I don't tell them
- The only negative impact would be not telling anyone what is turning my health around because of the views of some people with cannabis.
- Poor reception to cannibis at [HOSPITAL]. Serious lack of staff knowledge and support.

2

- The nay-sayers tire me out. Two [HOSPITAL] employees (my sister/aunt of my son and a [HOSPITAL] doctor friend of our family) insisted that there is no proof that medical cannabis helps. "You might as well give your son dirt". Was a comment I heard from the [HOSPITAL] MD friend. I typically, patiently, point out that our son is on 4'heavy duty anti seizure medicines, has been most of his life, that can't be increased due to ill effects, has a VNS, yet is still slammed to the ground, on to his face, from seizures many times a day, or can't breath for up to 30 seconds during a tonic seizure. So are we not to try anything that might help?! Now, 3-months in to starting medical cannabis, I can show anyonemwho,asks how,it is,going his seizure diary, where there are far fewer entries for daily seizures. Just a glance at my son's monthly calendar these past 3

months tells it all. Is medical cannabis perfect? No, it is not as fast acting as anti seizure mess (for those that work), it is a very slow process, ramping up the oil, trying to get it just right. The beauty of medical cannabis is that we are seeing no negative side effects! No shortening of his QT waves, no lowered white blood cell counts, no rage and attacks on family. Just a slow improvement on seizures, making all of our lives so much easier.

- People laugh when I tell them I'm trying Medical Marijuana. No one believes it can help they believe it's only recreation. The only people that understand are people like me that have run out of options.
- Public opinion.
- Stigma of MJ
- I have only shared that I use cannabis to very few people. One person shared her (negative) opinion. I let go of her.
- The only negative effect is the possible stigma that I face from using, what most people consider, a drug.
- Getting over the stigma of marijuana use in society. I.E. Some family members don't approve.

3

- New neighbors felt that it wasn't right for anyone to use medical cannabis.

4

- Care providers, other than my registered provider, that are apprehensive to participate in the program. Lack of education, wide spread communication in the medical community regarding the benefits and laws regarding medical cannabis in MN.
- Medical communities (hospitals) need to be educated on medical cannabis. We were not allowed to bring into the hospital
- embarrassment taking treatment with others around.

5

- People saying that I am on drugs
- Doctors don't want to treat medical cannabis patients. Cost.

Other Negative Effects

No Score

- Need more distributors

1: No Negative Effects

- It hasn't worked to stop her seizures
- any breakthrough seizures. [PATIENT] had 3 in November, yet none this month as of this writing.
- Not able to use it. Didn't like it and did not feel relief

- the same amount does not always have the same effect every time
- Wish it worked better.
- The pen leaks??
- not having proper bottle caps for liquid cannabis
- Running out month ago I have not been able to function
- OTHER TREATING PAIN CLINIC IS PROHIBITING USE OF MEDICAL MARIJUANA SO I HAVE BEEN UNABLE TO TAKE IT THE LAST 30 + DAYS
- I wish they could leave more of the recreational in the pot, it helps me forget that I have MS for a while, and street pot does this I think it's part of the therapy. So I am having a hard time giving up my street pot.
- Maybe if they add more so it can last longer it leaves so quickly even if I measure the time.
- A negative impact of having only THC and CBD products is that they aren't as effective as natural whole plant cannabis.

2

- Not fully effective
- Seizures cluster after 7 days or so and she gets tired too.
- Inconsistency of seizure activity.
- It took several tries to find an appropriate dosage and combination to work at minimizing tics.
- It has not helped the increased ammonia level [PATIENT] has had the past few years. With the direction of his neurologist, we are currently weaning off one of his seizure medications, depakote, which he has been taking for 26 years! We are hopeful that this may help reduce the ammonia level.
- Haven't been able to find the right form of treatment (Suspension/Vape/Pills) that works best for me.
- Prefer the oil but trying to utilize the syringe with my fingers is really tough! Would really like it if I could administer the oil myself with a different tool.
- I would like to have a type for bedtime. I can't always get to sleep and while I have cut down my 2 50mg a night Trazadone to one one 50mg maybe 3-4 times per week.
- Trying to determine correct dosages.
- I can't get other medicines due to being on this program.
- Having to take the medicine several times per day.
- having to refrigerate pills. if the tincture does not require refrigeration, I may try that...
- Program does not allow enough "options" or other products..VERY limited

3

- I do not want to drive after using medical cannabis for fear of being arrested for DUI even if I can pass the roadside sobriety tests because my blood has THC in it and I could

be charged with DUI just from using medical cannabis even if I have not used it for days before driving.

- Worry about changing jobs/company due to drug testing
- Im worried about my employer or future employment drug testing
- Regulating the correct amount and type correct which takes time and experience. Much easier to do with the pills it seems for me personally as smoking it made my lungs worse and often times would be hard for me to control the dosage.
- I would like more edible options

4

- I have more anxiety that police may take me for a blood test of charge me with DUI if they know I'm a patient at dispensary. I also had a Warning of illegal drug use in a urine test from the so called pain clinic I'm required to go to by [CLINIC] By my now ex primary Dr of 20 years. I told the pain clinic when I signed contract not to use illegal drugs that I took cannabis by prescription in medical form thru Dept of Health etc. The Dr said OK, as long as it wasn't in organic form for smoking! He said I was the 1st patient at [CLINIC] to be on legal cannabis. I advised him, I maybe to 1st but surely not the last patient. They said this will be resolved ok but I still was warned for illegal thc drug use, which is upsetting but it will be straightened out. Thank u!!
- The stick does not always work
- I have sciatica nerve pain, and don't get as much pain relief for that. Also, it is hard to get the dosages down right so that a steady stream of it stays in your system. I mainly use the gel caps.
- No help with seizures.
- As an adult with muscle spasms I need [HIGH CBD PRODUCT] or maybe even [HIGH CBD PRODUCT], I would like to have a broader range of treatments on the CBD CBD range. I understand that this is more for children, but vaporizer for adults would be wonderful. I can not take pills due to stomach problems. I do have vaporizers to help with pain, sleeping issues due to spasms. Please consider more CBD CBD VAPORIZERS for adults.
- Some negative ONLY because of the MCT, not the cannabis it self! Why do they add such an expensive product like (MCT) to something when it could be more reasonably priced without it??? I had to really do my research on MCT to know what this awful stuff can do. There is blog after blog with people complaining about MCT. There are people out there that have not done their research and think it is the cannabis. It is really too bad because they could really benefit from the cannabis without the MCT. Again it would be cheaper without the MCT in it.
- Variations in batches.
- Not quite strong enough or
- could use more

5

- Continued loose to diarrhea stools.
- Because certain types are not available yet, i haven't been able to try all of the varieties. Having all of them available may give patients better options as to what works best, especially in the first few months. I experience both muscle spasms and chronic pain, and have seen benefit from [1:1 THC:CBD PRODUCTS] and occasionally [HIGH THC PRODUCT]. But I do wonder if one of the other colors would work longer.

6

- Mixed strains make the medication unreliable. Made him very sedated and "high" acting even at very low doses.

7: Great Deal of Negative Effects

- My ex using it as an excuse to get custody of my children
- Seizures are the same and mobility is still down. She walks and sits hunched over:(

Benefits Reported on the Patient Self-Evaluation: Patients with First Enrollment July 2015-June 2017

Summary

Of patients included on the standard 8 symptom analysis (n = 6924), more than half experienced moderate to severe symptoms at baseline on all measures except for nausea (49%) and vomiting (23%). Of patients experiencing moderate to severe symptoms at baseline, anywhere between 33% and 66% achieved at least a 30% reduction in symptom severity (symptom improvement) within 4 months of their first medical cannabis purchase. The lowest proportion of patients reporting symptom improvements in the initial 4-month period were for pain (33%) and fatigue (44%) symptoms, while the greatest proportion of patients reporting symptom improvements were for vomiting (66%), nausea (60%), depression (59%), and lack of appetite (58%) symptoms. Similarly, a smaller proportion of patients were able to maintain those symptom improvements in the following 4-months for pain (41%) and fatigue (50%) symptoms compared to all other symptoms (maintained anywhere by 56%-66% of patients).

Benefits Reported on the Patient Self-Evaluation: Patients with First Enrollment July 2015-June 2017

The patient self-evaluation is required for patients to complete prior to each medical cannabis purchase. It includes questions to assess symptom severity, some of which are administered to all patients (standard set of 8 symptom measures) and some of which are tailored to symptoms for a given condition (condition-specific symptom measures). Since symptom data is collected prior to each patient's first medical cannabis purchase, symptom changes can be assessed over time and compared to baseline (baseline = patient responses to symptom questions just prior to their first medical cannabis purchase).

Standard 8 Symptom Measures

The standard 8 symptom measures that all patients receive are answered on a 0-10 numerical rating scale (NRS), with 0 indicating absence of the symptom to 10 indicating that the symptom is as bad as the patient can imagine (see Box 1). Therefore, higher scores on these measures indicate poorer management of these symptoms. Patients are asked to rate symptom severity over the past 24 hours.

Box 1. Listing of the Standard 8 symptom measures that all patients answer, including the response options available to patients.

<u>Standard 8 Symptom Measures:</u>										
Anxiety					Fatigue					
Lack of Appetite					Nausea					
Depression					Pain					
Disturbed Sleep					Vomiting					
<u>Response Options (0 – 10 NRS):</u>										
0 1 2 3 4 5 6 7 8 9 10										
Symptom not present					Symptom as bad as one can image					

To understand whether patients derived any symptom benefits during their participation in the program, the following two questions were explored for each Standard 8 symptom measure:

QUESTION 1

Of those patients who experienced moderate to severe symptoms at baseline (score of 4 or higher at baseline), what percentage of them experienced at least a 30% improvement in symptoms within four months of their first medical cannabis purchase? The threshold of $\geq 30\%$ reduction on a 0-10 point scale was chosen because this threshold has been documented in clinical trials to represent clinically meaningful change – especially for pain reduction and spasticity reduction. Examples of $\geq 30\%$ change include moving from a score of 10 to a score of 7, from 9 to 6, from 8 to 5, from 7 to 4, etc.

QUESTION 2

If a patient achieved at least a 30% improvement on symptoms within 4 months of their first medical cannabis purchase (determined in Question 1), what percentage of them will, on average, still maintain that level of improvement in the four months following that initial 30% symptom improvement? [Four-month follow-up period]

Results on Standard 8 Symptom Measures

See Table 1 for results. The third column displays the percentage and number of patients (out of 6924 patients) experiencing moderate to severe symptoms at baseline (baseline response ≥ 4) on a given Standard 8 measure. Fourth column represents answer to Question 1: percentage (and number) of moderate to severe scorers at baseline who achieved at least a 30% symptom improvement at any time within 4 months of their first medical cannabis purchase. Fifth column

BENEFITS REPORTED ON THE PATIENT SELF-EVALUATION: PATIENTS WITH FIRST
ENROLLMENT JULY 2015-JUNE 2017

shows the number of patients that had submitted symptom data during their designated 4-mo follow-up period (4 month time window that followed their initial symptom improvement). Symptom responses during this 4-mo time period were averaged together within each patient. The sixth column shows the percentage and number of patients who had achieved $\geq 30\%$ symptom improvement that had – on average – maintained at least that level of improvement in the 4-month follow-up period. Lastly, the seventh column shows the percentage of all patients who both achieved at least a 30% improvement in the first 4 months since their first medical cannabis purchase and maintained that improvement on average in the 4-month follow-up period.

Table 1. Overall Standard 8 Symptom Results (n = 6924).

All patients collapsed across conditions (n=6924)

*within 4 months of First Purchase (n)

**for at least 4 months (n)

Standard 8 Symptom Measure	% of Patients Reporting at Moderate to Severe Symptoms at Baseline (n)	% of Patients Achieving $\geq 30\%$ Symptom Improvement*	# of Patients with Data in 4-mo Period Following Initial $\geq 30\%$ Symptom Improvement	% of Patients Who Achieved $\geq 30\%$ Symptom Improvement that Maintained it**	% of Patients that Both Achieved $\geq 30\%$ Symptom Improvement and Maintained It**
Anxiety	76.1 (5270)	56.4 (2972)	2449	58.0 (1724)	32.7
