Besides the Standard 8 measures which are administered to all patients, some patients received additional symptom questions on the PSE to more adequately address condition-specific symptoms. These include, among others, questions on seizure frequency for seizure patients, questions on spasm frequency for muscle spasm and ALS patients, and Crohn's activity in Crohn's patients. While patients received the same response options on the Standard 8 measures (respond from 1-10 on a numerical rating scale), response options for condition-specific measures varied as indicated in Table 12.

All condition-specific measures were investigated within the same framework as the Standard 8 measures: 1) what percentage of patients achieved symptom improvement within the four months since their first medical cannabis purchase compared to their baseline responses, and 2) what percentage of those achieving symptom improvement showed general persistence in the 4-month follow-up period. A summary of results are similarly presented in a table like those presented for the Standard 8 measures (see Table 12 below).

Glaucoma patients were also administered their own condition-specific measure, which was to report on the most recent intraocular pressure test (IOP) result and the date the test was administered on each patient self-evaluation. However, rather than analyzing for changes on the IOP test compared to a baseline IOP result, these results are presented below as reported by the patients (see Table 13). All IOP test results represented to the left of the “First Visit” column indicate results from tests occurring prior to the patient’s first medical cannabis purchase; everything to the right of that column are results occurring after the patient’s first purchase. Column names refer to month in which the test was reported to occur prior to or after first purchase. Note that these results are not directly coming from the practitioner who administered the IOP test – reliance on patient documentation and/or memory is a limitation in interpreting these results.

Caution is needed when interpreting the patient self-reported intra-ocular pressure results. It is possible that patients report incorrect values and dates of testing. Importantly, reported data provides little or no insight into changes in glaucoma therapies or other medications during the period after medical cannabis initiation. And, though we have record of which products are purchased when, without patient-level comparison of changes in product with changes in observed effect, we could miss differential impact of products. That analysis is beyond the scope of this report. With those caveats, we make the following summary observations.

After initiating medical cannabis use, 23 of the 61 patients (38%) reported intraocular pressure measurements with a decrease in intraocular pressure (IOP) ≥ 4 mm Hg in at least one eye, 18 (30%) reported no follow-up results in the year after medical cannabis initiation, and 20 (33%) reported follow-up values with no decrease in IOP ≥ 4 mm Hg (three had IOP decrease = 3 mm Hg in one eye).

Among the 23 showing a decrease in IOP ≥ 4 mm Hg, 17 reported more than one measurement during the year after following medical cannabis initiation. Among these 17 with multiple reported measurements, the ≥ 4 mm Hg decrease in IOP was present in the first reported post-initiation result for eleven (at months 1[x6], 2[x3], 3, and 4). In six patients, the ≥ 4 mm Hg decrease in IOP wasn't seen in initial reported result(s), but was present in a later result (at months 4, 5, 7, 8[x2], and 9). Among the six with only one post-initiation reported result, the ≥ 4 mm Hg decrease in IOP was seen at months 1, 2, 3[x2], 4, and 10. From these patterns, it appears that if medical cannabis use results in decreased IOP, the timing of that effect varies considerably.

Benefits Reported on the Patient Self-Evaluation: Patients with First Enrollment July 2016-June 2017

Summary

Of patients included on the standard 8 symptom analysis (n = 5412), more than half experienced moderate to severe symptoms at baseline on all measures except for nausea (46%) and vomiting (20%). Of patients experiencing moderate to severe symptoms at baseline, anywhere between 32% and 68% achieved at least a 30% reduction in symptom severity (symptom improvement) within 4 months of their first medical cannabis purchase. The lowest proportion of patients reporting symptom improvements in the initial 4-month period were for pain (32%) and fatigue (45%) symptoms, while the greatest proportion of patients reporting symptom improvements were for vomiting (68%), nausea (61%), depression (60%), and lack of appetite (59%) symptoms. Similarly, a smaller proportion of patients were able to maintain those symptom improvements in the following 4-months for pain (40%) and fatigue (50%) symptoms compared to all other symptoms (maintained anywhere by 57%-69% of patients).

Benefits Reported on the Patient Self-Evaluation: Patients with First Enrollment July 2016-June 2017

The patient self-evaluation is required for patients to complete prior to each medical cannabis purchase. It includes questions to assess symptom severity, some of which are administered to all patients (standard set of 8 symptom measures) and some of which are tailored to symptoms for a given condition (condition-specific symptom measures). Since symptom data is collected prior to each patient's first medical cannabis purchase, symptom changes can be assessed over time and compared to baseline (baseline = patient responses to symptom questions just prior to their first medical cannabis purchase).

Standard 8 Symptom Measures

The standard 8 symptom measures that all patients receive are answered on a 0-10 numerical rating scale (NRS), with 0 indicating absence of the symptom to 10 indicating that the symptom is as bad as the patient can imagine (see Box 1). Therefore, higher scores on these measures indicate poorer management of these symptoms. Patients are asked to rate symptom severity over the past 24 hours.

Box 1. Listing of the Standard 8 symptom measures that all patients answer, including the response options available to patients.

Standard 8 Symptom Measures:

Anxiety; Lack of appetite; Depression; Disturbed Sleep; Fatigue; Nausea; Pain; Vomiting

Response Options (0-10 Numerical Rating Scale):

0 = Symptom not present;

10 = Symptom as bad as one can imagine

To understand whether patients derived any symptom benefits during their participation in the program, the following two questions were explored for each Standard 8 symptom measure:

QUESTION 1

Of those patients who experienced moderate to severe symptoms at baseline (score of 4 or higher at baseline), what percentage of them experienced at least a 30% improvement in symptoms within four months of their first medical cannabis purchase? The threshold of $\geq 30\%$ reduction on a 0-10 point scale was chosen because this threshold has been documented in clinical trials to represent clinically meaningful change – especially for pain reduction and spasticity reduction. Examples of $\geq 30\%$ change include moving from a score of 10 to a score of 7, from 9 to 6, from 8 to 5, from 7 to 4, etc.

QUESTION 2

If a patient achieved at least a 30% improvement on symptoms within 4 months of their first medical cannabis purchase (determined in Question 1), what percentage of them will, on average, still maintain that level of improvement in the four months following that initial 30% symptom improvement? [Four-month follow-up period]

To address Question 1 the following procedure was adopted for each standard 8 measure: all patients who scored 4 or higher at baseline were identified as those experiencing moderate to severe symptoms, and all standard 8 responses that were submitted within 4 months of their first medical cannabis purchase were retained. From this dataset, each patient's standard 8 responses were compared to their baseline response over time. The first instance a patient achieved at least a 30% symptom improvement was recorded, effectively demonstrating when – during the first 4 months following their first medical cannabis purchase – the patient achieved symptom improvement, if at all.

Calculating the percentage of patients who achieved $\geq 30\%$ symptom improvement within 4 months of their first medical cannabis purchase (Question 1) was done in two ways. In one method, the number of patients who achieved $\geq 30\%$ symptom improvement within 4 months

was divided by the total number of patients that ever made a first purchase (patients with baseline PSE data). In the other method, the number of patients achieving $\geq 30\%$ symptom improvement within 4 months was divided by patients who had submitted additional PSE data (beyond their baseline response) within 4 months of their first purchase. The denominator in the former method includes all patients who made a first purchase (all patients with a baseline PSE submission), while the latter method effectively restricts the denominator to those patients who submitted additional PSE symptom data following their baseline submission and within 4 months of their first purchase. Therefore, the former method allows for a more conservative estimation of symptom benefit. In the text of this report, we present results using the former, more conservative estimate of benefit. Those who made no additional purchases after their first purchase may have discontinued use because of lack of effectiveness, though they may have discontinued use for other reasons as well (i.e., medical cannabis cost, side effects, etc.).

Question 2 was addressed by observing all symptom responses in the four months following the time point when the patient first achieved $\geq 30\%$ symptom improvement. For each patient, all symptom responses identified during those follow-up four months were averaged together. Patients who, on average, still maintained at least a 30% symptom improvement from baseline were identified as those showing persistence in their symptom benefits.

Results on Standard 8 Symptom Measures

See Table 1 for results. The third column displays the percentage and number of patients (out of 5412 patients) experiencing moderate to severe symptoms at baseline (baseline response ≥ 4) on a given Standard 8 measure. Fourth column represents answer to Question 1: percentage (and number) of moderate to severe scorers at baseline who achieved at least a 30% symptom improvement at any time within 4 months of their first medical cannabis purchase. Fifth column shows the number of patients that had submitted symptom data during their designated 4-mo follow-up period (4 month time window that followed their initial symptom improvement). Symptom responses during this 4-mo time period were averaged together within each patient. The sixth column shows the percentage and number of patients who had achieved $\geq 30\%$ symptom improvement that had – on average – maintained at least that level of improvement in the 4-month follow-up period. Lastly, the seventh column shows the percentage of all patients who both achieved at least a 30% improvement in the first 4 months since their first medical cannabis purchase and maintained that improvement on average in the 4-month follow-up period.

Condition-Specific Symptom Measures

Besides the Standard 8 measures which are administered to all patients, some patients received additional symptom questions on the PSE to more adequately address condition-specific symptoms. These include, among others, questions on seizure frequency for seizure patients, questions on spasm frequency for muscle spasm and ALS patients, and Crohn's activity in Crohn's patients. While patients received the same response options on the Standard 8 measures (respond from 1-10 on a numerical rating scale), response options for condition-specific measures varied as indicated in Table 12.

All condition-specific measures were investigated within the same framework as the Standard 8 measures: 1) what percentage of patients achieved symptom improvement within the four months since their first medical cannabis purchase compared to their baseline responses, and 2) what percentage of those achieving symptom improvement showed general persistence in the 4-month follow-up period. A summary of results are similarly presented in a table like those presented for the Standard 8 measures (see Table 12 below).

Glaucoma patients were also administered their own condition-specific measure, which was to report on the most recent intraocular pressure test (IOP) result and the date the test was administered on each patient self-evaluation. However, rather than analyzing for changes on the IOP test compared to a baseline IOP result, these results are presented below as reported by the patients (see Table 13). All IOP test results represented to the left of the “First Visit” column indicate results from tests occurring prior to the patient’s first medical cannabis purchase; everything to the right of that column are results occurring after the patient’s first purchase. Column names refer to month in which the test was reported to occur prior to or after first purchase. Note that these results are not directly coming from the practitioner who administered the IOP test – reliance on patient documentation and/or memory is a limitation in interpreting these results.

Caution is needed when interpreting the patient self-reported intra-ocular pressure results. It is possible that patients report incorrect values and dates of testing. Importantly, reported data provides little or no insight into changes in glaucoma therapies or other medications during the period after medical cannabis initiation. And, though we have record of which products are purchased when, without patient-level comparison of changes in product with changes in observed effect, we could miss differential impact of products. That analysis is beyond the scope of this report. With those caveats, we make the following summary observations.

After initiating medical cannabis use, fifteen of the 40 patients (38%) reported intraocular pressure measurements with a decrease in intraocular pressure (IOP) ≥ 4 mm Hg in at least one eye, 14 (35%) reported no follow-up results in the year after medical cannabis initiation, and 11 (28%) reported follow-up values with no decrease in IOP ≥ 4 mm Hg (three had IOP decrease = 3 mm Hg in one eye).

Among the 15 showing a decrease in IOP ≥ 4 mm Hg, 11 reported more than one measurement during the year after following medical cannabis initiation. Among these 11 with multiple reported measurements, the ≥ 4 mm Hg decrease in IOP was present in the first reported post-initiation result for six (at months 1[x3], 2[x2], and 3). In five patients, the ≥ 4 mm Hg decrease in IOP wasn't seen in initial reported result(s), but was present in a later result (at months 4, 5, 7, and 8 [x2]). Among the four with only one post-initiation reported result, the ≥ 4 mm Hg decrease in IOP was seen at months 3[x2], 4, and 10. From these patterns, it appears that if medical cannabis use results in decreased IOP, the timing of that effect varies considerably.

Benefits Reported on the Patient Self-Evaluation: Patients with First Enrollment July 2015-June 2016

Summary

Of patients included on the standard 8 symptom analysis (n = 1512), more than half experienced moderate to severe symptoms at baseline on all measures except for vomiting (32%). Of patients experiencing moderate to severe symptoms at baseline, anywhere between 36% and 60% achieved at least a 30% reduction in symptom severity (symptom improvement) within 4 months of their first medical cannabis purchase. The lowest proportion of patients reporting symptom improvements in the initial 4-month period were for pain (36%) and fatigue (40%) symptoms, while the greatest proportion of patients reporting symptom improvements were for vomiting (60%), depression (57%), and nausea (56%) symptoms. Similarly, a smaller proportion of patients were able to maintain those symptom improvements in the following 4-months for pain (45%) and fatigue (49%) symptoms compared to all other symptoms (maintained anywhere by 52%-59% of patients).

Benefits Reported on the Patient Self-Evaluation: Patients with First Enrollment July 2015-June 2016

The patient self-evaluation is required for patients to complete prior to each medical cannabis purchase. It includes questions to assess symptom severity, some of which are administered to all patients (standard set of 8 symptom measures) and some of which are tailored to symptoms for a given condition (condition-specific symptom measures). Since symptom data is collected prior to each patient's first medical cannabis purchase, symptom changes can be assessed over time and compared to baseline (baseline = patient responses to symptom questions just prior to their first medical cannabis purchase).

Standard 8 Symptom Measures

The standard 8 symptom measures that all patients receive are answered on a 0-10 numerical rating scale (NRS), with 0 indicating absence of the symptom to 10 indicating that the symptom is as bad as the patient can imagine (see Box 1). Therefore, higher scores on these measures indicate poorer management of these symptoms. Patients are asked to rate symptom severity over the past 24 hours.

Box 1. Listing of the Standard 8 symptom measures that all patients answer, including the response options available to patients.

Standard 8 Symptom Measures:

Anxiety; Lack of appetite; Depression; Disturbed Sleep; Fatigue; Nausea; Pain; Vomiting

Response Options (0-10 Numerical Rating Scale):

0 = Symptom not present;

10 = Symptom as bad as one can imagine

To understand whether patients derived any symptom benefits during their participation in the program, the following two questions were explored for each Standard 8 symptom measure:

QUESTION 1

Of those patients who experienced moderate to severe symptoms at baseline (score of 4 or higher at baseline), what percentage of them experienced at least a 30% improvement in symptoms within four months of their first medical cannabis purchase? The threshold of $\geq 30\%$ reduction on a 0-10 point scale was chosen because this threshold has been documented in clinical trials to represent clinically meaningful change – especially for pain reduction and spasticity reduction. Examples of $\geq 30\%$ change include moving from a score of 10 to a score of 7, from 9 to 6, from 8 to 5, from 7 to 4, etc.

QUESTION 2

If a patient achieved at least a 30% improvement on symptoms within 4 months of their first medical cannabis purchase (determined in Question 1), what percentage of them will, on average, still maintain that level of improvement in the four months following that initial 30% symptom improvement? [Four-month follow-up period]

Results on Standard 8 Symptom Measures

See Table 1 for results. The third column displays the percentage and number of patients (out of 1,512 patients) experiencing moderate to severe symptoms at baseline (baseline response ≥ 4) on a given Standard 8 measure. Fourth column represents answer to Question 1: percentage (and number) of moderate to severe scorers at baseline who achieved at least a 30% symptom improvement at any time within 4 months of their first medical cannabis purchase. Fifth column shows the number of patients that had submitted symptom data during their designated 4-mo follow-up period (4 month time window that followed their initial symptom improvement). Symptom responses during this 4-mo time period were averaged together within each patient. The sixth column shows the percentage and number of patients who had achieved $\geq 30\%$

BENEFITS REPORTED ON THE PATIENT SELF-EVALUATION: PATIENTS WITH FIRST
ENROLLMENT JULY 2015-JUNE 2016

symptom improvement that had – on average – maintained at least that level of improvement in the 4-month follow-up period. Lastly, the seventh column shows the percentage of all patients who both achieved at least a 30% improvement in the first 4 months since their first medical cannabis purchase and maintained that improvement on average in the 4-month follow-up period.

Condition-Specific Symptom Measures

Besides the Standard 8 measures which are administered to all patients, some patients received additional symptom questions on the PSE to more adequately address condition-specific symptoms. These include, among others, questions on seizure frequency for seizure patients, questions on spasm frequency for muscle spasm and ALS patients, and Crohn's activity in Crohn's patients. While patients received the same response options on the Standard 8 measures (respond from 1-10 on a numerical rating scale), response options for condition-specific measures varied as indicated in Table 11.

All condition-specific measures were investigated within the same framework as the Standard 8 measures: 1) what percentage of patients achieved symptom improvement within the four months since their first medical cannabis purchase compared to their baseline responses, and 2) what percentage of those achieving symptom improvement showed general persistence in the 4-month follow-up period. A summary of results are similarly presented in a table like those presented for the Standard 8 measures (see Table 11 below).

Table 11. Results on Symptom Improvements on Condition-Specific Measures.

*within 4 months of First Purchase (n)

**for at least 4 months (n)

Condition	Condition-Specific Symptom Measure	# of Patients Included in Analysis	% of Patients Achieving Threshold Symptom Improvement*	# of Patients with Data in 4-mo Period Following Initial Threshold Symptom Improvement	% of Patients Who Achieved Threshold Symptom Improvement that Maintained it**	% of Patients that Both Achieved Threshold Symptom Improvement and Maintained it**
Muscle Spasms	Weekly Spasms Frequency	629	48.0 (302)	225	57.6 (174)	27.6
	0-10 Spasticity Scale	618	36.4 (225)	197	47.1 (106)	17.2

	0-10 Spasticity Scale	15	20.0 (3)	3	100.0 (3)	20.0

Glaucoma patients were also administered their own condition-specific measure, which was to report on the most recent intraocular pressure test (IOP) result and the date the test was administered on each patient self-evaluation. However, rather than analyzing for changes on the IOP test compared to a baseline IOP result, these results are presented below as reported by the patients (see Table 12). All IOP test results represented to the left of the “First Visit” column indicate results from tests occurring prior to the patient’s first medical cannabis purchase; everything to the right of that column are results occurring after the patient’s first purchase. Column names refer to month in which the test was reported to occur prior to or after first purchase. Note that these results are not directly coming from the practitioner who administered the IOP test – reliance on patient documentation and/or memory is a limitation in interpreting these results.

Table 12 Continued. Patient-Reported Intraocular Pressure Test Results from Glaucoma Patients (n = 21): Left Eye/Right Eye.

21						17 / 26	17 / 28		20 / 25				19 / 20				24 / 28

Caution is needed when interpreting the patient self-reported intra-ocular pressure results. It is possible that patients report incorrect values and dates of testing. Importantly, reported data provides little or no insight into changes in glaucoma therapies or other medications during the period after medical cannabis initiation. And, though we have record of which products are purchased when, without patient-level comparison of changes in product with changes in observed effect, we could miss differential impact of products. That analysis is beyond the scope of this report. With those caveats, we make the following summary observations.

After initiating medical cannabis use, eight of the 21 patients (38%) reported intraocular pressure measurements with a decrease in intraocular pressure (IOP) ≥ 4 mm Hg in at least one eye, 4 (19%) reported no follow-up results in the year after medical cannabis initiation, and 9 (43%) reported follow-up values with no decrease in IOP ≥ 4 mm Hg.

Among the 8 showing a decrease in IOP ≥ 4 mm Hg, 6 reported more than one measurement during the year after following medical cannabis initiation. Among these 6 with multiple reported measurements, the ≥ 4 mm Hg decrease in IOP was present in the first reported post-initiation result for five (at months 1[x3], 2, and 4). In one patient, the ≥ 4 mm Hg decrease in IOP wasn't seen in the initial reported result, but was present in a later result (at month 9). Among the two with only one post-initiation reported result, the ≥ 4 mm Hg decrease in IOP was seen at months 1 and 2. From these patterns, it appears that if medical cannabis use results in decreased IOP, that effect usually occurs within the first few months but can vary.

SB174

Measure Title: RELATING TO MEDICAL MARIJUANA.

Report Title: Medical Marijuana; Debilitating Medical Condition

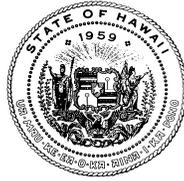

Description: Amends the definition of debilitating medical condition to include lupus, epilepsy, multiple sclerosis, arthritis, autism, anxiety, depression, insomnia, and stress as conditions that qualify for the legal use of medical marijuana.

Companion:

Package: None

Current Referral: CPH, JDL

Introducer(s): ESPERO, ENGLISH, RUDERMAN, S. Chang, Dela Cruz, Gabbard, Galuteria, Kidani

STATE OF HAWAII
DEPARTMENT OF HEALTH
P. O. Box 3378
Honolulu, HI 96801-3378
doh.testimony@doh.hawaii.gov

**Testimony in OPPOSITION to SB174
RELATING TO MEDICAL MARIJUANA**

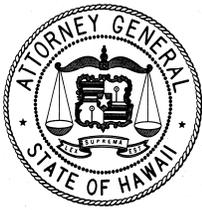

SENATOR ROSALYN H. BAKER, CHAIR
SENATE COMMITTEE ON COMMERCE, CONSUMER PROTECTION, AND HEALTH

Hearing Date: February 8, 2017

Room Number: 229

1 **Fiscal Implications:** None

2 **Department Testimony:** The purpose of this bill is to amend the list of debilitating conditions
3 for the medical use of marijuana by adding a number of new conditions. The Department
4 opposes the passage of new laws related to marijuana until the medical marijuana dispensaries
5 open and we can gauge the impact upon the State. The Department through its Hawaii
6 Administrative Rules §11-160-7 has already laid out a comprehensive annual process to consider
7 addition or deletion of qualifying conditions for the medical use of marijuana. Physicians or
8 potential medical marijuana patients may petition the Department for new conditions. This
9 process will focus on all available medical evidence and research on efficacy and safety for
10 patients. It will include a public hearing where testimony from the public can be provided. The
11 Department has already queried registering physicians and several plan to petition for a variety
12 of conditions. The first annual petition process will be implemented this year. Decisions will be
13 grounded in science that shows that medical marijuana helps treat or relieve any proposed
14 additional conditions.
15 Thank you for the opportunity to testify.

**TESTIMONY OF
THE DEPARTMENT OF THE ATTORNEY GENERAL
TWENTY-NINTH LEGISLATURE, 2017**

ON THE FOLLOWING MEASURE:

S.B. NO. 174, RELATING TO MEDICAL MARIJUANA.

BEFORE THE:

SENATE COMMITTEE ON COMMERCE, CONSUMER PROTECTION, AND HEALTH

DATE: Wednesday, February 8, 2017 **TIME:** 9:00 a.m.

LOCATION: State Capitol, Room 229

TESTIFIER(S): Douglas S. Chin, Attorney General, or
Jill T. Nagamine, Deputy Attorney General

Chair Baker and Members of the Committee:

The Department of the Attorney General opposes this bill. We generally oppose the passage of new laws related to marijuana until the medical marijuana dispensaries open and we get the chance to gauge the impact on the State.

This bill would expand the list of medical conditions for which a patient can be certified for the medical use of marijuana. It would add lupus, epilepsy, multiple sclerosis, arthritis, autism, anxiety, depression, insomnia, and stress to the list of debilitating medical conditions already approved in section 329-121, Hawaii Revised Statutes.

The Attorney General's specific concern about this bill is that, without a scientific or other basis to indicate that the use of marijuana helps treat or provide relief for the additional proposed conditions, the proposed expansion may appear to move the State closer to deregulation of marijuana, a schedule I controlled substance under federal law. Adding so many new conditions, some of which are common and have multiple traditional treatments, could be viewed by the federal government as contrary to the goal of having a robust regulatory scheme for the medical use of marijuana in Hawaii.

We respectfully ask this Committee to hold this bill.

Dedicated to safe, responsible, humane and effective drug policies since 1993

TO: Senate Committee on Commerce, Consumer Protection and Health
FROM: Carl Bergquist, Executive Director
HEARING DATE: 9 February 2017, 9AM
RE: SB174, Relating to Medical Marijuana, **SUPPORT**

Dear Chair Baker, Vice Chair Nishihara, Committee Members:

The Drug Policy Forum of Hawai'i (DPFHI) supports this measure to add various new medical conditions as qualifying for the legal use of medical cannabis in Hawai'i. Several of these conditions are specifically listed by various other states (lupus, autism, multiple sclerosis, arthritis and epilepsy) while the others (anxiety, depression, insomnia or stress) are broad conditions with symptoms that are arguably better relieved with medical cannabis than with various prescription pharmaceutical products.

While we support the Department of Health's ongoing process to set up a petition process to add further conditions – indeed we are planning to help petition for “opiate use disorder” – we see it as a complement to expeditiously adding specific conditions by statute. Accordingly, we respectfully request your support for this bill that can help relieve the suffering of many patients who otherwise may find no relief or risk becoming addicted to more powerful narcotics.

Mahalo for the opportunity to testify.

SB174

Submitted on: 2/6/2017

Testimony for CPH on Feb 8, 2017 09:00AM in Conference Room 229

Submitted By	Organization	Testifier Position	Present at Hearing
Michelle Tippens	Hawaii Veteran's Cannabis Alliance	Support	Yes

Comments: Aloha members of the Senate Committee on Commerce, Consumer Protection, and Health. My name is Michelle Tippens, I am the founder and Executive Director of the Hawaii Veteran's Cannabis Alliance and Legislative Liaison for the Libertarian Party of Hawaii. These comments are regarding measure SB174, heard February 8, 2017 at 9am. As an expert in the field of Criminal Justice (I hold both a BA and MS in the field), specializing in vice and drug crimes, I have a well-documented academic background and demonstrated aptitude in all aspects of the Crime and Justice field, including an extensive knowledge regarding the development of American drug law. Along with this, I am a veteran of the US Army, single mother of 4 and medical marijuana patient. Although I look "healthy" to most people, I not only suffer from PTSD, I also have fibromyalgia, prosthetic neck implants, 5 fractured thoracic vertebrae and several other injuries. I am able to manage all of these conditions with cannabis therapy and was able to discontinue use of a pulmonary walker in 2012, less than two years after beginning cannabis therapy. When examining SB174 it is easy to see this piece of legislation is a positive step toward ensuring patients with severe, debilitating diseases have a full complement of treatment options available to them. Both the HVCA and I feel this legislation reflects the desire of the Hawaiian people to see the medical use of marijuana program expanded to cover more conditions. I personally support this legislation and the HVCA is in support of this legislation, particularly considering many of the conditions mentioned are commonly diagnosed in our veterans.

Please note that testimony submitted less than 24 hours prior to the hearing, improperly identified, or directed to the incorrect office, may not be posted online or distributed to the committee prior to the convening of the public hearing.

HAWAII EDUCATIONAL ASSOCIATION FOR LICENSED THERAPEUTIC HEALTHCARE

To: Senator Rosalyn Baker, Chair Consumer Protection and Health
Senator Clarence Nishihara, Vice-Chair Consumer Protection and
Health
Members of the Senate Consumer Protection and Health Committee

Fr: Blake Oshiro, Esq. on behalf of the HEALTH Assn.

Re: Testimony in **Support of Senate Bill (SB) 174**

RELATING TO MEDICAL MARIJUANA.

Amends the definition of debilitating medical condition to include lupus, epilepsy, multiple sclerosis, arthritis, autism, anxiety, depression, insomnia, and stress as conditions that qualify for the legal use of medical marijuana.

Dear Chair Baker, Vice-Chair Nishihara, and Members of the Committee:

HEALTH is a recently formed trade association made up of the eight (8) licensed medical marijuana dispensaries under Haw. Rev. Stat. (HRS) Chapter 329D. HEALTH's members are all committed to ensuring the goals of patient safety, product safety and public safety.

We **strongly support** SB174 which adds additional conditions to qualify for the legal use of medical marijuana. Attached, is a list of the state's that allow medical marijuana and the qualifying conditions. See <https://www.leafly.com/news/health/qualifying-conditions-for-medical-marijuana-by-state>

While we note that the range of conditions vary state to state with some more restrictive, some broader, than Hawaii, we think it is important to note that Hawaii was one of the first states to authorize the use of medical marijuana program in 2000. Yet, since that time, the list of conditions remained the same until 2015's Act 241 added "post-traumatic stress disorder."

However, we believe that there is an abundance of evidence to demonstrate and substantiate the medicinal benefits of medical marijuana for certain conditions, including those in this bill.

As with any other medication, a patient has the opportunity to try the product and see if it produces positive results, and weigh that against any negative side-effects. In close collaboration with their physician who provided the certification,

they can then make their own decision whether to continue or discontinue the use of medical marijuana.

Therefore, we support this bill. Thank you for your consideration.

Alaska

Qualifying conditions to become a medical marijuana patient in Alaska include:

- Cancer
- Glaucoma
- HIV/AIDS
- Cachexia (wasting syndrome)
- Pain
- Nausea
- Seizures
- Muscle spasms
- Multiple sclerosis

For a complete list of qualifying conditions and guidelines, please refer to Alaska's application for medical marijuana registry, or catch up on the latest Alaska cannabis news.

Arizona

Qualifying conditions to become a medical marijuana patient in Arizona include:

- Cancer
- Glaucoma
- HIV/AIDS
- Cachexia (wasting syndrome)
- Pain
- Nausea
- Seizures
- Muscle spasms
- Multiple sclerosis
- PTSD

For a complete list of qualifying conditions and guidelines, please refer to the Arizona state legislature concerning medical marijuana, or catch up on the latest Arizona cannabis news.

Arkansas

Qualifying conditions for the Arkansas Medical Marijuana Amendment include:

- Cancer
- Glaucoma
- HIV/AIDS
- Hepatitis C
- ALS or Lou Gehrig's Disease
- Tourette's Syndrome
- Crohn's disease
- PTSD
- Severe arthritis
- Fibromyalgia
- Alzheimer's disease
- A chronic or debilitating disease that produces:
 - Cachexia or wasting syndrome
 - Peripheral neuropathy
 - Intractable pain
 - Severe nausea
 - Seizures

- Severe or persistent muscle spasms

Arkansas' medical marijuana qualifying conditions are currently effective, but licenses for dispensaries will not be accepted until June 1, 2017.

California

Qualifying conditions to become a medical marijuana patient in California include:

- Cancer
- Anorexia
- AIDS
- Chronic pain
- Cachexia
- Persistent muscle spasms, including those associated with multiple sclerosis
- Seizures, including, but not limited to, those associated with epilepsy
- Severe nausea
- Glaucoma
- Arthritis
- Migraines
- Any other chronic or persistent medical symptom that substantially limits the ability of the person to conduct one or more major life activities (as defined by the Americans with Disabilities Act of 1990) or, if not alleviated, may cause serious harm to the patient's safety or physical or mental health

For a complete list of qualifying conditions and guidelines, please refer to [California Proposition 215](#), with revised [Senate Bill 420](#), or catch up on the latest [California cannabis news](#).

Colorado

Although Colorado has implemented a legal recreational cannabis market, it still operates medical marijuana dispensaries for valid patients. Colorado medical marijuana patients still pay standard sales tax on cannabis but are exempt from the high excise taxes and additional state taxes collected from recreational cannabis sales.

Qualifying conditions to become a medical marijuana patient in Colorado include:

- Cancer
- Glaucoma
- HIV/AIDS
- Cachexia (wasting syndrome)
- Persistent muscle spasms
- Seizures
- Severe nausea
- Severe pain

For a complete list of qualifying conditions and guidelines, please refer to [Colorado's Debilitating Conditions for Medical Marijuana Use](#), or catch up on the latest [Colorado cannabis news](#).

Connecticut

Qualifying conditions to become a medical marijuana patient in Connecticut include:

- Cancer
- Glaucoma
- HIV/AIDS
- Parkinson's disease
- Multiple sclerosis

- Damage to the nervous tissue of the spinal cord with objective neurological indication of intractable spasticity
- Epilepsy
- Cachexia (wasting syndrome)
- Wasting syndrome
- Crohn's disease
- Post-traumatic stress disorder (PTSD)

For a complete list of qualifying conditions and guidelines, please refer to [Connecticut's medical marijuana qualification requirements](#), or catch up on the latest [Connecticut cannabis news](#).

Delaware

Qualifying conditions to become a medical marijuana patient in Delaware include:

- Cancer
- HIV/AIDS
- Hepatitis C
- Lou Gehrig's disease (amyotrophic lateral sclerosis, or ALS)
- Alzheimer's
- Post-traumatic stress disorder (PTSD)
- Cachexia (wasting syndrome)
- Intractable nausea
- Seizures
- Muscle spasms
- Multiple sclerosis

For a complete list of qualifying conditions and guidelines, please refer to [Delaware's medical marijuana program guidelines](#), or catch up on the latest [Delaware cannabis news](#).

District of Columbia (Washington, D.C.)

Qualifying conditions to become a medical marijuana patient in Washington, D.C. include:

- HIV/AIDS
- Cancer
- Glaucoma
- Muscle spasms
- Multiple sclerosis
- Lou Gehrig's disease (ALS)
- Cachexia (wasting syndrome)
- Decompensated cirrhosis
- Alzheimer's
- Seizure disorders
- Any condition diagnosed as "debilitating" by a licensed physician

For a complete list of qualifying conditions and guidelines, please refer to the [District of Columbia's Medical Marijuana Program Patient FAQ](#), or catch up on the latest [Washington, D.C. cannabis news](#).

Florida

Qualifying conditions to become a medical marijuana patient in Florida include:

- Cancer
- Epilepsy
- Glaucoma
- HIV/AIDS

- PTSD
- ALS or Lou Gehrig's disease
- Crohn's disease
- Parkinson's disease
- Multiple sclerosis

For more information on the Florida Medical Marijuana Legalization, please refer to Amendment 2.

Georgia

Georgia only allows for the use of low THC oil (less than 5% THC by weight).

Qualifying conditions to become a medical marijuana patient in Georgia include:

- Cancer
- Lou Gehrig's disease (ALS)
- Seizure disorders related to diagnosis of epilepsy or trauma-related head injuries
- Multiple sclerosis
- Crohn's disease
- Mitochondrial disease
- Parkinson's disease
- Sickle cell disease

For a complete list of qualifying conditions and guidelines, please refer to House Bill 1 (Haleigh's Hope Act), or catch up on the latest [Georgia cannabis news](#).

Hawaii

Qualifying conditions to become a medical marijuana patient in Hawaii include:

- Cancer
- Glaucoma
- HIV/AIDS
- Cachexia (wasting syndrome)
- Pain
- Nausea
- Seizures
- Muscle spasms
- Multiple sclerosis

For a complete list of qualifying conditions and guidelines, please refer to Hawaii Senate Bill 862, or catch up on the latest [Hawaii cannabis news](#).

Illinois

Qualifying conditions to become a medical marijuana patient in Illinois include:

- Acquired Immunodeficiency Syndrome (AIDS)
- Alzheimer's disease
- Lou Gehrig's disease (ALS)
- Arnold-Chiari malformation and syringomyelia
- Cachexia/wasting syndrome
- Cancer
- Causalgia
- Chronic inflammatory demyelinating polyneuropathy
- Crohn's disease
- CRPS (Complex Regional Pain Syndrome Type I)
- CRPS (Complex Regional Pain Syndrome Type II)

- Dystonia
- Fibromyalgia (severe)
- Fibrous dysplasia
- Glaucoma
- Hepatitis C
- Human Immunodeficiency Virus (HIV)
- Hydrocephalus
- Hydromyelia
- Interstitial cystitis
- Lupus
- Multiple sclerosis
- Muscular dystrophy
- Myasthenia gravis
- Myoclonus
- Nail-patella syndrome
- Neurofibromatosis
- Parkinson's disease
- Post-concussion syndrome
- Post-Traumatic Stress Disorder (PTSD)
- Reflex sympathetic dystrophy
- Residual limb pain
- Rheumatoid arthritis (RA)
- Seizures
- Sjogren's syndrome
- Spinal cord disease (including but not limited to arachnoiditis, Tarlov cysts, hydromyelia & syringomyelia)
- Spinal cord injury
- Spinocerebellar ataxia (SCA)
- Syringomyelia
- Tarlov cysts
- Tourette syndrome
- Traumatic brain injury (TBI)

For a complete list of qualifying conditions and guidelines, please refer to the [Illinois Medical Cannabis Pilot Program's FAQ](#), or catch up on the [latest Illinois cannabis news](#).

Iowa

Iowa allows for the use of high-CBD cannabis extracts with less than .3% THC.

Qualifying conditions to become a medical marijuana patient in Iowa include:

- Intractable epilepsy

For a complete list of guidelines, please refer to [Iowa Medical Cannabidiol Act Quick Facts](#), or catch up on the [latest Iowa cannabis news](#).

Kentucky

Kentucky allows for the use of low-THC cannabis or industrial hemp-derived CBD oil. Only those who are participating in a clinical trial or expanded access program are legally allowed to possess CBD oil.

For more information on accessing CBD in Kentucky, please refer to [Senate Bill 124](#), or catch up on the [latest Kentucky cannabis news](#).

Louisiana

Qualifying conditions to become a medical marijuana patient in Louisiana include:

- Symptoms related to cancer
- Glaucoma
- Spastic quadriplegia

For more information on Louisiana's medical marijuana law, please refer to [Senate Bill 143](#), or catch up on the latest [Louisiana cannabis news](#).

Maine

Qualifying conditions to become a medical marijuana patient in Maine include:

- Chronic pain that has not responded to conventional therapy for more than six months
- Post-traumatic stress disorder (PTSD)
- Lou Gehrig's disease (ALS)
- Alzheimer's
- Cachexia (wasting syndrome)
- Cancer
- Crohn's disease
- Glaucoma
- Hepatitis C (active form)
- HIV
- Inflammatory bowel disease (IBS)
- Seizure disorders
- Severe muscle spasms (including multiple sclerosis and other diseases causing severe and persistent muscle spasms)
- Severe nausea

For a complete list of qualifying conditions and guidelines, please refer to [Maine's medical use of marijuana guidelines](#), or catch up on the latest [Maine cannabis news](#).

Maryland

Qualifying conditions to become a medical marijuana patient in Maryland include:

- Cachexia (wasting syndrome)
- Severe, debilitating, or chronic pain
- Severe nausea
- Seizures, including those characteristic of epilepsy
- Severe and persistent muscle spasms
- Multiple sclerosis
- Crohn's disease
- Alzheimer's
- Cancer
- Glaucoma
- HIV/AIDS
- Hepatitis C

For a complete list of qualifying conditions and guidelines, please refer to [Maryland Senate Bill 757](#), or catch up on the latest [Maryland cannabis news](#).

Massachusetts

Qualifying conditions to become a medical marijuana patient in Massachusetts include:

- Cancer

- Glaucoma
 - AIDS
 - Hepatitis C
 - Lou Gehrig's disease (ALS)
 - Crohn's disease
 - Parkinson's disease
 - Multiple sclerosis
 - Other debilitating conditions as determined in writing by a qualifying patient's certifying physician.
- For a complete list of qualifying conditions and guidelines, please refer to the [Massachusetts medical use of marijuana overview](#), or catch up on the latest [Massachusetts cannabis news](#).

Michigan

Qualifying conditions to become a medical marijuana patient in Michigan include:

- Cancer
- Glaucoma
- HIV/AIDS
- Hepatitis C
- Lou Gehrig's disease (Amyotrophic lateral sclerosis, or ALS)
- Alzheimer's
- Nail-patella syndrome
- Cachexia (wasting disease)
- Severe and chronic pain
- Severe nausea
- Seizures
- Epilepsy
- Muscle spasms
- Multiple sclerosis

For a complete list of qualifying conditions and guidelines, please refer to the [Michigan Medical Marihuana Registry Program FAQ](#), or catch up on the latest [Michigan cannabis news](#).

Minnesota

Minnesota does not allow for smokeable cannabis, only a 30-day supply of oils, edibles, and concentrates. Qualifying conditions to become a medical marijuana patient in Minnesota include:

- Lou Gehrig's disease (Amyotrophic lateral sclerosis, or ALS)
- Cancer
- Cachexia
- Crohn's disease
- Glaucoma
- HIV/AIDS
- Seizures
- Severe and persistent muscle spasms
- Terminal illness
- Tourette syndrome
- Intractable pain*

*Recently recommended qualifying condition soon to be available for Minnesota patients.

For more information, please visit the [Minnesota Department of Health – Medical Cannabis](#), or catch up on the latest [Minnesota cannabis news](#).

Mississippi

Mississippi allows access to CBD oil only. Qualifying conditions to become a medical marijuana patient in Mississippi include:

- Debilitating epileptic seizure disorders

Patients must receive medical recommendations by a physician from the University of Mississippi Medical Center to participate in the clinical trial. For more information, please refer to [House Bill 1231](#) or [Harper Grace's Law](#), or catch up on the latest [Mississippi cannabis news](#).

Missouri

Missouri allows access to CBD oil only. Qualifying conditions to become a medical marijuana patient in Missouri include:

- Intractable epilepsy

For more information, please refer to [House Bill 2238](#), or catch up on the latest [Missouri cannabis news](#).

Montana

Qualifying conditions to become a medical marijuana patient in Montana include:

- Cancer
- Glaucoma
- HIV/AIDS
- Cachexia (wasting syndrome)
- Chronic pain
- Intractable nausea or vomiting
- Epilepsy or an intractable seizure disorder
- Multiple sclerosis
- Crohn's disease
- Painful peripheral neuropathy
- A central nervous system disorder resulting in chronic, painful spasticity or muscle spasms

For a complete list of qualifying conditions and guidelines, please refer to [Montana Code Annotated 2013](#), or catch up on the latest [Montana cannabis news](#).

Nevada

Qualifying conditions to become a medical marijuana patient in Nevada include:

- AIDS
- Cancer
- Glaucoma
- Condition or treatment for a medical condition that produces cachexia (general physical wasting and malnutrition)
- Persistent muscle spasms (including multiple sclerosis)
- Seizures (including epilepsy)
- Severe nausea
- Severe pain

For a complete list of qualifying conditions and guidelines, please refer to the [Nevada Medical Marijuana Program](#), or catch up on the latest [Nevada cannabis news](#).

New Hampshire

Qualifying conditions to become a medical marijuana patient in New Hampshire include:

- A chronic or terminal disease
- Cachexia (wasting syndrome)

- Severe pain
- Severe nausea/vomiting
- Seizures
- Severe, persistent muscle spasms

For a complete list of qualifying conditions and guidelines, please refer to [New Hampshire House Bill 573](#), or catch up on the latest [New Hampshire cannabis news](#).

New Jersey

Qualifying conditions to become a medical marijuana patient in New Jersey include:

- Lou Gehrig's disease (amyotrophic lateral sclerosis, or ALS)
- Multiple sclerosis
- Terminal cancer
- Muscular dystrophy
- Inflammatory bowel disease (IBS)
- Crohn's disease
- Terminal illness if the physician has determined a prognosis of less than 12 months of life
- Seizure disorder, including epilepsy
- Intractable skeletal muscular spasticity
- Glaucoma
- HIV/AIDS
- Cancer

For a complete list of qualifying conditions and guidelines, please refer to the [New Jersey Medicinal Marijuana Program](#), or catch up on the latest [New Jersey cannabis news](#).

New Mexico

Qualifying conditions to become a medical marijuana patient in New Mexico include:

- Severe chronic pain
- Painful peripheral neuropathy
- Intractable nausea/vomiting
- Severe anorexia
- Cachexia (wasting syndrome)
- Hepatitis C infection currently receiving antiviral treatment
- Crohn's disease
- Post-traumatic stress disorder (PTSD)
- Lou Gehrig's disease (amyotrophic lateral sclerosis, or ALS)
- Cancer
- Glaucoma
- Multiple sclerosis
- Damage to the nervous tissue of the spinal cord with intractable spasticity
- Epilepsy
- HIV/AIDS
- Inflammatory autoimmune-mediated arthritis
- Hospice patients

For a complete list of qualifying conditions and guidelines, please refer to the [New Mexico Medical Cannabis Program FAQ](#), or catch up on the latest [New Mexico cannabis news](#).

New York

Qualifying conditions to become a medical marijuana patient in New York include:

- Cancer
- Epilepsy
- HIV/AIDS
- Huntington's disease
- Inflammatory Bowel Disease (IBS)
- Lou Gehrig's disease (ALS)
- Parkinson's disease
- Multiple sclerosis (MS)
- Neuropathies
- Spinal cord damage

For a complete list of qualifying conditions and guidelines, please refer to the [New York State Medical Marijuana Program FAQ](#), or catch up on the [latest New York cannabis news](#).

North Carolina

North Carolina allows for the use of CBD oil only. Qualifying conditions to become a medical marijuana patient in North Carolina include:

- Intractable epilepsy

For more information, please refer to [House Bill 1220](#), or catch up on the [latest North Carolina cannabis news](#).

North Dakota

North Dakota's qualifying conditions for the North Dakota Compassionate Care Act include:

- Cancer and its treatments
- HIV/AIDS
- Hepatitis C
- ALS or Lou Gehrig's disease
- PTSD
- Alzheimer's disease, dementia, or treatment of these conditions
- Crohn's disease
- Fibromyalgia
- Spinal stenosis
- Chronic back pain, including:
 - Neuropathy or damage to the nervous tissue of the spinal cord with objective neurological indication of intractable spasticity
- Glaucoma
- Epilepsy
- A chronic or debilitating disease, medical condition, or its treatment that produces one or more of the following:
 - Cachexia or wasting syndrome
 - Severe, debilitating pain that has not responded to previously prescribed medication or surgical measures for more than three months or for which other treatment options produced serious side effects
 - Intractable nausea
 - Seizures
 - Severe or persistent muscle spasms, including but not limited to those characteristic of multiple sclerosis.

For more information, please refer to the [North Dakota Compassionate Care Act](#).

Oklahoma

Oklahoma allows for the use of CBD oil only. Qualifying conditions to become a medical marijuana patient in Oklahoma include:

- Must be under the age of 18 suffering from:
 - Lennox-Gastaut syndrome
 - Dravet syndrome
 - Severe myoclonic epilepsy of infancy
 - Any form of refractory epilepsy not treatable by traditional medical therapies

For more information, please refer to [Katie and Cayman's Law \(House Bill 2154\)](#), or catch up on the latest [Oklahoma cannabis news](#).

Oregon

Qualifying conditions to become a medical marijuana patient in Oregon include:

- Cancer
- Glaucoma
- Alzheimer's
- HIV/AIDS
- Cachexia (wasting syndrome)
- Severe pain
- Severe nausea
- Seizures, including but not limited to seizures caused by epilepsy
- Persistent muscle spasms
- Multiple sclerosis

For a complete list of qualifying conditions and guidelines, please refer to the [Oregon Medical Marijuana Act](#), or catch up on the latest [Oregon cannabis news](#).

Pennsylvania

Qualifying conditions to become a medical marijuana patient in Pennsylvania include:

- Cancer
- HIV/AIDS
- Amyotrophic Lateral Sclerosis (ALS)
- Parkinson's Disease
- Multiple sclerosis
- Damage to the nervous tissue of the spinal cord with objective neurological indication of intractable spasticity
- Epilepsy
- Inflammatory bowel disease (IBS)
- Neuropathies
- Huntington's disease
- Post-traumatic stress disorder (PTSD)
- Intractable seizures
- Glaucoma
- Sickle cell anemia
- Severe, chronic or intractable pain of neuropathic origin or severe chronic or intractable pain in which conventional therapeutic intervention and opiate therapy is contraindicated or ineffective
- Autism
- "Terminally ill" – a medical prognosis or life expectancy of approximately one year or less if the illness runs its normal course.

For more information, please refer to [Senate Bill 3](#).

Rhode Island

Qualifying conditions to become a medical marijuana patient in Rhode Island include:

- Cancer
- Glaucoma
- HIV/AIDS
- Hepatitis C
- Cachexia (wasting syndrome)
- Chronic pain
- Severe nausea
- Seizures, including but not limited to those characteristic of epilepsy
- Severe and persistent muscle spasms
- Multiple sclerosis
- Crohn's disease
- Alzheimer's

For a complete list of qualifying conditions and guidelines, please refer to Rhode Island's medical marijuana approved qualifying debilitating medical conditions, or catch up on the latest Rhode Island cannabis news.

South Carolina

South Carolina allows for the use of CBD oil only. Qualifying conditions to become a medical marijuana patient in South Carolina include:

- Certain forms of epilepsy as part of a state-run clinical trial

For more information, please refer to the Medical Cannabis Therapeutic Treatment Research Act, or catch up on the latest South Carolina cannabis news.

Tennessee

Tennessee allows for the use of CBD oil only. Qualifying conditions to become a medical marijuana patient in Tennessee include:

- Intractable seizures (as part of a clinical research study)

For more information, please refer to Senate Bill 280, or catch up on the latest Tennessee cannabis news.

Texas

Texas allows for the use of CBD oil only. Qualifying conditions to become a medical marijuana patient in Texas include:

- Intractable epilepsy

For more information, please refer to Senate Bill 339, or catch up on the latest Texas cannabis news.

Utah

Utah allows for the use of CBD oil only. Qualifying conditions to become a medical marijuana patient in Utah include:

- Intractable epilepsy

For more information, please refer to House Bill 105, or catch up on the latest Utah cannabis news.

Vermont

Qualifying conditions to become a medical marijuana patient in Vermont include:

- Cancer
- AIDS/HIV
- Multiple sclerosis

- Cachexia (wasting syndrome)
- Severe pain
- Nausea
- Seizures

For a complete list of qualifying conditions and guidelines, please refer to the [Vermont patient marijuana registry FAQ](#), or catch up on the latest [Vermont cannabis news](#).

Washington

Changes to Washington state's marijuana laws via Senate Bill 5052 will result in the state's medical marijuana industry being absorbed by its recreational cannabis market. These changes will go into full effect July 1, 2016. Until then, medical marijuana dispensaries will still be operational but are ultimately expected to close or incorporate themselves into an existing licensed retail cannabis shop.

Qualifying conditions to become a medical marijuana patient in Washington include:

- Cancer
- HIV/AIDS
- Multiple sclerosis
- Epilepsy or other seizure disorder
- Spasticity disorders
- Intractable pain
- Glaucoma
- Crohn's disease
- Hepatitis C
- Diseases, including anorexia, which result in nausea, vomiting, wasting, appetite loss, cramping, seizures, muscle spasms, or spasticity

For a complete list of qualifying conditions and guidelines, please refer to the [Washington state legislature regarding medical cannabis](#), or catch up on the latest [Washington state cannabis news](#).

Wisconsin

Wisconsin allows for the use of non-psychoactive CBD oil only. Qualifying conditions to become a medical marijuana patient in Wisconsin include:

- Seizure disorders

For more information, please refer to [Lydia's Law \(Act 267\)](#), or catch up on the latest [Wisconsin cannabis news](#).

Wyoming

Wyoming allows for the use of CBD oil only. Qualifying conditions include:

- Intractable epilepsy

For more information, please refer to [House Bill 32](#), or catch up on the latest [Wyoming cannabis news](#).

ON THE FOLLOWING MEASURE:

SB174, RELATING TO MEDICAL MARIJUANA

BEFORE THE:

SENATE COMMITTEE ON COMMERCE, CONSUMER PROTECTION,
AND HEALTH

DATE: Wednesday, February 8, 2017

TIME: 9:00 a.m.

LOCATION: State Capitol, Conference Room 229

TESTIFIER: Christopher Garth, Executive Director

Honorable Chair Baker and Members of the Committee:

The Hawai'i Dispensary Alliance submits the following testimony in **SUPPORT of SB174 RELATING TO MEDICAL MARIJUANA**, which amends the definition of debilitating medical condition to include lupus, epilepsy, multiple sclerosis, arthritis, autism, anxiety, depression, insomnia, and stress as conditions that qualify for the legal use of medical marijuana.

The Hawaii Dispensary Alliance is a patient-centric organization that aims to appropriately introduce the legitimate cannabis industry to the state of Hawaii. Our membership is drawn from patients and caregivers, ancillary businesses related to and involved in the physical and intellectual cannabis space, and those who generally support the value of a legal right to cannabis-based medicine. The Alliance has established itself as a consistent voice in the conversation for greater patient access to safe and quality cannabis resources; and it is from this perspective that we support SB174.

Our board and membership find that the language of this measure will provide greater access to less invasive medical solutions, by expanding the applicability of cannabis-based medicine. If passed, this measure will place Hawaii on the list of states as one of the more inclusive state regulated medical cannabis programs in the nation. Including these qualifying conditions on our roster would benefit future medical cannabis studies conducted by the University of Hawaii system as well as those conducted in private by local firms. This is an opportunity to help more patients and to conduct the sound medical research the international medical cannabis industry desperately needs.

For all of the foregoing reasons, the Hawai'i Dispensary Alliance **SUPPORTS** the language of this measure and recommends that **SB174** be moved forward for further discussion.

A 2016 version of a state-by-state list of qualifying conditions has been attached for your review and comparison. This list has been vetted and approved by the State of Hawaii Department of Health.

Thank you very much for the opportunity to provide testimony on this measure.

SB174

RELATING TO MEDICAL MARIJUANA

Senate Committee on Commerce, Consumer Protection, and Health

Wednesday February 8, 2017

9:00 AM

State Capitol, Conference Room 229

Aloha Chair Baker, Vice Chair Nishihara, and Members of the Committee,

Pakalōlō Suite, a Hawai'i based community organization of qualified medical marijuana patients, STRONGLY SUPPORTS SB174. SB174 would amend the definition of “debilitating medical condition” to include lupus, epilepsy, multiple sclerosis, arthritis, autism, anxiety, depression, insomnia, and stress.”

The medical use of marijuana has provided comfort and relief to countless individuals suffering from medical conditions that they would undoubtedly define as “debilitating.” However, state laws have narrowly defined, or left ambiguous, those qualifying medical conditions necessary to become a qualified medical marijuana patient. Cannabidiol, or CBD, a non-psychoactive compound of marijuana (cannabis), has gained momentum in its positive treatment of the debilitating symptoms of neurodevelopmental disorders like autism or neurological disorders like epilepsy – two medical conditions enumerated in SB174’s expanded definition of “debilitating medical condition.”

The state’s progression toward a compassionate approach to the medical use of marijuana has authorized the licensing and establishment of medical marijuana dispensaries. Individuals suffering from debilitating medical conditions now have greater access to proven medical treatment. By expanding the definition of “debilitating medical condition,” the state would provide greater access to medical treatment for a much larger group of people in need.

Mahalo nui loa for this opportunity to share our testimony,

Māhealani Traub
Pakalōlō Suite Prime Advocate

February 6, 2017

Senator Rosalyn H. Baker
Chair, Senate Committee on
Commerce, Consumer Protection,
and Health

Hawaii State Capitol, Room 230

Senator Clarence K. Nishihara
Vice Chair, Senate Committee on
Commerce, Consumer Protection, and
Health
Hawaii State Senate
Hawaii State Capitol, Room 214

RE: **SB174 – Support**

Senator Baker and Senator Nishihara,

My name is Robert Wiedmeyer, and I have been a resident of Waikoloa, Hawaii for two and a half years. My legislators are Representative Cindy Evans and Senator Lorraine Inouye.

I am writing to express my support for SB174, which amends the definition of debilitating medical conditions to include lupus, epilepsy, multiple sclerosis, arthritis, autism, anxiety, depression, insomnia, and stress as conditions that qualify for the legal use of medical marijuana.

SB174 takes positive steps toward updating Hawaii law to enhance access to a safe, effective medication for a number of serious and sometimes chronic medical conditions. When used under the supervision of a qualified medical professional, cannabis has been shown to help relieve these conditions and potentially allow patients to reduce reliance on opiates and other medicines that have potentially serious, harmful side effects.

With the state's dispensaries set to open in the near future, this is the time to expand legal access to more patients who stand to benefit from cannabis-based medicine.

I appreciate your thoughtful consideration of this legislation.

Sincerely,
Robert Wiedmeyer

PATIENTS WITHOUT TIME

February 7, 2017

TO: HAWAII STATE LEGISLATURE

TESTIMONY

Aloha Legislators,

LEGALIZE MARIJUANA NOW!

SAVE LIVES! 90,000 Americans die from alcohol every year, yet Hawaii celebrates the success of Hawaii's wineries and microbreweries. Tourists are encouraged to visit production centers and tasting rooms. Meanwhile, requiring cannabis production centers to have 24/7 video surveillance, and concealment from the public view. This is unfounded prejudice and paranoia. The CDC states marijuana kills ZERO Americans, so why the prejudice against it?

For 16 years, Hawaii has practiced **SELECTIVE PROSECUTION** against marijuana consumers. Protecting some folks with "329 cards" from prosecution (stating that marijuana is medicine), while sending others to jail for "marijuana crimes," (stating marijuana has no medical value). There exists a clear, facial contradiction between marijuana's classification as a schedule I drug and its allowable use by qualifying patients for medical conditions.

The only just solution is to legalize marijuana. Tax and regulate Hawaii's estimated \$billion-plus dollar-a-year illegal marijuana industry, and raise a \$100-million-plus dollars-a-year in revenue, decrease expenses fighting the failed prohibition, clear court dockets, save families broken by incarceration, and create thousands of new legal jobs and business. WIN- WIN -WIN

Mahalo for your kind consideration,

Comments: Aloha. My name is Fehren Jones, I reside in the Honolulu area. I am in full support of SB174 which states that "Amends the definition of debilitating medical condition to include lupus, epilepsy, multiple sclerosis, arthritis, autism, anxiety, depression, insomnia, and stress as conditions that qualify for the legal use of medical marijuana." At the moment, no, I do not have any of these serious health conditions, but, I am starting to feel the arthritis, it comes with age. I do come across anxiety from time to time and the daily stress, but who doesn't come across stress and anxiety from time to time? I am a medical marijuana card holder and, yes, I do use my medical marijuana medicine when these symptoms arrive and IT DOES HELP. As for the lupus, epilepsy, and multiple sclerosis I do not know what it feels like to go through those uncomfortable diseases/sickness but I have read numerous of articles and I have watched many shows on how medical marijuana have helped countless of individuals get through the day, and to just getting through the day is a milestone for many of these ones. Mahalo for your time and patients. I'm sure its not easy to read every single testimony that's submitted. I appreciate the time that you spend on going through it all.

Please note that testimony submitted less than 24 hours prior to the hearing, improperly identified, or directed to the incorrect office, may not be posted online or distributed to the committee prior to the convening of the public hearing.

D. DOUGLAS SMITH, M.D.
229 Aiokoa Street
KAILUA, HAWAII 96734

February 7, 2016 at 9:00 AM

Room 229

To: COMMITTEE ON COMMERCE, CONSUMER PROTECTION & HEALTH
Senator Rosalyn H. Baker, Chair
Senator Clarence K. Nishihara, Vice Chair

From: D. Douglas Smith, M.D.

Re: SB 174, Relating to Medical Marijuana

IN OPPOSE

I would like to thank Chair Baker, Vice Chair Nishihara, and members of the Senate Committee on Commerce, Consumer Protection and Health for the opportunity to submit comments on SB174.

I am a physician who specializes in psychiatry and have spent my career practicing in Hawaii. For 11 years I was on the faculty of the JABSOM department of psychiatry and I treated patients and supervised residents at the Hawaii State Hospital and Queens Medical Center. I have also worked in private practice and with the Adult Mental Health Division's Assertive Community Treatment Program.

I oppose this bill, and urge you to reconsider some of its important health implications for access to mental health care in Hawaii.

SB174 would expand the definition of "debilitating medical conditions" that qualify for the legal use of medical marijuana to include "autism, anxiety, depression, insomnia, and stress as conditions." This is reckless expansion of qualifying diagnoses flies in the face of clinical experience and available medical literature. It would be a regrettable health policy that promises to add to the burdens on our strained mental health system.

The 2013 position statement of the American Psychiatric Association (APA) is clear in this regard. It states, "There is no current scientific evidence that marijuana is in any way

beneficial for the treatment of any psychiatric disorder. In contrast, current evidence supports, at minimum, a strong association of cannabis use with the onset of psychiatric disorders. Adolescents are particularly vulnerable to harm, given the effects of cannabis on neurological development.” (see attachment)

Before authorizing this legislation, committee members should consider the evidence of limited benefit and serious mental health risks posed by high-potency medical cannabis, including its association with an increased incidence and worse outcomes for Depression, Bipolar disorder, Schizophrenia and other psychotic conditions. As the referenced APA resource document concludes:

There is currently no scientific evidence to support the use of marijuana as an effective treatment for any psychiatric illness. Several studies have shown that cannabis use may in fact exacerbate or hasten the onset of psychiatric illnesses, as evidenced by both international trials and meta-analyses. This includes the contribution of marijuana to symptoms of mood disorders, anxiety and psychosis, particularly in young adulthood. Cannabis use is associated with the emergence of mood disorders, particularly symptoms of bipolar disorder, among those with a family history of mood disorder. Among those with major depressive disorder, co-morbid cannabis use is associated with increased rates of both suicidal ideation and attempts, raising grave safety concerns. Among those with a predisposition to psychotic disorders, cannabis may hasten the emergence of both positive and negative psychotic symptoms. The use of higher potency cannabis, for longer periods of time and with more frequency, is also associated with increased risk of psychosis.

Several studies have demonstrated the link between marijuana use and mood, anxiety and psychotic disorders among adolescents. Cannabis use is associated with increased depression, suicidal ideation, use of other substances and risky behavior among adolescents. Regular adolescent cannabis use is also associated with increased incidence of anxiety disorders. Cannabis use significantly increases the risk of psychotic disorders

among young adults. Additionally, younger age of cannabis use is associated with an earlier onset of psychosis among those at risk. Adolescents with a history of cannabis use tend to have higher severity of illness, lower psychosocial functioning, less insight, and longer courses of untreated psychosis compared to those without a history of cannabis use. These findings are of particular concern as symptoms often persist into adulthood, and therefore cannabis use may increase the risk of lifelong symptoms and disability due to mental illness. (see attachment)

While there exist the future possibility that certain varieties of cannabis, administered at certain predictable dosages and schedules will be proven to benefit certain mental health conditions while avoiding the risks of toxicity or withdrawal symptoms, this is not yet the case. As with any potent psychotropic drug, unpredictable composition and strengths will inevitably lead to inconsistent effects with problems from excessive dose (i.e. intoxication) and inadequate dose (withdrawal).

In my medical opinion, the one area of expanded indication for medical cannabis, where the benefits are likely to outweigh the risks, would be as an alternative to the management of chronic pain with harmful and ineffective opioids.

There are several other Medical Marijuana bills that have been scheduled for hearing (SB1159, SB173, SB716, SB319, SB970), indicating that expanding access to high-potency cannabis has a higher priority for the legislature, than doing the work necessary to ensure that health plan members have access to the safe and effective medical care they are paying for and are legally entitled to. With all the oversight and attention being paid to expanded use of high potency cannabis, a marginal issue for most people, why has there been so little legislative oversight of the health plan provider networks that nearly all of our people depend on for access to proven care?

Most worrisome is the foreseeable worsening of the shortage of psychiatric physicians likely due to this bill. By expanding the numbers of individuals with qualifying diagnoses, particularly to those most vulnerable to adverse effects of high-potency medical cannabis, SB174 would predictably increase the burden of mental illness on Hawaii's

health system. In addition to the triggering of episodes of Anxiety, Depression, Mania or Psychosis, the likelihood of toxicity from excessive dosing or of withdrawal from reduced dose will add to the burden on our strained mental health system. This is the opposite of the preventive approach needed to reduce unnecessary demands on our healthcare system. From the perspective of consumer protection and public health, this makes no sense.

Please, committee members, defer SB174, or amend qualifying conditions to include treatment for chronic pain and to remove the list of mental health problems it is known to cause or worsen (autism, anxiety, depression, insomnia, and stress).

Thank you for allowing me to testify on SB174, and your consideration of these concerns is appreciated.

Sincerely,

A handwritten signature in cursive script that reads "D. Douglas Smith".

D. Douglas Smith, M.D.

Position Statement on Marijuana as Medicine

Approved by the Board of Trustees, December 2013
Approved by the Assembly, November 2013

"Policy documents are approved by the APA Assembly and Board of Trustees...These are...position statements that define APA official policy on specific subjects..." – *APA Operations Manual*.

- There is no current scientific evidence that marijuana is in any way beneficial for the treatment of any psychiatric disorder. In contrast, current evidence supports, at minimum, a strong association of cannabis use with the onset of psychiatric disorders. Adolescents are particularly vulnerable to harm, given the effects of cannabis on neurological development.
- Further research on the use of cannabis-derived substances as medicine should be encouraged and facilitated by the federal government. The adverse effects of marijuana, including, but not limited to, the likelihood of addiction, must be simultaneously studied.
- Policy and practice surrounding cannabis-derived substances should not be altered until sufficient clinical evidence supports such changes.
- If scientific evidence supports the use of cannabis-derived substances to treat specific conditions, the medication should be subject to the approval process of the FDA.

Regarding state initiatives to authorize the use of marijuana for medical purposes:

- Medical treatment should be evidence-based and determined by professional standards of care; it should not be authorized by ballot initiatives.
- No medication approved by the FDA is smoked. Marijuana that is dispensed under a state-authorized program is not a specific product with controlled dosages. The buyer has no way of knowing the strength or purity of the product, as cannabis lacks the quality control of FDA-approved medicines.
- Prescribers and patients should be aware that the dosage administered by smoking is related to the depth and duration of the inhalation, and therefore difficult to standardize. The content and potency of various cannabinoids contained in marijuana can also vary, making dose standardization a challenging task.
- Physicians who recommend use of smoked marijuana for "medical" purposes should be fully aware of the risks and liabilities inherent in doing so.

Robert Milin, M.D.

Abstract

The medical use of marijuana has received considerable attention as several states have voted to remove civil and criminal penalties for patients with qualifying conditions. Yet, on a national level, marijuana remains a schedule I substance under the Controlled Substances Act (CSA), the most restrictive schedule enforced by the Drug Enforcement Administration (DEA) (1). The Food and Drug Administration (FDA), responsible for approving treatments after appropriate and rigorous study, additionally does not support the use of marijuana for medical purposes. This juxtaposition of practice and policy has prompted many professional medical organizations to issue official positions on the topic. This statement reflects the position of the American Psychiatric Association (APA) on the use of marijuana for psychiatric indications. It does not cover the use of synthetic cannabis-derived medications such as Dronabinol (Marinol), which has been studied and approved by the FDA for specific indications.

Medical Indications for Marijuana as Medicine

Much of the evidence supporting marijuana use for non-psychiatric medical diagnoses remains anecdotal. The indications with the most evidence include: severe nausea and vomiting associated with cancer chemotherapy (2), cachexia associated with Acquired Immune Deficiency Syndrome (AIDS) (3), spasticity secondary to neurological diseases such as muscular sclerosis (4), management of neuropathic pain (5), and rheumatoid arthritis (6). Several medical organizations have issued statements regarding indications for marijuana as medicine based on scientific evidence.

Contribution of Marijuana to Psychiatric Illness

There is currently no scientific evidence to support the use of marijuana as an effective treatment for any psychiatric illness. Several studies have shown that cannabis use may in fact exacerbate or hasten the onset of psychiatric illnesses, as evidenced by both international trials and meta-analyses (7-9). This includes the contribution of marijuana to symptoms of mood disorders, anxiety and psychosis, particularly in young adulthood^{10, 11}. Cannabis use is associated with the emergence of mood disorders,

particularly symptoms of bipolar disorder, among those with a family history of mood disorder (12). Among those with major depressive disorder, co-morbid cannabis use is associated with increased rates of both suicidal ideation and attempts, raising grave safety concerns (13). Among those with a predisposition to psychotic disorders, cannabis may hasten the emergence of both positive and negative psychotic symptoms (14). The use of higher potency cannabis, for longer periods of time and with more frequency, is also associated with increased risk of psychosis (15).

Several studies have demonstrated the link between marijuana use and mood, anxiety and psychotic disorders among adolescents. Cannabis use is associated with increased depression, suicidal ideation, use of other substances and risky behavior among adolescents¹⁶. Regular adolescent cannabis use is also associated with increased incidence of anxiety disorders (17). Cannabis use significantly increases the risk of psychotic disorders among young adults (18). Additionally, younger age of cannabis use is associated with an earlier onset of psychosis among those at risk (19). Adolescents with a history of cannabis use tend to have higher severity of illness, lower psychosocial functioning, less insight, and longer courses of untreated psychosis compared to those without a history of cannabis use²⁰. These findings are of particular concern as symptoms often persist into adulthood, and therefore cannabis use may increase the risk of lifelong symptoms and disability due to mental illness.

Serious Adverse Effects of Marijuana Use

Cognitive and Functional

Marijuana use is associated with serious cognitive problems such as short-term memory deficits, poor concentration, attention, and information processing (21). These impairments might be caused by neurotoxic effects of cannabis on the developing brain, the effects of which can lead to long-term cognitive problems well into adulthood (22, 23). Adolescents with daily cannabis use show deficits in learning up to six weeks after stopping marijuana use (24). This may contribute to significantly decreased academic achievement, including increased rates of school dropout, failure to enter higher education or attain higher degrees (25). Among both adolescents and adults, cannabis significantly impairs driving, particularly as the drug affects automatic driving functions in a highly dose-dependent fashion (26). Cannabis use, particularly in combination with alcohol, greatly increases the risk of motor vehicle crashes due to effects on cognition and coordination (27). Addiction and burden of psychiatric illness:

Cannabis use is associated with an increased risk of developing a cannabis use disorder. Studies indicate that 9% of users become dependent on cannabis, and this number increases to 25-50% among daily users and to 1 in 6 among adolescents (28). Adolescents remain at particular risk for cannabis use disorder, and can experience significant withdrawal symptoms including appetite changes, restlessness, irritability, depression, twitches and shakes, perspiration, and thoughts/cravings of cannabis (29). Marijuana use is also associated with poorer outcomes among those with mental illness. Among individuals with schizophrenia, cannabis use is associated with poorer long-term clinical outcomes (30). Individuals with psychotic illness may be more sensitive to both the psychosis-inducing and mood-altering effects of cannabis (31). This may explain why even among those taking medications for psychotic disorders, cannabis use is associated with an increased risk of relapse into psychotic symptoms (32).

Legalization of medical marijuana may reduce the perceived risks of use, the perception of societal disapproval, or the barriers to access, and potentially increase the incidence of the adverse events noted above.

Summary

Given the gravity of concerns regarding marijuana as medicine, professionals in both neurology and psychiatry have emphasized the importance of prospective studies to understand the mechanisms by which cannabis functions, and its impact on mental health and behavior before instituting changes in practice and policy (33, 34).

Re: SB174 – Relating to Marijuana

Hearing: Wednesday, February 8, 2017, 9:00 am, Room 229

From: Clifton Otto, MD

Position: Support

Please consider also adding Amyotrophic Lateral Sclerosis (ALS) to this list of debilitating conditions.

Stress can certainly lead to worsening of symptoms in Autism, Anxiety, Depression, Epilepsy, Insomnia, Lupus, and Multiple Sclerosis, but may be difficult to justify as a stand-alone qualifying condition.

Please don't give in to the myth that only FDA approval justifies medical use. The intent of our Medical Use of Marijuana Program is to reduce the suffering of our patients by respecting the right of patients to choose the type of medical treatment that works best for them. Tens of thousands of patient years of use in Hawaii have already shown that marijuana is safe for medical use under supervision of a healthcare professional.

Thank you.

Medical Cannabis Registry

Instructions

1. ALL items on the form MUST be completed.
2. Petitions and any supporting documents may be submitted as follows:
 - a. Email to: medicalmarijuana@doh.hawaii.gov before the close of business (4:30PM) on **Thursday, April 30, 2020**. Please use the subject line: **Petition to Add New Condition**. Note that the DOH will not make public any information that is protected pursuant to Chapter 92F, HRS, the Uniform Information Practices Act.
 - b. Postal mail to: 4348 Waialea Avenue, #648, Honolulu, Hawaii 96816. Mailed petitions must be received by **Thursday, April 30, 2020**.
 - c. Hand delivered to: Kinau Hale at 1250 Punchbowl Street, Honolulu, Hawaii 96813 before the close of business (4:30PM) on **Thursday, April 30, 2020**. Hand delivered petitions must be left with the security guard and addressed to the Medical Cannabis Registry Program **ATTN: Petition to Add New Condition**.
3. For best results, complete and thorough petitions that include substantiated and reputable research have the best chance of succeeding. DOH recommends that you do the following for items #2- #8 on the petition form:
 - a. Please cite research, published evidence, or findings using the standard American Medical Association (AMA) format for each piece of research, published evidence, or findings that you reference in your submittal or at a minimum the following:
Author's Name; Title of Article; Name of Publication; Date of Publication; Volume/Section/Chapter/Page/Line as applicable; and URL (if applicable).
 - b. Please attach a PDF copy of the cited material to your submittal. These documents will NOT be returned.
 - c. Please be sure to indicate the specific section, page(s), lines, etc., of the attachment that you want reviewed/considered as evidence.
4. To view a list of current conditions click here: [Current Debilitating Medical Conditions](#)

Petitioner

Name

- I am a Physician/APRN
 Potentially qualifying patient (a person who has been diagnosed with the medical condition for which the petition is being made)

Street Address

City

State Zip Code

Email

I prefer the following and give my consent for all notifications about my petition to be by:

- Mailing address
 Email address
 Both mailing and email addresses

If I have indicated communication via email, and if for any reason email communication is not successful (i.e. email provided bounces or is kicked back to DOH), then I further understand that communication will be by regular U.S. postal service to the mailing address that I have provided. I also take full responsibility for any inaccurate email or U.S. postal mail address provided.

Petitioner Content

(1) State the specific medical condition or its treatment for which the petition is being made.

Anxiety

(2) State the reason(s) why the medical condition or its treatment should be added to the list of qualifying debilitating medical conditions for which medical cannabis may be used. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

This petition includes new scientific research supporting the request to add "Anxiety" as a qualifying condition that was not present in the "General Anxiety Disorder" petition. This petition should be reviewed and not rejected for its similarity to an earlier petition due to the new evidence published by the Minnesota Department of Health, the Massachusetts Department of Health and other peer-reviewed medical research attached and included.

<https://www.mass.gov/report/massachusetts-department-of-public-health-marijuana-research>
(REF #77) <https://www.mass.gov/files/documents/2019/07/09/MBHS-full-report-final.pdf>
The Marijuana Baseline Health Study (MBHS)

A legislative mandate required the Massachusetts [Department of Public Health \(DPH\)](#) to conduct a baseline study to investigate marijuana use in Massachusetts. The report published confirms the consensus that marijuana use improves mood and or mental health for a large percentage of people.

Page 148:

Results from this survey suggest that respondents appear to be treating a wide range of medical conditions, and often more than one at a time. **The top 5 medical conditions being treated were anxiety (60% or all respondents)**, chronic pain (46%), insomnia (43%), depression (42%), and stress (41%), and the average number of conditions being treated by medical marijuana is 4.7.

In the 1999 National Academy of Sciences Institute of Medicine report on marijuana, the National Academy of Science found that thorough medical research shows that marijuana reduces anxiety for "many people".

(REF #99) <https://www.nap.edu/catalog/6376/marijuana-and-medicine-assessing-the-science-base>

(REF #99) <https://www.nap.edu/download/6376>

page 165

The movement disorders most often considered for marijuana or cannabinoid therapy are dystonia, Huntington's disease, Parkinson's disease, and Tourette's syndrome.

Movement disorders are often transiently exacerbated by stress and activity and

improved by factors that reduce stress. **This is of particular interest because for many people marijuana reduces anxiety.**

In a study of medical marijuana patients in Arizona, many patients reported significant relief levels of anxiety.

(REF #13) <https://www.ncbi.nlm.nih.gov/pubmed/26317379>

367 medical marijuana patients in Arizona were surveyed.

181 patients reported using medical marijuana to experience relief from Anxiety

General relief from Anxiety symptoms was 82.9% with medical marijuana,

Relief by medical marijuana compared to other medications was 79.3% for Anxiety

Less frequent use of other medications was 85.9% for Anxiety

Patients who suffer from Post Traumatic Stress Disorder find relief of anxiety with medical cannabis. PTSD is a

qualifying condition in Hawaii and other states. It makes logical sense to allow people who do not have PTSD to gain relief of anxiety by adding anxiety to the list of qualifying conditions.

In a small percentage of people, medical cannabis can aggravate their anxiety. For the majority of people, cannabis reduces anxiety. This contraindication is similar to other anti-anxiety prescriptions, for whom a small percentage, their anxiety can be aggravated. This is not a reason to reject a qualifying condition, merely a reality of using any medication. Some epilepsy medicines make seizures worse or more frequent.

Marijuana is safer than all prescription medications and most of OTC medications. Cannabis has less side effects, and no severe, toxic or dangerous side effects compared to all of the prescription medications used to treat Anxiety.

<https://www.nimh.nih.gov/health/topics/mental-health-medications/index.shtml>

For example Benzodiazepines commonly used as anti anxiety medications, are responsible for hundreds of deaths each year in the United States.

<https://www.drugabuse.gov/related-topics/trends-statistics/overdose-death-rates>

<https://directorsblog.nih.gov/2014/04/10/anxiety-reduction-exploring-the-role-of-cannabinoid-receptors/>

Relief of anxiety and stress is one of the most common reasons that people give for using marijuana

Anti-Anxiety medication Ativan may be implicated in Soundgarden's lead singer Chris Cornell's suicide.

<http://www.rollingstone.com/culture/news/ativan-what-you-need-to-know-about-anxiety-pills-w483638>

A safety profile of Medical Marijuana can be found in the first year report of the Minnesota medical marijuana program. The Minnesota Department of Health surveyed 1500+ medical marijuana patients enrolled in the program.

(REF #98) <https://www.health.state.mn.us/people/cannabis/about/firstyearreport.html>

Adverse Side Effects: At this point, the safety profile of the medical cannabis products available through the Minnesota program seems quite favorable. Approximately 20-25% of enrolled patients report negative physical or mental side effects of some kind, with the majority – around 60% - reporting only one and 90% reporting three or fewer. The vast majority of adverse side effects, around 90%, are mild to moderate in severity. An assessment of the 30 patients reporting severe side effects, meaning “interrupts usual daily activities,” found no apparent pattern of patient age, medical condition, or type of medical cannabis used. The most common adverse side effects are dry mouth, drowsiness, and fatigue. Fortunately, up to the present no serious adverse events (life threatening or requiring hospitalization) have been reported.

Medical Marijuana's mild to moderate side effects of dry mouth, drowsiness and fatigue are easily tolerated by the vast majority of patients.

The Mayo Clinic website has assembled dosage information on Medical Marijuana.

<http://www.mayoclinic.org/drugs-supplements/marijuana/dosing/hrb-20059701>

In the latest petition to add Anxiety to Ohio's medical marijuana program, the New Jersey Department of Health's final decision on a petition to add anxiety in New Jersey was included.

(REF 96) [https://med.ohio.gov/Portals/0/Publications/Medical%20Marijuana%20Petitions%202019/0133%20-%20Anxiety%20\[Rosenberger\].pdf?ver=2020-01-28-104750-247](https://med.ohio.gov/Portals/0/Publications/Medical%20Marijuana%20Petitions%202019/0133%20-%20Anxiety%20[Rosenberger].pdf?ver=2020-01-28-104750-247)

(REF 97)

https://www.nj.gov/health/medicalmarijuana/documents/agency_decision_letters/MMP_FAD_conditions_012319.pdf

New Jersey's medical cannabis program is similar to Hawaii's medical cannabis program. With similar requirements for petitions to meet.

On July 5, 2016, the Department published the Request for Petitions in the New Jersey Register advising

that from August 1, 2016 to August 31, 2016, it was accepting petitions to establish additional medical conditions as "debilitating" under the MMP. 43 NJR. 1395(a). The Request for Petitions stated that the Department was seeking petitions in accordance with the Act, which authorizes the Department to include additional debilitating medical conditions under the MMP.

In the Request for Petitions, the public was advised that submitted petitions were required to include the following information, pursuant to N.J.A.C. 8:64-53:

- (1) The extent to which the condition is generally accepted by the medical community and other experts as a valid, existing medical condition;
- (2) If one or more treatments of the condition, rather than the condition itself, are alleged to be the cause of the patient's suffering, the extent to which the treatments causing suffering are generally accepted by the medical community and other experts as valid treatments for the condition;
- (3) The extent to which the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting, or otherwise severely impair the patient's ability to carry on activities of daily living;
- (4) The availability of conventional medical therapies other than those that cause suffering to alleviate suffering caused by the condition and/or the treatment thereof;
- (5) The extent to which evidence that is generally accepted among the medical community and other experts supports a finding that the use of marijuana alleviates suffering caused by the condition and/or the treatment thereof; and
- (6) Letters of support from physicians or other licensed health care professionals knowledgeable about the condition.

New Jersey found that Anxiety met the requirements and accepted Anxiety as a qualifying condition.

Anxiety

Based upon my independent review of the petitions, I am granting those seeking to add anxiety to the MMP. In coming to this conclusion, I reviewed these petitions against the six regulatory criteria cited above and found that the condition meets the requirements for inclusion in the MMP.

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that anxiety satisfies this criteria.

Specifically, the American Psychiatric Association defines anxiety and anxiety disorders as conditions characterized by excessive fear and behavioral disturbances. Anxiety results from anticipation of a future threat and may be associated with symptoms of muscle tension, vigilance in preparation for future danger, and overly cautious or avoidant behaviors. Additionally, there are multiple ICD-10-CM codes for anxiety disorders. Because anxiety maintains a common definition in the medical community and has ICD-10-CM codes, I find that anxiety is a valid and recognized medical condition.

Under the second factor, I must consider whether the treatments for the condition, rather than the condition itself, are causing the patient's suffering and the extent to which the treatments causing the patient suffering are generally accepted by the medical community and other experts as valid treatments for the condition. From my review of this condition, the generally accepted treatments for anxiety are dependent on the symptoms and the severity of the particular disorder.

Mild and moderate forms of anxiety may not require a pharmacologic intervention, but may necessitate other

forms of treatment, such as meditation, mindfulness, breathing techniques as well as psychotherapy (counseling) or cognitive therapy.” The most common classes of medications used to combat anxiety disorders are antidepressants, anti-anxiety drugs, and beta— blockers.⁴⁹ Antidepressants are safe and effective but they may be risky for children, teens, and young adults.⁵⁰ Antidepressants also come with a “black box” warning — the FDA’s strongest warning — advising that some people may have suicidal thoughts or make suicide attempts while taking the medication.⁵¹ The most common anti-anxiety medications are called benzodiazepines.

As noted by the Panel, the common side effects of benzodiazepines include headache, confusion, tiredness, and in some cases nightmares and memory impairments.⁵² And, benzodiazepines carry a risk of dependence and addiction.⁵³ Furthermore, the FDA notes that the number of patients who were prescribed both an opioid analgesic and benzodiazepine increased by 41% between 2002 and 2014.⁵⁴ As a result, the FDA requires black box warnings and patient-focused Medication Guides for prescription opioid analgesics, opioid-containing cough products, and benzodiazepines to inform the patient about the serious risks associated with using these medications at the same time.⁵⁵ Thus, I find that the treatments for anxiety are recognized and accepted by the medical community as the treatments for this condition and relate to the suffering of the patient.

As for the third factor, which is whether the condition itself and for the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient’s ability to carry on activities of daily living, I find that both the anxiety condition itself as well as the treatments for this condition cause severe suffering for patients. Specifically, anxiety may lead to problems that negatively impact an individual’s activities of daily living and quality of life and may lead to suicide and depression. Anxiety disorders can also cause significant distress or interfere with social, occupational, and other areas of functioning. In fact, an estimated 31.1% of US. adults experience an anxiety disorder at some time in their lives.⁵⁶ Medications, in some instances, may exacerbate the symptoms and are associated with debilitating side effects that can prevent a patient from engaging in activities of daily living, thereby diminishing one’s quality of life. Accordingly, I find that both the condition of anxiety as well as the therapies to treat it cause severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patients suffering caused by the condition and or the treatment thereof. As discussed above, mild and moderate forms of anxiety may be treated with meditation, mindfulness, breathing techniques as well as counseling or cognitive therapy that can be effective. Progression to medication therapy may be initiated; however, in both instances, one must consider the therapeutic response. Failure to respond to therapies or side effects associated with treatments may result in significant impacts on quality of life. As such, I find that there is an absence of medically-accepted, alternative medical therapies to the conventional therapies currently prescribed for migraine that cause suffering.

Regarding the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I find that cannabis is generally accepted as an effective treatment for anxiety.

The Panel discussed medical evidence that cannabis may exacerbate anxiety symptoms or that an effect related to cannabis may be associated with anxiety, such as dependence and cravings. Literature suggests that individuals with anxiety sensitivity may be more likely to turn to cannabis as a mechanism for coping with stress, which may in turn lead to problematic use behaviors.⁵⁷ However, the Panel further discussed a review published by the National Academies of Sciences, Engineering, and Medicine in 2017, which found that there is limited evidence that cannabidiol is an effective treatment for the improvement of anxiety symptoms, which was assessed by a public speaking test utilizing individuals with social anxiety disorders.⁵⁸

On balance, the Panel recommended adding anxiety as an allowable condition under the MMP as research suggests that it could be helpful to some patients with this condition. I agree. While marijuana may not be effective for all anxiety sufferers, there is research evidencing that it may be helpful to some, especially those with social anxiety disorders. Thus, I find that there is acceptance in the medical community that marijuana is likely to relieve the suffering associated with some anxiety conditions. However, like any medical condition, the use of medical marijuana to treat anxiety must be explored by the medical professional treating the patient to determine whether it is the best and most appropriate course of treatment for the patient.

As for the final factor, which is whether there were letters from physicians or other licensed health care

professionals knowledgeable about the condition supporting the inclusion of anxiety under the MMP, I find that the petitions were submitted with support from medical professionals.

Based upon the above analysis, I find that the condition of anxiety is “debilitating” and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the debilitating effect of this condition. As such, I find that anxiety should be added to the MMP.

In a previous qualifying condition petition for Generalized Anxiety Disorder, the Director of Health at the Hawaii Department of Health rejected adding the condition to the medical marijuana program. The main reason being that there is a lack of peer-reviewed scientific evidence showing beneficial use to treat GAD. This idea that peer-reviewed scientific evidence needs to conclusively show medical benefit or else no other qualifying conditions could be approved is wrong; due to the political nature of marijuana. Please allow me to explain.

The Hawaii medical cannabis law was created based on medical and anecdotal evidence. Anecdotal evidence was accepted because there is a lack of scientific research on the benefits of marijuana. Due to cannabis’s placement in schedule 1 of controlled substances in both state and federal laws. Quoting from the Hawaii Medical Cannabis Law:

https://www.capitol.hawaii.gov/session2000/acts/Act228_SB862_HD1_.htm

There is sufficient medical and **anecdotal evidence** to support the proposition that these diseases and conditions may respond favorably to a medically controlled use of marijuana.

This lack of research is due to the funding of marijuana research being regulated by NIDA, the National Institute of Drug Abuse. NIDA’s purpose is investigating the abuse potential of drugs, including cannabis, with focus solely on trying to prove the negatives of marijuana use. Since NIDA funds negative effects of marijuana research, research is granted on the flimsiest of theories and has corrupted and biased science. Forcing researchers to chase more NIDA grants for research to ensure they continue to have jobs.

Negative research findings are promoted wildly by NIDA when they are published. Even if the methodology of the study is flawed beyond belief. Even when other researchers try to duplicate the results and fail, NIDA continues to promote the flawed study as though it still has merit. An example of this can be found on NIDA's website

<https://www.drugabuse.gov/news-events/nida-notes/2016/08/study-questions-role-marijuana-in-teen-users-iq-decline>

This finding suggests that the twins’ IQ was affected by factors that twins share in their genes or family background, rather than factors in which they differed (e.g., drug use). A further analysis, comparing the impact of marijuana use on fraternal versus identical twins, suggested that family-wide environmental influences are more decisive than genes for determining IQ trajectory.

NIDA, without any evidence to back up the statement, goes on:

These findings contrast but are not entirely inconsistent with those of an earlier study that linked teen-onset regular marijuana use to IQ deficits in the fourth decade of life (see Early-Onset, Regular Cannabis Use Is Linked to IQ Decline). The researchers say that although their evidence indicates that marijuana exposure does not cause persistent loss of intellectual function up to age 20, **prolonged regular exposure for decades might do so.**

NIDA contradicts itself often, and continues to promote failed theories that bear no relationship to reality. Especially trying to say that marijuana is a gateway drug.

<https://www.drugabuse.gov/publications/research-reports/marijuana/marijuana-gateway-drug>

These findings are consistent with the idea of marijuana as a "gateway drug." However, the majority of people who use marijuana do not go on to use other, "harder" substances.

A more sinister theory promoted by NIDA, the DEA, and even physicians is that marijuana use increases the risk of Schizophrenia. This is so unbelievable that it is a slap in the face of science. Simply looking at reality, the larger numbers of people using, or admitting to use of marijuana, the large number of registered medical cannabis patients in the USA (roughly 1,000,000 to 2,000,000) and the flat schizophrenia rates as reported by the NIH and WHO completely invalidate all peer-reviewed published research on the topic of marijuana causing schizophrenia.

<https://www.nimh.nih.gov/health/statistics/schizophrenia.shtml>

<https://www.who.int/news-room/fact-sheets/detail/schizophrenia>

In fact, a percentage of people diagnosed with schizophrenia use marijuana to reduce anxiety and help with symptoms. People with more severe schizophrenia use more marijuana, this is the basis for the theory that marijuana causes more severe symptoms of schizophrenia. Similar thinking is used against patients who have more severe pain, that marijuana somehow makes pain worse for patients and they have to use more marijuana to gain pain relief. Instead of the observable theory that people with more severe pain use more marijuana to treat their more severe pain than people who have less severe pain. No one makes the theory that aspirin makes pain worse, because people with more pain use more aspirin. Bad science.

The whole point of a state medical marijuana law is that the federal government has engineered a catch-22 circular logic loop about marijuana. States, mostly via people's ballot initiatives have sideswiped the FDA in approving a medicine. This is because the FDA has adopted a policy of only endorsing and approving of monotherapies, e.g. one or two isolated and specific chemicals per approved medicine. There is another policy to reject crude botanical medicines due to variations from plant to plant. These comments by the FDA are found in the DEA response to a petition to reschedule marijuana to schedule 2 and in congressional testimony. Even if a company submitted an IND to the FDA to study marijuana for the treatment of a disease, it would be rejected by the FDA on both of those policies.

The catch-22 comes when patients, nurses, physicians, governors, senators and representatives suggest that marijuana be investigated as a medicine. In congressional testimony, the FDA says we need more research before endorsing that. NIDA says we need more research before utilizing marijuana as a medicine. The DEA says we need more research before marijuana could be considered a medicine. So, if everyone agrees we need more research, where exactly is the research?

Individual physicians have attempted to research the benefits of marijuana within universities. What happens is that, at every turn, approval to study is blocked, delayed and rejected. See for example the 10 years of trying to study medical marijuana for treatment of PTSD in veterans.

<https://www.stripes.com/marijuana-ptsd-study-concludes-after-10-years-of-planning-research-1.570986>

Sisley and her team had to gain approval and support from the U.S. Food and Drug Administration, the Drug Enforcement Administration and the National Institute on Drug Abuse to initiate the research – a process that lasted years.

One study took several years just to begin. After NIDA provided marijuana for research that was full of seeds, stems and mold.

<https://health.hawaii.gov/medicalcannabisregistry/files/2017/08/Generalized-Anxiety-Disorder-08.09.17-Redacted.pdf>

The GAD petition submitted in 2017 included anecdotal evidence, peer-reviewed patient surveys, marijuana use reports and other information. It was rejected by the director due to not having enough peer-reviewed scientific research. One reason given for the rejection was that there was "no specific evidence to GAD". This is why exact specific conditions and waiting for peer-reviewed medical research will never work as an administrative rule for reviewing qualifying condition petitions. There will never be medical marijuana research that specifically mentions each of the hundreds of conditions that include anxiety as a symptom. Research studies are done with one drug and one condition. A rejection for not having a specific condition mentioned seems more like a pedantic nitpick and less like a legitimate reason when both GAD and anxiety share anxiety as the core symptom.

This GAD petition rejection uses the same reason the federal government does not approve of medical marijuana. If this requirement barrier of peer-reviewed research was erected, no state would have a medical marijuana program. Due to the federal policies which are a de facto prohibition on research for medical marijuana benefits. These state medical marijuana programs were created because the federal government failed to do research, and continues to prohibit new research. While the reality is that cannabis is a non toxic medicine, has always been a medicine and always will be a medicine.

Anxiety was also included with a bill in the Hawaii legislature to add qualifying conditions. The Department of Health testified, and in opposing the bill, the DOH stated it would rather include conditions via the petition process. The HDOH also gave another reason, that the dept wanted to delay adding the condition until dispensaries were active. Try naming another medication that is delayed and kept illegal because the department was waiting for a pharmacy to open. The

DOH needs to stop these petty games played with sick people's lives, rights and freedoms.

(REF #95) https://www.capitol.hawaii.gov/session2018/testimony/SB174_TESTIMONY_CPH_02-08-17.pdf

This is another wrong-headed approach to the process, and ignores why and what the medical marijuana law does. Allow me to explain the purpose of the law and the role of the DOH in it.

From the Hawaii medical cannabis law:

The legislature is aware of the legal problems associated with the legal acquisition of marijuana for medical use. However, the legislature believes that medical scientific evidence on the medicinal benefits of marijuana should be recognized.

...

Therefore, the purpose of this Act is to ensure that seriously ill people are not penalized by the State for the use of marijuana for strictly medical purposes when the patient's treating physician provides a professional opinion that the benefits of medical use of marijuana would likely outweigh the health risks for the qualifying patient.

The whole point of the medical marijuana program is not to endorse, nor recommend medical marijuana to patients. The purpose of the law is to NOT PENALIZE patients using medical marijuana with recommendations from their physicians. To protect patients from the laws prohibiting the use of marijuana.

Said another way, it is not the Department of Health's role to become the FDA and research medical marijuana. It is not the DOH's role to judge if medical marijuana is a medicine or not. It is not the DOH's role to decide which conditions marijuana is beneficial for either. That role is solely for a patient to decide if medical marijuana works for their conditions or not. Physicians have a role to make sure the patient's health is first priority over any medication.

The DOH's only role in the petition process is to protect medical marijuana patients from arrest.

People are currently illegally using marijuana to treat their conditions, specifically anxiety. The DOH has the power to protect these patients by adding qualifying conditions. Instead, the DOH has assumed the role of the FDA, denying petitions and opposing adding conditions legislatively. Waiting for peer-reviewed medical evidence that by all accounts is not coming within the next two decades.

This delay and denial of the reality of medical marijuana patients conditions needs to stop.

- (3) Describe the **extent to which** the medical condition is generally accepted by the medical community as a valid, existing medical condition. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Anxiety is a recognized medical condition affecting millions of Americans each year.

<https://www.nimh.nih.gov/health/statistics/any-anxiety-disorder.shtml>

The wide variety of anxiety disorders differ by the objects or situations that induce them, but share features of excessive anxiety and related behavioral disturbances. Anxiety disorders can interfere with daily activities such as job performance, school work, and relationships.

Based on diagnostic interview data from the National Comorbidity Study Replication (NCS-R), Figure 1 shows past year prevalence of any anxiety disorder among U.S. adults aged 18 or older.¹

An estimated 19.1% of U.S. adults had any anxiety disorder in the past year.

Past year prevalence of any anxiety disorder was higher for females (23.4%) than for males (14.3%).

An estimated 31.1% of U.S. adults experience any anxiety disorder at some time in their lives.

Anxiety affects a large portion of the people in the United States, costing billions of dollars in medical treatment costs.

<https://www.cdc.gov/mentalhealth/basics/burden.htm>

Anxiety:

- Anxiety disorders, which include panic disorder, generalized anxiety disorder, post-traumatic stress disorder, phobias, and separation anxiety disorder, are the most common class of mental disorders present in the general population.
 - The estimated lifetime prevalence of any anxiety disorder is over 15%, while the 12-month prevalence is more than 10%.
 - Prevalence estimates of anxiety disorders are generally higher in developed countries than in developing countries.
 - Most anxiety disorders are more prevalent in women than in men.
- One study estimated the annual cost of anxiety disorders in the United States to be approximately \$42.3 billion in the 1990s, a majority of which was due to non-psychiatric medical treatment costs. This estimate focused on short-term effects and did not include the effect of outcomes such as the increased risk of other disorders.

(4) Describe the symptoms and other physiological or psychological effects experienced by an individual suffering from the medical condition or its treatment and **the extent to which** these symptoms and physiological or psychological effects are debilitating. Note: "Debilitating" generally means impairing the ability of a person to accomplish activities of daily living. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Anxiety can cause a person to withdrawal from talking to other people or even going outside. Anxiety can diminish or completely debilitate a person from interviewing for a job, making day to day decisions, making personal relationships or thriving.

Instead of dealing and treating anxiety, the world instead decided to call anxiety being an introvert. An "introvert" is a "shy, reticent person". In other words, a person who has so much anxiety that they would rather hide than speak to someone else. Shyness is anxiety.

<https://www.nimh.nih.gov/health/publications/social-anxiety-disorder-more-than-just-shyness/index.shtml>

The reason this petition is for "Anxiety" and not "social anxiety disorder" is because each year there seems to be a new disorder with the core symptom being anxiety. Panic Disorder, Generalized Anxiety Disorder, Social Anxiety Disorder, PTSD. Anxiety is the common condition.

<https://www.nimh.nih.gov/health/statistics/any-anxiety-disorder.shtml>

Any Anxiety Disorder with Impairment Among Adults

Of adults with any anxiety disorder in the past year, degree of impairment ranged from mild to severe, as shown in Figure 2. Impairment was determined by scores on the Sheehan Disability Scale.

Among adults with any anxiety disorder, an estimated 22.8% had serious impairment, and 33.7% had moderate impairment.¹

A majority of people with any anxiety disorder experienced mild impairment (43.5%).¹

1. Harvard Medical School, 2007. National Comorbidity Survey (NCS). (2017, August 21). Retrieved from <https://www.hcp.med.harvard.edu/ncs/index.php>. Data Table 2: 12-month prevalence DSM-IV/WMH-CIDI disorders by sex and cohort.

<https://www.ncbi.nlm.nih.gov/pmc/articles/PMC181171/>

Although the principal symptoms of anxiety disorders include fear, excessive worry, nervousness, and obsessions, a multitude of physical symptoms also may be present. These somatic symptoms—which include heart palpitations, gastrointestinal problems, sweating, fainting, and chronic pain—can confound the diagnosis and resist all forms of medical management, unless the underlying anxiety source is identified and treated. Delays in diagnosis and treatment can be expensive for the patient, physician, and society: unnecessary tests and ineffective treatments increase medical costs, and **anxiety symptoms may lead to loss of income and productivity, financial dependence, and even suicide.**

(5) If one or more treatments for the medical condition, rather than the condition itself, are alleged to be the cause of a person's suffering, describe **the extent to which the treatments causing suffering are generally accepted by the medical community as valid treatments** for the medical condition. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

N/A

(6) Describe the availability of conventional medical therapies other than those that cause suffering to alleviate symptoms caused by the medical condition or its treatment. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

(7) Describe the extent to which evidence supports a finding that the use of cannabis alleviates symptoms caused by the medical condition or its treatment. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Selected quotes and transcribed tables are taken from the following research and presented below.

1. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3998228/>

Ninety-seven per cent of respondents used cannabis primarily for chronic pain. Average pain improvement on a 0–10 pain scale was 5.0 (from 7.8 to 2.8), which translates to a 64% relative decrease in average pain. Half of all respondents also noted relief from stress/anxiety, and nearly half (45%) reported relief from insomnia. Most patients (71%) reported no adverse effects, while 6% reported a cough or throat irritation and 5% feared arrest even though medical cannabis is legal in Hawai'i. No serious adverse effects were reported.

These results suggest that Cannabis is an extremely safe and effective medication for many chronic pain patients. Cannabis appears to alleviate pain, insomnia, and may be helpful in relieving anxiety. Cannabis has shown extreme promise in the treatment of numerous medical problems and deserves to be released from the current Schedule I federal prohibition against research and prescription.

2. <https://harmreductionjournal.biomedcentral.com/articles/10.1186/1477-7517-2-18>

Approximately three quarters of participants (71%) claimed to have experienced a return of their symptoms or condition on stopping cannabis, especially: pain (53% of those who claimed a return of symptoms), depression or anxiety (30%), insomnia (11%), spasm (10%) and nausea/vomiting or lack of appetite (9%).

3. <https://doi.org/10.1016/j.jpain.2007.09.002>

A randomized, double-blind, placebo-controlled trial was conducted to determine the benefit of nabilone in pain management and quality of life improvement in 40 patients with fibromyalgia.

There were significant decreases in the VAS, FIQ, and anxiety in the nabilone treated group at 4 weeks. There were no significant improvements in the placebo group. The treatment group experienced more side effects per person at 2 and 4 weeks, respectively. Nabilone appears to be a beneficial, well-tolerated treatment option for fibromyalgia patients, with

significant benefits in pain relief and functional improvement.

4. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2683812/>

Thematic analysis revealed that these teens differentiated themselves from recreational users and positioned their use of marijuana for relief by emphasizing their inability to find other ways to deal with their health problems, the sophisticated ways in which they titrated their intake, and the benefits that they experienced. These teens used marijuana to gain relief from difficult feelings (including depression, anxiety and stress), sleep difficulties, problems with concentration and physical pain.

5. <https://doi.org/10.1080/02791072.2011.587700>

Of 1,746 patients, 37.8% self-reported therapeutic benefits from medical marijuana for anxiety.

16.9% of patients self-reported therapeutic benefits from medical marijuana for panic attacks.

6. <https://www.ncbi.nlm.nih.gov/pubmed/6117575>

The results of the study showed a dramatic improvement in anxiety in the nabilone group when compared with placebo (P less than 0.001). Side effects reported were dry mouth, dry eyes, and drowsiness. Patients did not report any of the subjective "altered state" experience of marijuana.

7. <https://www.ncbi.nlm.nih.gov/pubmed/15857739>

Following Ethics Committee approval, HIV-positive individuals attending a large clinic were recruited into an anonymous cross-sectional questionnaire study. Up to one-third (27%, 143/523) reported using cannabis for treating symptoms. Patients reported improved appetite (97%), muscle pain (94%), nausea (93%), **anxiety (93%)**, nerve pain (90%), depression (86%), and paresthesia (85%).

8. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5101100/>

Cannabidiol oil, an increasingly popular treatment of anxiety and sleep issues, has been documented as being an effective alternative to pharmaceutical medications. This case study provides clinical data that support the use of cannabidiol oil as a safe treatment for reducing anxiety and improving sleep in a young girl with posttraumatic stress disorder.

9. <https://www.ncbi.nlm.nih.gov/pubmed/24095000>

Patients reported using cannabis to treat multiple symptoms, with sleep, pain, and anxiety being the most common. Cannabis was perceived to provide effective symptoms relief across medical conditions. Patterns of use were also consistent across medical conditions. Notable differences were observed with regard to modes of access.

10. <https://www.ncbi.nlm.nih.gov/pubmed/15184623/>

Of 21 patients reporting stress, 20 said medical marijuana helped moderate-complete relief.

Of 16 patients reporting mood, all 16 said medical marijuana helped moderate-complete relief.

The symptoms reported by medical cannabis users to be most effectively relieved were stress, sleep, mood, stiffness/spasm, and pain.

11. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5312634/>

Finally, preliminary clinical trials suggest that high-dose oral CBD (150–600 mg per day) may exert a therapeutic effect for epilepsy, insomnia, and social anxiety disorder. Nonetheless, such doses of CBD have also been shown to cause sedation.

12. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5165161/>

In addition, we have assessed the role of the cannabinoid system and marijuana constituents in neuroprotection as well as considered other beneficial effects of marijuana. Marijuana has been shown to improve nonmotor symptoms of PD such as depression, pain, sleep, and anxiety.

Moreover, components of cannabis have been demonstrated to have neuroprotective effect due to their anti-inflammatory, antioxidative, and antiexcitotoxic properties.

13. <https://www.ncbi.nlm.nih.gov/pubmed/26317379>

367 medical marijuana patients in Arizona were surveyed.
181 patients reported using medical marijuana to experience relief from Anxiety
164 patients reported using medical marijuana to experience relief from Stress.
General relief from Anxiety symptoms was 82.9% and 87.2% for Stress,

Relief by medical marijuana compared to other medications was 79.3% for Anxiety and 91.6 for Stress.

Less frequent use of other medications was 85.9% for Anxiety and 79.1% for Stress.

14. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3285527/>

One Hundred Canadian medical marijuana patients were surveyed in 2007-2008. 60.2% said they used medical marijuana to reduce anxiety.

15. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1262744/>

This exploratory study examined the patterns of medicinal cannabis use among a sample of 128 Australian adults who responded to media stories about this issue.

Nearly one in ten (8%) reported no effect on depression or anxiety . More than one in ten (14%) specified that while cannabis could ease their symptoms and enabled them to cope, they realised that it could not cure their underlying condition.

Approximately three quarters of participants (71%) claimed to have experienced a return of their symptoms or condition on stopping cannabis, especially: pain (53% of those who claimed a return of symptoms), depression or anxiety (30%) , insomnia (11%), spasm (10%) and nausea/vomiting or lack of appetite (9%).

Almost two thirds (62%) of respondents claimed that they decreased or discontinued their use of other medicines when they started using cannabis medicinally. This was more common in males (65% vs. 58% of females) and older participants (aged 50 years +) (70% vs. 59% among younger participants). For some people this was a substantial change, representing a shift away from chronic, high-dose medication use.

Perhaps not surprisingly, cannabis was typically perceived as superior to other medications in terms of undesirable effects, and the extent of relief provided . Thus, cannabis was rated to produce equivalent (8%) or worse side effects (3%) by a minority of therapeutic users. It was considered to work "a bit" or "much better" than other medicines, or to be the only source of relief, by more than three quarters (82%).

16. <https://www.ncbi.nlm.nih.gov/pubmed/28189912>

In regards to conditions, pain-related conditions were the most common, reported by 53% of participants (n = 144; chronic pain 36%; (n = 98), arthritis 12% (n = 32), headache 5% (n = 14)). The second most prominent class was mental health (eating disorder, PTSD & psychiatric disorder), reported by 15% (n = 41). Other prominent conditions included gastrointestinal disorders (11%, n = 29), insomnia (7%, n = 18) and multiple sclerosis (4%, n = 11). In regards to symptoms; the most highly endorsed were chronic pain (73%, n = 197), stress (60%,n=162), insomnia (57%, n = 155), depression (46%, n = 126) and headache (32%, n = 87). gastrointestinal (GI) issues also featured prominently, with 29% (n = 79) citing appetite loss and another 29% (n = 79) nausea. Cannabis was perceived to be very effective at symptom relief, with 95% (n = 257) reporting that it "often" or "always" helped alleviate their symptoms.

17. <https://doi.org/10.1111/dar.12323>

Participants presented with the range of conditions that is generally consistent with surveys of CTP users, the most prominent conditions being pain (32%), mood (i.e. anxiety and depression (18%), arthritis (15%), HIV (10%), gastrointestinal disorder (7%)

18. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5422566/>

We previously reported in an earlier survey that of 1,429 respondents, 61% reported using cannabis for managing pain, 58% reported using cannabis for anxiety and 50% reported using cannabis for depression. In the current analysis, these same conditions were also the most commonly reported conditions by respondents. Of the 1,040 participants reporting pain and/or intractable pain, 619 (59.52%) reported depression and anxiety as comorbidities. As such, the odds of reporting substituting cannabis for prescription drugs were more than one and a half times greater (OR, 1.66; 95% CI,

1.27–2.16) among those reporting using it to manage pain, anxiety and depression than among those using it to manage only one of the three conditions.

This team previously reported that in a survey of 1,429 medical cannabis users, 61% reported cannabis use for pain, 58% reported cannabis use for anxiety and 50% reported using cannabis to manage depression. In 2016, Dale and Stacey reported that those using cannabis for pain were more likely to be substituting for prescription drugs. In 2017, Walsh et al published a review of medical cannabis and mental health to try to better understand how medical cannabis use may impact areas of potential concern for clinicians. "Relaxation and relief of anxiety" and "relief of negative mood" or depression were among the most widely reported conditions in 60 publications included in their analysis. Because it is common for chronic pain patients to be prescribed combinatorial pharmacotherapy to address comorbidity with depression and/or anxiety, it is largely unknown how often patients may be discontinuing prescription medications when initiating cannabis use.

Taken with preclinical data on the role of the endocannabinoid system in stress, pain processing and immune homeostasis, it is clear that future investigation is warranted using controlled trials with human subjects to better understand the role that cannabis may play in treating pain, anxiety, depression and other conditions.

19. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4277530/>

Most of the respondents (from the clinic and online groups) reported that cannabis improved their mood, pain, muscle spasms, and sleep.

20. <https://www.ncbi.nlm.nih.gov/pubmed/11210205>

Of 628 Canadian medical marijuana patients:

463 patients reported using medical marijuana to treat anxiety.

This article reports on an exploratory study of medical cannabis users. Interviews were completed with 50 self-identified medical cannabis users recruited through notices in newspapers and on bulletin boards. They reported using cannabis for a variety of conditions including HIV-AIDS-related problems, chronic pain, depression, anxiety, menstrual cramps, migraine, narcotic addiction as well as everyday aches, pains, stresses and sleeping difficulties.

However, cannabis was also used to treat menstrual cramps, anorexia, narcotic addiction, migraine, Tourette's Syndrome, lupus, Grave's Disease, epilepsy, retinitis, chemotherapy-induced loss of appetite, Crohn's Disease, arthritis and everyday aches, pains, stresses and sleeping difficulties.

Many reported benefits of cannabis were consistent with those reported elsewhere. Cannabis was typically used for its sedative, analgesic, antispasmodic, appetite stimulating, anticonvulsant and euphoric properties. These properties were well known in the past century when cannabis was used to treat conditions that required medications with these properties.

Although scientific evidence in favor of medical cannabis is limited (Gurley, Aranow & Katz 1998), self-treatment with cannabis could become popular as more users publicize their own experiences. This is especially so if the everyday aches and pains and psychological problems are promoted as medical reasons for using cannabis.

21. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2683812/>

The use of marijuana to manage stress and anxiety was described by 12 teens in our sample. Dealing with bullying at school, heavy demands of school work, taxing shifts at work, and just "giving as much as you can" along side difficult relationships with parents or guardians, and receiving threats from neighbors all took its toll on these youth. For some, these experiences contributed to high levels of stress and anxiety, and for others uncomfortable levels of anger – both were difficult to manage. Although some had friends they could turn to, marijuana provided an additional source of stress relief that was ready at hand.

"Lots of people know me, know I do pot and they think that I'm a pot head but really the thing they don't realize is that I have a reason for it. It's for my stress and an antidepressant. I get really upset. It [pot] helps me feel better about myself, because you know people don't do that [help me], like my friend [name] can, but nobody else can." [Female, 14 years, non-daily use]

There was general agreement among the teens that marijuana calmed them down, and helped them feel "not so nervous" and "not so uptight about everything." One teen recognized, however, that despite the fact that marijuana could be a very effective stress reliever, it might not work for everyone:

“Well as far as pot goes, the good thing is that it's definitely a stress reliever, hands down. I know lots of people who would be just a complete wreck if they weren't smoking pot but then there's also people who are a complete wreck because they do smoke pot, so it's kind of a hard thing.” [Male, 16 years, non-daily use]

22. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3691841/>

While the controversies surrounding cannabis are far from subdued (and are often permeated and masked by conflicting ideological credos), standardized studies on cannabinoids have highlighted that the psychological and behavioral outcomes of this substance are highly variable and range from relaxation, euthymia and heightened sociability to panic, paranoid ideation and psychosis [112 - 116]. A corollary of this observation is that the high comorbidity rate between cannabis use disorders and psychiatric conditions [100 - 105] may indicate that cannabis consumption is either a concurring cause or a “self-therapeutic” strategy for anxiety and mood disorders [117 - 123]. The latter interpretation is supported by the observation that anxiety-spectrum disturbances and traumas in early developmental stages are a strong predictor for later cannabis use disorders [124 - 127]; furthermore, several lines of evidence suggest that the anxiolytic effects of THC may partially account for the high prevalence of cannabis use in patients affected by PTSD [128 - 131] and OCD [132]. Accordingly, recent clinical studies have shown that THC elicits therapeutic effects in OCD [133] and trichotillomania, an impulse-control disorder characterized by compulsive hair-pulling [134].

23. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4604171/>

Overall, current evidence indicates CBD has considerable potential as a treatment for multiple anxiety disorders, with need for further study of chronic and therapeutic effects in relevant clinical populations.

24. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4604174/>

Although clinical studies in this area are difficult to do, even in countries where the use of cannabis has been allowed for years, there is a clear role for cannabis products in symptom management for these difficult conditions.

25. <https://www.ncbi.nlm.nih.gov/pubmed/22729452>

RESULTS:

Studies using animal models of anxiety and involving healthy volunteers clearly suggest an anxiolytic-like effect of CBD. Moreover, CBD was shown to reduce anxiety in patients with social anxiety disorder.

CONCLUSION:

Future clinical trials involving patients with different anxiety disorders are warranted, especially of panic disorder, obsessive-compulsive disorder, social anxiety disorder, and post-traumatic stress disorders. The adequate therapeutic window of CBD and the precise mechanisms involved in its anxiolytic action remain to be determined.

26. <https://doi.org/10.2202/1941-2851.1017>

1655 Patients reported using medical marijuana for these conditions:

Anxiety disorders 18.7% of patients

Applicants most frequently reported using medical marijuana for pain relief (82.6%), improved sleep (70.6%), and relaxation (55.6%) . The next most frequently reported benefits included relief of muscle spasms (41.3%), headache (40.8%), relief of anxiety (38.1%) , improved appetite (38.0%), relief of nausea and vomiting (27.7%), and relief of depression (26.1%). Half the applicants (50.8%) reported using marijuana as a substitute for prescription medication and 13.2% reported using marijuana as a substitute for alcohol.

27. <https://doi.org/10.1176/appi.ajp.2007.07061016>

Hence, it can be speculated that the anti-obsessive effect observed in our patients may have been a consequence of the glutamate modulation of the cannabinoid dronabinol.

28. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4349825/>

The findings from the study indicate that cannabis use is associated with a subsequent change in positive affect, depressive symptoms and manic symptoms over the course of daily life. No evidence for the use of cannabis to self-

medicate minor fluctuations in negative affect or BD symptoms was revealed. Participants in the study were currently well and out of episode. Future research should explore whether the self-medication hypothesis is more relevant to individuals that are in the acute stages of depression or mania. This would be consistent with the broader self-medication hypothesis in BD where individuals have reported finding cannabis useful in the management of their symptoms.

29. <https://www.ncbi.nlm.nih.gov/pubmed/9692379>

The authors present case histories indicating that a number of patients find cannabis (marihuana) useful in the treatment of their bipolar disorder. Some used it to treat mania, depression, or both. They stated that it was more effective than conventional drugs, or helped relieve the side effects of those drugs. One woman found that cannabis curbed her manic rages; she and her husband have worked to make it legally available as a medicine.

Others described the use of cannabis as a supplement to lithium (allowing reduced consumption) or for relief of lithium's side effects. Another case illustrates the fact that medical cannabis users are in danger of arrest, especially when children are encouraged to inform on parents by some drug prevention programs. An analogy is drawn between the status of cannabis today and that of lithium in the early 1950s, when its effect on mania had been discovered but there were no controlled studies. In the case of cannabis, the law has made such studies almost impossible, and the only available evidence is anecdotal. The potential for cannabis as a treatment for bipolar disorder unfortunately can not be fully explored in the present social circumstances.

30. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4898690/>

Findings suggest that for some bipolar patients, marijuana may result in partial alleviation of clinical symptoms. Moreover, this improvement is not at the expense of additional cognitive impairment.

31. <https://www.ncbi.nlm.nih.gov/pubmed/17703715>

Subjective reports by patients suggest an overall positive effect, but these may be unreliable. We herein report a case in which mood data was prospectively collected over two years of total substance abstinence and two years of extreme marijuana use. Marijuana use did not alter the total number of days of abnormal mood, however, marijuana was associated with an increase in the number of hypomanic days and a decrease in the number of depressed days. While not conclusive, the data suggest that marijuana may indeed have an effect on mood in bipolar patients that needs to be systematically examined.

32. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5652027/>

Cannabis use diminishes some of the adverse effects of neurological and psychiatric disorders.

33. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4323143/>

These results suggest that cannabis use has clinical implications for the early course of BD (Bipolar Disorder) by increasing mood level.

34. <https://doi.org/10.1111/j.1368-5031.2005.00271.x>

Medicinal cannabis use was Reported by patients with chronic pain(25%), multiple sclerosis and depression (22% each), arthritis (21%) and neuropathy (19%).

(8) Provide any information, studies, or research reports regarding any beneficial or adverse effects from the use of cannabis in patients with the medical condition. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Minnesota has undertaken the most comprehensive research on the medical cannabis patients in its medical cannabis program in the United States. Including surveys by both the patients and their physicians. Tracking which medical cannabis products they purchase, use and continue using to treat each qualifying condition.

The Minnesota Department of Health publishes reports of the medical cannabis patients and how medical marijuana

helps them with anxiety.

In its first year of reports, the Minnesota DOH published patient comments about the beneficial effects of the medical marijuana.

(REF #98) <https://www.health.state.mn.us/people/cannabis/about/firstyearreport.html>

(REF #94) <https://www.health.state.mn.us/people/cannabis/docs/about/appendixa.pdf>

Many such comments are found within the above report.

Further reports in the following years also track which patients under each condition report benefits of medical marijuana on anxiety.

<https://www.health.state.mn.us/people/cannabis/about/omcreport.html>

<https://www.health.state.mn.us/people/cannabis/about/cohort.html>

(REF #93) https://www.health.state.mn.us/people/cannabis/docs/about/cohort/2015_2016_benefitspse.pdf

The patient self-evaluation is required for patients to complete prior to each medical cannabis purchase. It includes questions to assess symptom severity, some of which are administered to all patients (standard set of 8 symptom measures) and some of which are tailored to symptoms for a given condition (condition-specific symptom measures). Since symptom data is collected prior to each patient's first medical cannabis purchase, symptom changes can be assessed over time and compared to baseline (baseline = patient responses to symptom questions just prior to their first medical cannabis purchase)

These reports are useful to show that medical marijuana patients find a greater than 30% reduction in anxiety symptoms, and a large percentage of patients continue to maintain that reduction of anxiety for 4 months.

(REF #92) https://www.health.state.mn.us/people/cannabis/docs/about/cohort/2016_2017_benefitspse.pdf

(REF #91) https://www.health.state.mn.us/people/cannabis/docs/about/cohort/c2015_2017_benefitspse.pdf

MDOH publishes Adverse Side Effects reports which show a very small percentage of people experience a worsening of anxiety symptoms. I urge you to read them all as it shows how small the number of adverse anxiety reports are.

<https://www.health.state.mn.us/people/cannabis/about/cohort.html>

(REF #90)

https://www.health.state.mn.us/people/cannabis/docs/about/cohort/appendix_c_2015_2016_patientreportednegativeeffects.pdf

Although the comments mention anxiety as a side effect, sometimes it is not the cannabis's fault, but prohibition's fault, as this comment rated at score level 4 shows:

I have more anxiety that police may take me for a blood test of charge me with DUI if they know I'm a patient at dispensary. I also had a Warning of illegal drug use in a urine test from the so called pain clinic I'm required to go to by [CLINIC]By my now ex primary Dr of 20 years. I told the pain clinic when I signed contract not to use illegal drugs that I took cannabis by prescription in medical form thru Dept of Health etc. The Dr said OK, as long as it wasn't in organic form for smoking! He said I was the 1st patient at [CLINIC]to be on legal cannabis. I advised him, I maybe to 1st but surely not the last patient. They said this will be resolved ok but I still was warned for illegal THC drug use, which is upsetting but it will be straightened out. Thank u!

Massachusetts published a report on its medical marijuana patients and their benefits.

<https://www.mass.gov/report/massachusetts-department-of-public-health-marijuana-research>

(REF #77) <https://www.mass.gov/files/documents/2019/07/09/MBHS-full-report-final.pdf>

The Marijuana Baseline Health Study (MBHS)

A legislative mandate required the Massachusetts [Department of Public Health \(DPH\)](#) to conduct a baseline study to investigate marijuana use in Massachusetts. The report published confirms the consensus that marijuana use improves

mood and or mental health for a large percentage of people.

Page 10:

Among all respondents, **78% reported positive changes in their mood or mental health**, and 67% reported improved physical health. In addition, 83% of respondents reported no negative outcomes/consequences related to their marijuana use.

Page 148:

Results from this survey suggest that respondents appear to be treating a wide range of medical conditions, and often more than one at a time. **The top 5 medical conditions being treated were anxiety (60% or all respondents), chronic pain (46%), insomnia (43%), depression (42%), and stress (41%),** and the average number of conditions being treated by medical marijuana is 4.7.

(9) Attach letters of support from physicians or other licensed health care professionals knowledgeable about the medical condition.

Medical Cannabis Registry

Instructions

1. ALL items on the form MUST be completed.
2. Petitions and any supporting documents may be submitted as follows:
 - a. Email to: medicalmarijuana@doh.hawaii.gov before the close of business (4:30PM) on **Thursday, April 30, 2020**. Please use the subject line: **Petition to Add New Condition**. Note that the DOH will not make public any information that is protected pursuant to Chapter 92F, HRS, the Uniform Information Practices Act.
 - b. Postal mail to: 4348 Waialea Avenue, #648, Honolulu, Hawaii 96816. Mailed petitions must be received by **Thursday, April 30, 2020**.
 - c. Hand delivered to: Kinau Hale at 1250 Punchbowl Street, Honolulu, Hawaii 96813 before the close of business (4:30PM) on **Thursday, April 30, 2020**. Hand delivered petitions must be left with the security guard and addressed to the Medical Cannabis Registry Program **ATTN: Petition to Add New Condition**.
3. For best results, complete and thorough petitions that include substantiated and reputable research have the best chance of succeeding. DOH recommends that you do the following for items #2- #8 on the petition form:
 - a. Please cite research, published evidence, or findings using the standard American Medical Association (AMA) format for each piece of research, published evidence, or findings that you reference in your submittal or at a minimum the following:
Author's Name; Title of Article; Name of Publication; Date of Publication; Volume/Section/Chapter/Page/Line as applicable; and URL (if applicable).
 - b. Please attach a PDF copy of the cited material to your submittal. These documents will NOT be returned.
 - c. Please be sure to indicate the specific section, page(s), lines, etc., of the attachment that you want reviewed/considered as evidence.
4. To view a list of current conditions click here: [Current Debilitating Medical Conditions](#)

Petitioner

Name

- I am a
- Physician/APRN
- Potentially qualifying patient (a person who has been diagnosed with the medical condition for which the petition is being made)

Street Address

City

State Zip Code

Email

I prefer the following and give my consent for all notifications about my petition to be by:

- Mailing address
- Email address
- Both mailing and email addresses

If I have indicated communication via email, and if for any reason email communication is not successful (i.e. email provided bounces or is kicked back to DOH), then I further understand that communication will be by regular U.S. postal service to the mailing address that I have provided. I also take full responsibility for any inaccurate email or U.S. postal mail address provided.

Petitioner Content

(1) State the specific medical condition or its treatment for which the petition is being made.

Anxiety

(2) State the reason(s) why the medical condition or its treatment should be added to the list of qualifying debilitating medical conditions for which medical cannabis may be used. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

This petition includes new scientific research supporting the request to add "Anxiety" as a qualifying condition that was not present in the "General Anxiety Disorder" petition. This petition should be reviewed and not rejected for its similarity to an earlier petition due to the new evidence published by the Minnesota Department of Health, the Massachusetts Department of Health and other peer-reviewed medical research attached and included.

<https://www.mass.gov/report/massachusetts-department-of-public-health-marijuana-research>
(REF #77) <https://www.mass.gov/files/documents/2019/07/09/MBHS-full-report-final.pdf>
The Marijuana Baseline Health Study (MBHS)

A legislative mandate required the Massachusetts [Department of Public Health \(DPH\)](#) to conduct a baseline study to investigate marijuana use in Massachusetts. The report published confirms the consensus that marijuana use improves mood and or mental health for a large percentage of people.

Page 148:

Results from this survey suggest that respondents appear to be treating a wide range of medical conditions, and often more than one at a time. **The top 5 medical conditions being treated were anxiety (60% or all respondents)**, chronic pain (46%), insomnia (43%), depression (42%), and stress (41%), and the average number of conditions being treated by medical marijuana is 4.7.

In the 1999 National Academy of Sciences Institute of Medicine report on marijuana, the National Academy of Science found that thorough medical research shows that marijuana reduces anxiety for "many people".

(REF #99) <https://www.nap.edu/download/6376>

page 165

The movement disorders most often considered for marijuana or cannabinoid therapy are dystonia, Huntington's disease, Parkinson's disease, and Tourette's syndrome.

Movement disorders are often transiently exacerbated by stress and activity and

improved by factors that reduce stress. **This is of particular interest because for many people marijuana reduces anxiety.**

In a study of medical marijuana patients in Arizona, many patients reported significant relief levels of anxiety.

(REF #13) <https://www.ncbi.nlm.nih.gov/pubmed/26317379>

367 medical marijuana patients in Arizona were surveyed.

181 patients reported using medical marijuana to experience relief from Anxiety

General relief from Anxiety symptoms was 82.9% with medical marijuana,

Relief by medical marijuana compared to other medications was 79.3% for Anxiety

Less frequent use of other medications was 85.9% for Anxiety

Patients who suffer from Post Traumatic Stress Disorder find relief of anxiety with medical cannabis. PTSD is a

qualifying condition in Hawaii and other states. It makes logical sense to allow people who do not have PTSD to gain relief of anxiety by adding anxiety to the list of qualifying conditions.

In a small percentage of people, medical cannabis can aggravate their anxiety. For the majority of people, cannabis reduces anxiety. This contraindication is similar to other anti-anxiety prescriptions, for whom a small percentage, their anxiety can be aggravated. This is not a reason to reject a qualifying condition, merely a reality of using any medication. Some epilepsy medicines make seizures worse or more frequent.

Marijuana is safer than all prescription medications and most of OTC medications. Cannabis has less side effects, and no severe, toxic or dangerous side effects compared to all of the prescription medications used to treat Anxiety.

<https://www.nimh.nih.gov/health/topics/mental-health-medications/index.shtml>

For example Benzodiazepines commonly used as anti anxiety medications, are responsible for hundreds of deaths each year in the United States.

A safety profile of Medical Marijuana can be found in the first year report of the Minnesota medical marijuana program. The Minnesota Department of Health surveyed 1500+ medical marijuana patients enrolled in the program.

(REF #98) <https://www.health.state.mn.us/people/cannabis/about/firstyearreport.html>

Adverse Side Effects: At this point, the safety profile of the medical cannabis products available through the Minnesota program seems quite favorable. Approximately 20-25% of enrolled patients report negative physical or mental side effects of some kind, with the majority – around 60% - reporting only one and 90% reporting three or fewer. The vast majority of adverse side effects, around 90%, are mild to moderate in severity. An assessment of the 30 patients reporting severe side effects, meaning "interrupts usual daily activities," found no apparent pattern of patient age, medical condition, or type of medical cannabis used. The most common adverse side effects are dry mouth, drowsiness, and fatigue. Fortunately, up to the present no serious adverse events (life threatening or requiring hospitalization) have been reported.

Medical Marijuana's mild to moderate side effects of dry mouth, drowsiness and fatigue are easily tolerated by the vast majority of patients.

The Mayo Clinic website has assembled dosage information on Medical Marijuana.

<http://www.mayoclinic.org/drugs-supplements/marijuana/dosing/hrb-20059701>

In the latest petition to add Anxiety to Ohio's medical marijuana program, the New Jersey Department of Health's final decision on a petition to add anxiety in New Jersey was included.

(REF 96) [https://med.ohio.gov/Portals/0/Publications/Medical%20Marijuana%20Petitions%202019/0133%20-%20Anxiety%20\[Rosenberger\].pdf?ver=2020-01-28-104750-247](https://med.ohio.gov/Portals/0/Publications/Medical%20Marijuana%20Petitions%202019/0133%20-%20Anxiety%20[Rosenberger].pdf?ver=2020-01-28-104750-247)

(REF 97)

https://www.nj.gov/health/medicalmarijuana/documents/agency_decision_letters/MMP_FAD_conditions_012319.pdf

New Jersey's medical cannabis program is similar to Hawaii's medical cannabis program. With similar requirements for petitions to meet.

On July 5, 2016, the Department published the Request for Petitions in the New Jersey Register advising

that from August 1, 2016 to August 31, 2016, it was accepting petitions to establish additional medical conditions as "debilitating" under the MMP. 43 NJR. 1395(a). The Request for Petitions stated that the Department was seeking petitions in accordance with the Act, which authorizes the Department to include additional debilitating medical conditions under the MMP.

In the Request for Petitions, the public was advised that submitted petitions were required to include the following information, pursuant to N.J.A.C. 8:64-53:

- (1) The extent to which the condition is generally accepted by the medical community and other experts as a valid, existing medical condition;
- (2) If one or more treatments of the condition, rather than the condition itself, are alleged to be the cause of the patient's suffering, the extent to which the treatments causing suffering are generally accepted by the medical community and other experts as valid treatments for the condition;
- (3) The extent to which the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting, or otherwise severely impair the patient's ability to carry on activities of daily living;
- (4) The availability of conventional medical therapies other than those that cause suffering to alleviate suffering caused by the condition and/or the treatment thereof;
- (5) The extent to which evidence that is generally accepted among the medical community and other experts supports a finding that the use of marijuana alleviates suffering caused by the condition and/or the treatment thereof; and
- (6) Letters of support from physicians or other licensed health care professionals knowledgeable about the condition.

New Jersey found that Anxiety met the requirements and accepted Anxiety as a qualifying condition.

Anxiety

Based upon my independent review of the petitions, I am granting those seeking to add anxiety to the MMP. In coming to this conclusion, I reviewed these petitions against the six regulatory criteria cited above and found that the condition meets the requirements for inclusion in the MMP.

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that anxiety satisfies this criteria.

Specifically, the American Psychiatric Association defines anxiety and anxiety disorders as conditions characterized by excessive fear and behavioral disturbances. Anxiety results from anticipation of a future threat and may be associated with symptoms of muscle tension, vigilance in preparation for future danger, and overly cautious or avoidant behaviors. Additionally, there are multiple ICD-10-CM codes for anxiety disorders. Because anxiety maintains a common definition in the medical community and has ICD-10-CM codes, I find that anxiety is a valid and recognized medical condition.

Under the second factor, I must consider whether the treatments for the condition, rather than the condition itself, are causing the patient's suffering and the extent to which the treatments causing the patient suffering are generally accepted by the medical community and other experts as valid treatments for the condition. From my review of this condition, the generally accepted treatments for anxiety are dependent on the symptoms and the severity of the particular disorder.

Mild and moderate forms of anxiety may not require a pharmacologic intervention, but may necessitate other

forms of treatment, such as meditation, mindfulness, breathing techniques as well as psychotherapy (counseling) or cognitive therapy.” The most common classes of medications used to combat anxiety disorders are antidepressants, anti-anxiety drugs, and beta— blockers.⁴⁹ Antidepressants are safe and effective but they may be risky for children, teens, and young adults.⁵⁰ Antidepressants also come with a “black box” warning — the FDA’s strongest warning — advising that some people may have suicidal thoughts or make suicide attempts while taking the medication.⁵¹ The most common anti-anxiety medications are called benzodiazepines.

As noted by the Panel, the common side effects of benzodiazepines include headache, confusion, tiredness, and in some cases nightmares and memory impairments.⁵² And, benzodiazepines carry a risk of dependence and addiction.⁵³ Furthermore, the FDA notes that the number of patients who were prescribed both an opioid analgesic and benzodiazepine increased by 41% between 2002 and 2014.⁵⁴ As a result, the FDA requires black box warnings and patient-focused Medication Guides for prescription opioid analgesics, opioid-containing cough products, and benzodiazepines to inform the patient about the serious risks associated with using these medications at the same time.⁵⁵ Thus, I find that the treatments for anxiety are recognized and accepted by the medical community as the treatments for this condition and relate to the suffering of the patient.

As for the third factor, which is whether the condition itself and for the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient’s ability to carry on activities of daily living, I find that both the anxiety condition itself as well as the treatments for this condition cause severe suffering for patients. Specifically, anxiety may lead to problems that negatively impact an individual’s activities of daily living and quality of life and may lead to suicide and depression. Anxiety disorders can also cause significant distress or interfere with social, occupational, and other areas of functioning. In fact, an estimated 31.1% of US. adults experience an anxiety disorder at some time in their lives.⁵⁶ Medications, in some instances, may exacerbate the symptoms and are associated with debilitating side effects that can prevent a patient from engaging in activities of daily living, thereby diminishing one’s quality of life. Accordingly, I find that both the condition of anxiety as well as the therapies to treat it cause severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patients suffering caused by the condition and or the treatment thereof. As discussed above, mild and moderate forms of anxiety may be treated with meditation, mindfulness, breathing techniques as well as counseling or cognitive therapy that can be effective. Progression to medication therapy may be initiated; however, in both instances, one must consider the therapeutic response. Failure to respond to therapies or side effects associated with treatments may result in significant impacts on quality of life. As such, I find that there is an absence of medically-accepted, alternative medical therapies to the conventional therapies currently prescribed for migraine that cause suffering.

Regarding the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I find that cannabis is generally accepted as an effective treatment for anxiety.

The Panel discussed medical evidence that cannabis may exacerbate anxiety symptoms or that an effect related to cannabis may be associated with anxiety, such as dependence and cravings. Literature suggests that individuals with anxiety sensitivity may be more likely to turn to cannabis as a mechanism for coping with stress, which may in turn lead to problematic use behaviors.⁵⁷ However, the Panel further discussed a review published by the National Academies of Sciences, Engineering, and Medicine in 2017, which found that there is limited evidence that cannabidiol is an effective treatment for the improvement of anxiety symptoms, which was assessed by a public speaking test utilizing individuals with social anxiety disorders.⁵⁸

On balance, the Panel recommended adding anxiety as an allowable condition under the MMP as research suggests that it could be helpful to some patients with this condition. I agree. While marijuana may not be effective for all anxiety sufferers, there is research evidencing that it may be helpful to some, especially those with social anxiety disorders. Thus, I find that there is acceptance in the medical community that marijuana is likely to relieve the suffering associated with some anxiety conditions. However, like any medical condition, the use of medical marijuana to treat anxiety must be explored by the medical professional treating the patient to determine whether it is the best and most appropriate course of treatment for the patient.

As for the final factor, which is whether there were letters from physicians or other licensed health care

professionals knowledgeable about the condition supporting the inclusion of anxiety under the MMP, I find that the petitions were submitted with support from medical professionals.

Based upon the above analysis, I find that the condition of anxiety is “debilitating” and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the debilitating effect of this condition. As such, I find that anxiety should be added to the MMP.

In a previous qualifying condition petition for Generalized Anxiety Disorder, the Director of Health at the Hawaii Department of Health rejected adding the condition to the medical marijuana program. The main reason being that there is a lack of peer-reviewed scientific evidence showing beneficial use to treat GAD. This idea that peer-reviewed scientific evidence needs to conclusively show medical benefit or else no other qualifying conditions could be approved is wrong; due to the political nature of marijuana. Please allow me to explain.

The Hawaii medical cannabis law was created based on medical and anecdotal evidence. Anecdotal evidence was accepted because there is a lack of scientific research on the benefits of marijuana. Due to cannabis’s placement in schedule 1 of controlled substances in both state and federal laws. Quoting from the Hawaii Medical Cannabis Law:

https://www.capitol.hawaii.gov/session2000/acts/Act228_SB862_HD1_.htm

There is sufficient medical and **anecdotal evidence** to support the proposition that these diseases and conditions may respond favorably to a medically controlled use of marijuana.

This lack of research is due to the funding of marijuana research being regulated by NIDA, the National Institute of Drug Abuse. NIDA’s purpose is investigating the abuse potential of drugs, including cannabis, with focus solely on trying to prove the negatives of marijuana use. Since NIDA funds negative effects of marijuana research, research is granted on the flimsiest of theories and has corrupted and biased science. Forcing researchers to chase more NIDA grants for research to ensure they continue to have jobs.

Negative research findings are promoted wildly by NIDA when they are published. Even if the methodology of the study is flawed beyond belief. Even when other researchers try to duplicate the results and fail, NIDA continues to promote the flawed study as though it still has merit. An example of this can be found on NIDA's website

<https://www.drugabuse.gov/news-events/nida-notes/2016/08/study-questions-role-marijuana-in-teen-users-iq-decline>

This finding suggests that the twins’ IQ was affected by factors that twins share in their genes or family background, rather than factors in which they differed (e.g., drug use). A further analysis, comparing the impact of marijuana use on fraternal versus identical twins, suggested that family-wide environmental influences are more decisive than genes for determining IQ trajectory.

NIDA, without any evidence to back up the statement, goes on:

These findings contrast but are not entirely inconsistent with those of an earlier study that linked teen-onset regular marijuana use to IQ deficits in the fourth decade of life (see Early-Onset, Regular Cannabis Use Is Linked to IQ Decline). The researchers say that although their evidence indicates that marijuana exposure does not cause persistent loss of intellectual function up to age 20, **prolonged regular exposure for decades might do so.**

NIDA contradicts itself often, and continues to promote failed theories that bear no relationship to reality. Especially trying to say that marijuana is a gateway drug.

<https://www.drugabuse.gov/publications/research-reports/marijuana/marijuana-gateway-drug>

These findings are consistent with the idea of marijuana as a "gateway drug." However, the majority of people who use marijuana do not go on to use other, "harder" substances.

A more sinister theory promoted by NIDA, the DEA, and even physicians is that marijuana use increases the risk of Schizophrenia. This is so unbelievable that it is a slap in the face of science. Simply looking at reality, the larger numbers of people using, or admitting to use of marijuana, the large number of registered medical cannabis patients in the USA (roughly 1,000,000 to 2,000,000) and the flat schizophrenia rates as reported by the NIH and WHO completely invalidate all peer-reviewed published research on the topic of marijuana causing schizophrenia.

<https://www.nimh.nih.gov/health/statistics/schizophrenia.shtml>

<https://www.who.int/news-room/fact-sheets/detail/schizophrenia>

In fact, a percentage of people diagnosed with schizophrenia use marijuana to reduce anxiety and help with symptoms. People with more severe schizophrenia use more marijuana, this is the basis for the theory that marijuana causes more severe symptoms of schizophrenia. Similar thinking is used against patients who have more severe pain, that marijuana somehow makes pain worse for patients and they have to use more marijuana to gain pain relief. Instead of the observable theory that people with more severe pain use more marijuana to treat their more severe pain than people who have less severe pain. No one makes the theory that aspirin makes pain worse, because people with more pain use more aspirin. Bad science.

The whole point of a state medical marijuana law is that the federal government has engineered a catch-22 circular logic loop about marijuana. States, mostly via people's ballot initiatives have sideswiped the FDA in approving a medicine. This is because the FDA has adopted a policy of only endorsing and approving of monotherapies, e.g. one or two isolated and specific chemicals per approved medicine. There is another policy to reject crude botanical medicines due to variations from plant to plant. These comments by the FDA are found in the DEA response to a petition to reschedule marijuana to schedule 2 and in congressional testimony. Even if a company submitted an IND to the FDA to study marijuana for the treatment of a disease, it would be rejected by the FDA on both of those policies.

The catch-22 comes when patients, nurses, physicians, governors, senators and representatives suggest that marijuana be investigated as a medicine. In congressional testimony, the FDA says we need more research before endorsing that. NIDA says we need more research before utilizing marijuana as a medicine. The DEA says we need more research before marijuana could be considered a medicine. So, if everyone agrees we need more research, where exactly is the research?

Individual physicians have attempted to research the benefits of marijuana within universities. What happens is that, at every turn, approval to study is blocked, delayed and rejected. See for example the 10 years of trying to study medical marijuana for treatment of PTSD in veterans.

<https://www.stripes.com/marijuana-ptsd-study-concludes-after-10-years-of-planning-research-1.570986>

Sisley and her team had to gain approval and support from the U.S. Food and Drug Administration, the Drug Enforcement Administration and the National Institute on Drug Abuse to initiate the research – a process that lasted years.

One study took several years just to begin. After NIDA provided marijuana for research that was full of seeds, stems and mold.

<https://health.hawaii.gov/medicalcannabisregistry/files/2017/08/Generalized-Anxiety-Disorder-08.09.17-Redacted.pdf>

The GAD petition submitted in 2017 included anecdotal evidence, peer-reviewed patient surveys, marijuana use reports and other information. It was rejected by the director due to not having enough peer-reviewed scientific research. One reason given for the rejection was that there was "no specific evidence to GAD". This is why exact specific conditions and waiting for peer-reviewed medical research will never work as an administrative rule for reviewing qualifying condition petitions. There will never be medical marijuana research that specifically mentions each of the hundreds of conditions that include anxiety as a symptom. Research studies are done with one drug and one condition. A rejection for not having a specific condition mentioned seems more like a pedantic nitpick and less like a legitimate reason when both GAD and anxiety share anxiety as the core symptom.

This GAD petition rejection uses the same reason the federal government does not approve of medical marijuana. If this requirement barrier of peer-reviewed research was erected, no state would have a medical marijuana program. Due to the federal policies which are a de facto prohibition on research for medical marijuana benefits. These state medical marijuana programs were created because the federal government failed to do research, and continues to prohibit new research. While the reality is that cannabis is a non toxic medicine, has always been a medicine and always will be a medicine.

Anxiety was also included with a bill in the Hawaii legislature to add qualifying conditions. The Department of Health testified, and in opposing the bill, the DOH stated it would rather include conditions via the petition process. The HDOH also gave another reason, that the dept wanted to delay adding the condition until dispensaries were active. Try naming another medication that is delayed and kept illegal because the department was waiting for a pharmacy to open. The

DOH needs to stop these petty games played with sick people's lives, rights and freedoms.

(REF #95) https://www.capitol.hawaii.gov/session2018/testimony/SB174_TESTIMONY_CPH_02-08-17.pdf

This is another wrong-headed approach to the process, and ignores why and what the medical marijuana law does. Allow me to explain the purpose of the law and the role of the DOH in it.

From the Hawaii medical cannabis law:

The legislature is aware of the legal problems associated with the legal acquisition of marijuana for medical use. However, the legislature believes that medical scientific evidence on the medicinal benefits of marijuana should be recognized.

...

Therefore, the purpose of this Act is to ensure that seriously ill people are not penalized by the State for the use of marijuana for strictly medical purposes when the patient's treating physician provides a professional opinion that the benefits of medical use of marijuana would likely outweigh the health risks for the qualifying patient.

The whole point of the medical marijuana program is not to endorse, nor recommend medical marijuana to patients. The purpose of the law is to NOT PENALIZE patients using medical marijuana with recommendations from their physicians. To protect patients from the laws prohibiting the use of marijuana.

Said another way, it is not the Department of Health's role to become the FDA and research medical marijuana. It is not the DOH's role to judge if medical marijuana is a medicine or not. It is not the DOH's role to decide which conditions marijuana is beneficial for either. That role is solely for a patient to decide if medical marijuana works for their conditions or not. Physicians have a role to make sure the patient's health is first priority over any medication.

The DOH's only role in the petition process is to protect medical marijuana patients from arrest.

People are currently illegally using marijuana to treat their conditions, specifically anxiety. The DOH has the power to protect these patients by adding qualifying conditions. Instead, the DOH has assumed the role of the FDA, denying petitions and opposing adding conditions legislatively. Waiting for peer-reviewed medical evidence that by all accounts is not coming within the next two decades.

This delay and denial of the reality of medical marijuana patients conditions needs to stop.

- (3) Describe the **extent to which** the medical condition is generally accepted by the medical community as a valid, existing medical condition. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Anxiety is a recognized medical condition affecting millions of Americans each year.

<https://www.nimh.nih.gov/health/statistics/any-anxiety-disorder.shtml>

The wide variety of anxiety disorders differ by the objects or situations that induce them, but share features of excessive anxiety and related behavioral disturbances. Anxiety disorders can interfere with daily activities such as job performance, school work, and relationships.

Based on diagnostic interview data from the National Comorbidity Study Replication (NCS-R), Figure 1 shows past year prevalence of any anxiety disorder among U.S. adults aged 18 or older.¹

An estimated 19.1% of U.S. adults had any anxiety disorder in the past year.

Past year prevalence of any anxiety disorder was higher for females (23.4%) than for males (14.3%).

An estimated 31.1% of U.S. adults experience any anxiety disorder at some time in their lives.

Anxiety affects a large portion of the people in the United States, costing billions of dollars in medical treatment costs.

<https://www.cdc.gov/mentalhealth/basics/burden.htm>

Anxiety:

- Anxiety disorders, which include panic disorder, generalized anxiety disorder, post-traumatic stress disorder, phobias, and separation anxiety disorder, are the most common class of mental disorders present in the general population.
 - The estimated lifetime prevalence of any anxiety disorder is over 15%, while the 12-month prevalence is more than 10%.
 - Prevalence estimates of anxiety disorders are generally higher in developed countries than in developing countries.
 - Most anxiety disorders are more prevalent in women than in men.
- One study estimated the annual cost of anxiety disorders in the United States to be approximately \$42.3 billion in the 1990s, a majority of which was due to non-psychiatric medical treatment costs. This estimate focused on short-term effects and did not include the effect of outcomes such as the increased risk of other disorders.

(4) Describe the symptoms and other physiological or psychological effects experienced by an individual suffering from the medical condition or its treatment and **the extent to which** these symptoms and physiological or psychological effects are debilitating. Note: "Debilitating" generally means impairing the ability of a person to accomplish activities of daily living. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Anxiety can cause a person to withdrawal from talking to other people or even going outside. Anxiety can diminish or completely debilitate a person from interviewing for a job, making day to day decisions, making personal relationships or thriving.

Instead of dealing and treating anxiety, the world instead decided to call anxiety being an introvert. An "introvert" is a "shy, reticent person". In other words, a person who has so much anxiety that they would rather hide than speak to someone else. Shyness is anxiety.

<https://www.nimh.nih.gov/health/publications/social-anxiety-disorder-more-than-just-shyness/index.shtml>

The reason this petition is for "Anxiety" and not "social anxiety disorder" is because each year there seems to be a new disorder with the core symptom being anxiety. Panic Disorder, Generalized Anxiety Disorder, Social Anxiety Disorder, PTSD. Anxiety is the common condition.

<https://www.nimh.nih.gov/health/statistics/any-anxiety-disorder.shtml>

Any Anxiety Disorder with Impairment Among Adults

Of adults with any anxiety disorder in the past year, degree of impairment ranged from mild to severe, as shown in Figure 2. Impairment was determined by scores on the Sheehan Disability Scale.

Among adults with any anxiety disorder, an estimated 22.8% had serious impairment, and 33.7% had moderate impairment.¹

A majority of people with any anxiety disorder experienced mild impairment (43.5%).¹

1. Harvard Medical School, 2007. National Comorbidity Survey (NCS). (2017, August 21). Retrieved from <https://www.hcp.med.harvard.edu/ncs/index.php>. Data Table 2: 12-month prevalence DSM-IV/WMH-CIDI disorders by sex and cohort.

<https://www.ncbi.nlm.nih.gov/pmc/articles/PMC181171/>

Although the principal symptoms of anxiety disorders include fear, excessive worry, nervousness, and obsessions, a multitude of physical symptoms also may be present. These somatic symptoms—which include heart palpitations, gastrointestinal problems, sweating, fainting, and chronic pain—can confound the diagnosis and resist all forms of medical management, unless the underlying anxiety source is identified and treated. Delays in diagnosis and treatment can be expensive for the patient, physician, and society: unnecessary tests and ineffective treatments increase medical costs, and **anxiety symptoms may lead to loss of income and productivity, financial dependence, and even suicide.**

(5) If one or more treatments for the medical condition, rather than the condition itself, are alleged to be the cause of a person's suffering, describe **the extent to which the treatments causing suffering are generally accepted by the medical community as valid treatments** for the medical condition. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

N/A

(6) Describe the availability of conventional medical therapies other than those that cause suffering to alleviate symptoms caused by the medical condition or its treatment. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

(7) Describe the extent to which evidence supports a finding that the use of cannabis alleviates symptoms caused by the medical condition or its treatment. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Selected quotes and transcribed tables are taken from the following research and presented below.

1. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3998228/>

Ninety-seven per cent of respondents used cannabis primarily for chronic pain. Average pain improvement on a 0–10 pain scale was 5.0 (from 7.8 to 2.8), which translates to a 64% relative decrease in average pain. Half of all respondents also noted relief from stress/anxiety, and nearly half (45%) reported relief from insomnia. Most patients (71%) reported no adverse effects, while 6% reported a cough or throat irritation and 5% feared arrest even though medical cannabis is legal in Hawai'i. No serious adverse effects were reported.

These results suggest that Cannabis is an extremely safe and effective medication for many chronic pain patients. Cannabis appears to alleviate pain, insomnia, and may be helpful in relieving anxiety. Cannabis has shown extreme promise in the treatment of numerous medical problems and deserves to be released from the current Schedule I federal prohibition against research and prescription.

2. <https://harmreductionjournal.biomedcentral.com/articles/10.1186/1477-7517-2-18>

Approximately three quarters of participants (71%) claimed to have experienced a return of their symptoms or condition on stopping cannabis, especially: pain (53% of those who claimed a return of symptoms), depression or anxiety (30%), insomnia (11%), spasm (10%) and nausea/vomiting or lack of appetite (9%).

3. <https://doi.org/10.1016/j.jpain.2007.09.002>

A randomized, double-blind, placebo-controlled trial was conducted to determine the benefit of nabilone in pain management and quality of life improvement in 40 patients with fibromyalgia.

There were significant decreases in the VAS, FIQ, and anxiety in the nabilone treated group at 4 weeks. There were no significant improvements in the placebo group. The treatment group experienced more side effects per person at 2 and 4 weeks, respectively. Nabilone appears to be a beneficial, well-tolerated treatment option for fibromyalgia patients, with

significant benefits in pain relief and functional improvement.

4. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2683812/>

Thematic analysis revealed that these teens differentiated themselves from recreational users and positioned their use of marijuana for relief by emphasizing their inability to find other ways to deal with their health problems, the sophisticated ways in which they titrated their intake, and the benefits that they experienced. These teens used marijuana to gain relief from difficult feelings (including depression, anxiety and stress), sleep difficulties, problems with concentration and physical pain.

5. <https://doi.org/10.1080/02791072.2011.587700>

Of 1,746 patients, 37.8% self-reported therapeutic benefits from medical marijuana for anxiety.

16.9% of patients self-reported therapeutic benefits from medical marijuana for panic attacks.

6. <https://www.ncbi.nlm.nih.gov/pubmed/6117575>

The results of the study showed a dramatic improvement in anxiety in the nabilone group when compared with placebo (P less than 0.001). Side effects reported were dry mouth, dry eyes, and drowsiness. Patients did not report any of the subjective "altered state" experience of marijuana.

7. <https://www.ncbi.nlm.nih.gov/pubmed/15857739>

Following Ethics Committee approval, HIV-positive individuals attending a large clinic were recruited into an anonymous cross-sectional questionnaire study. Up to one-third (27%, 143/523) reported using cannabis for treating symptoms. Patients reported improved appetite (97%), muscle pain (94%), nausea (93%), **anxiety (93%)**, nerve pain (90%), depression (86%), and paresthesia (85%).

8. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5101100/>

Cannabidiol oil, an increasingly popular treatment of anxiety and sleep issues, has been documented as being an effective alternative to pharmaceutical medications. This case study provides clinical data that support the use of cannabidiol oil as a safe treatment for reducing anxiety and improving sleep in a young girl with posttraumatic stress disorder.

9. <https://www.ncbi.nlm.nih.gov/pubmed/24095000>

Patients reported using cannabis to treat multiple symptoms, with sleep, pain, and anxiety being the most common. Cannabis was perceived to provide effective symptoms relief across medical conditions. Patterns of use were also consistent across medical conditions. Notable differences were observed with regard to modes of access.

10. <https://www.ncbi.nlm.nih.gov/pubmed/15184623/>

Of 21 patients reporting stress, 20 said medical marijuana helped moderate-complete relief.
Of 16 patients reporting mood, all 16 said medical marijuana helped moderate-complete relief.
The symptoms reported by medical cannabis users to be most effectively relieved were stress, sleep, mood, stiffness/spasm, and pain.

11. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5312634/>

Finally, preliminary clinical trials suggest that high-dose oral CBD (150–600 mg per day) may exert a therapeutic effect for epilepsy, insomnia, and social anxiety disorder. Nonetheless, such doses of CBD have also been shown to cause sedation.

12. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5165161/>

In addition, we have assessed the role of the cannabinoid system and marijuana constituents in neuroprotection as well as considered other beneficial effects of marijuana. Marijuana has been shown to improve nonmotor symptoms of PD such as depression, pain, sleep, and anxiety.

Moreover, components of cannabis have been demonstrated to have neuroprotective effect due to their anti-inflammatory, antioxidative, and antiexcitotoxic properties.

13. <https://www.ncbi.nlm.nih.gov/pubmed/26317379>

367 medical marijuana patients in Arizona were surveyed.

181 patients reported using medical marijuana to experience relief from Anxiety

164 patients reported using medical marijuana to experience relief from Stress.

General relief from Anxiety symptoms was 82.9% and 87.2% for Stress,

Relief by medical marijuana compared to other medications was 79.3% for Anxiety and 91.6 for Stress.

Less frequent use of other medications was 85.9% for Anxiety and 79.1% for Stress.

14. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3285527/>

One Hundred Canadian medical marijuana patients were surveyed in 2007-2008. 60.2% said they used medical marijuana to reduce anxiety.

15. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1262744/>

This exploratory study examined the patterns of medicinal cannabis use among a sample of 128 Australian adults who responded to media stories about this issue.

Nearly one in ten (8%) reported no effect on depression or anxiety . More than one in ten (14%) specified that while cannabis could ease their symptoms and enabled them to cope, they realised that it could not cure their underlying condition.

Approximately three quarters of participants (71%) claimed to have experienced a return of their symptoms or condition on stopping cannabis, especially: pain (53% of those who claimed a return of symptoms), depression or anxiety (30%) , insomnia (11%), spasm (10%) and nausea/vomiting or lack of appetite (9%).

Almost two thirds (62%) of respondents claimed that they decreased or discontinued their use of other medicines when they started using cannabis medicinally. This was more common in males (65% vs. 58% of females) and older participants (aged 50 years +) (70% vs. 59% among younger participants). For some people this was a substantial change, representing a shift away from chronic, high-dose medication use.

Perhaps not surprisingly, cannabis was typically perceived as superior to other medications in terms of undesirable effects, and the extent of relief provided . Thus, cannabis was rated to produce equivalent (8%) or worse side effects (3%) by a minority of therapeutic users. It was considered to work "a bit" or "much better" than other medicines, or to be the only source of relief, by more than three quarters (82%).

16. <https://www.ncbi.nlm.nih.gov/pubmed/28189912>

In regards to conditions, pain-related conditions were the most common, reported by 53% of participants (n = 144; chronic pain 36%; (n = 98), arthritis 12% (n = 32), headache 5% (n = 14)). The second most prominent class was mental health (eating disorder, PTSD & psychiatric disorder), reported by 15% (n = 41). Other prominent conditions included gastrointestinal disorders (11%, n = 29), insomnia (7%, n = 18) and multiple sclerosis (4%, n = 11). In regards to symptoms; the most highly endorsed were chronic pain (73%, n = 197), stress (60%,n=162), insomnia (57%, n = 155), depression (46%, n = 126) and headache (32%, n = 87). gastrointestinal (GI) issues also featured prominently, with 29% (n = 79) citing appetite loss and another 29% (n = 79) nausea. Cannabis was perceived to be very effective at symptom relief, with 95% (n = 257) reporting that it "often" or "always" helped alleviate their symptoms.

17. <https://doi.org/10.1111/dar.12323>

Participants presented with the range of conditions that is generally consistent with surveys of CTP users, the most prominent conditions being pain (32%), mood (i.e. anxiety and depression (18%), arthritis (15%), HIV (10%), gastrointestinal disorder (7%)

18. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5422566/>

We previously reported in an earlier survey that of 1,429 respondents, 61% reported using cannabis for managing pain, 58% reported using cannabis for anxiety and 50% reported using cannabis for depression. In the current analysis, these same conditions were also the most commonly reported conditions by respondents. Of the 1,040 participants reporting pain and/or intractable pain, 619 (59.52%) reported depression and anxiety as comorbidities. As such, the odds of reporting substituting cannabis for prescription drugs were more than one and a half times greater (OR, 1.66; 95% CI,

1.27–2.16) among those reporting using it to manage pain, anxiety and depression than among those using it to manage only one of the three conditions.

This team previously reported that in a survey of 1,429 medical cannabis users, 61% reported cannabis use for pain, 58% reported cannabis use for anxiety and 50% reported using cannabis to manage depression. In 2016, Dale and Stacey reported that those using cannabis for pain were more likely to be substituting for prescription drugs. In 2017, Walsh et al published a review of medical cannabis and mental health to try to better understand how medical cannabis use may impact areas of potential concern for clinicians. "Relaxation and relief of anxiety" and "relief of negative mood" or depression were among the most widely reported conditions in 60 publications included in their analysis. Because it is common for chronic pain patients to be prescribed combinatorial pharmacotherapy to address comorbidity with depression and/or anxiety, it is largely unknown how often patients may be discontinuing prescription medications when initiating cannabis use.

Taken with preclinical data on the role of the endocannabinoid system in stress, pain processing and immune homeostasis, it is clear that future investigation is warranted using controlled trials with human subjects to better understand the role that cannabis may play in treating pain, anxiety, depression and other conditions.

19. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4277530/>

Most of the respondents (from the clinic and online groups) reported that cannabis improved their mood, pain, muscle spasms, and sleep.

20. <https://www.ncbi.nlm.nih.gov/pubmed/11210205>

Of 628 Canadian medical marijuana patients:

463 patients reported using medical marijuana to treat anxiety.

This article reports on an exploratory study of medical cannabis users. Interviews were completed with 50 self-identified medical cannabis users recruited through notices in newspapers and on bulletin boards. They reported using cannabis for a variety of conditions including HIV-AIDS-related problems, chronic pain, depression, anxiety, menstrual cramps, migraine, narcotic addiction as well as everyday aches, pains, stresses and sleeping difficulties.

However, cannabis was also used to treat menstrual cramps, anorexia, narcotic addiction, migraine, Tourette's Syndrome, lupus, Grave's Disease, epilepsy, retinitis, chemotherapy-induced loss of appetite, Crohn's Disease, arthritis and everyday aches, pains, stresses and sleeping difficulties.

Many reported benefits of cannabis were consistent with those reported elsewhere. Cannabis was typically used for its sedative, analgesic, antispasmodic, appetite stimulating, anticonvulsant and euphoric properties. These properties were well known in the past century when cannabis was used to treat conditions that required medications with these properties.

Although scientific evidence in favor of medical cannabis is limited (Gurley, Aranow & Katz 1998), self-treatment with cannabis could become popular as more users publicize their own experiences. This is especially so if the everyday aches and pains and psychological problems are promoted as medical reasons for using cannabis.

21. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2683812/>

The use of marijuana to manage stress and anxiety was described by 12 teens in our sample. Dealing with bullying at school, heavy demands of school work, taxing shifts at work, and just "giving as much as you can" along side difficult relationships with parents or guardians, and receiving threats from neighbors all took its toll on these youth. For some, these experiences contributed to high levels of stress and anxiety, and for others uncomfortable levels of anger – both were difficult to manage. Although some had friends they could turn to, marijuana provided an additional source of stress relief that was ready at hand.

"Lots of people know me, know I do pot and they think that I'm a pot head but really the thing they don't realize is that I have a reason for it. It's for my stress and an antidepressant. I get really upset. It [pot] helps me feel better about myself, because you know people don't do that [help me], like my friend [name] can, but nobody else can." [Female, 14 years, non-daily use]

There was general agreement among the teens that marijuana calmed them down, and helped them feel "not so nervous" and "not so uptight about everything." One teen recognized, however, that despite the fact that marijuana could be a very effective stress reliever, it might not work for everyone:

“Well as far as pot goes, the good thing is that it's definitely a stress reliever, hands down. I know lots of people who would be just a complete wreck if they weren't smoking pot but then there's also people who are a complete wreck because they do smoke pot, so it's kind of a hard thing.” [Male, 16 years, non-daily use]

22. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3691841/>

While the controversies surrounding cannabis are far from subdued (and are often permeated and masked by conflicting ideological credos), standardized studies on cannabinoids have highlighted that the psychological and behavioral outcomes of this substance are highly variable and range from relaxation, euthymia and heightened sociability to panic, paranoid ideation and psychosis [112 - 116]. A corollary of this observation is that the high comorbidity rate between cannabis use disorders and psychiatric conditions [100 - 105] may indicate that cannabis consumption is either a concurring cause or a “self-therapeutic” strategy for anxiety and mood disorders [117 - 123]. The latter interpretation is supported by the observation that anxiety-spectrum disturbances and traumas in early developmental stages are a strong predictor for later cannabis use disorders [124 - 127]; furthermore, several lines of evidence suggest that the anxiolytic effects of THC may partially account for the high prevalence of cannabis use in patients affected by PTSD [128 - 131] and OCD [132]. Accordingly, recent clinical studies have shown that THC elicits therapeutic effects in OCD [133] and trichotillomania, an impulse-control disorder characterized by compulsive hair-pulling [134].

23. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4604171/>

Overall, current evidence indicates CBD has considerable potential as a treatment for multiple anxiety disorders, with need for further study of chronic and therapeutic effects in relevant clinical populations.

24. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4604174/>

Although clinical studies in this area are difficult to do, even in countries where the use of cannabis has been allowed for years, there is a clear role for cannabis products in symptom management for these difficult conditions.

25. <https://www.ncbi.nlm.nih.gov/pubmed/22729452>

RESULTS:

Studies using animal models of anxiety and involving healthy volunteers clearly suggest an anxiolytic-like effect of CBD. Moreover, CBD was shown to reduce anxiety in patients with social anxiety disorder.

CONCLUSION:

Future clinical trials involving patients with different anxiety disorders are warranted, especially of panic disorder, obsessive-compulsive disorder, social anxiety disorder, and post-traumatic stress disorders. The adequate therapeutic window of CBD and the precise mechanisms involved in its anxiolytic action remain to be determined.

26. <https://doi.org/10.2202/1941-2851.1017>

1655 Patients reported using medical marijuana for these conditions:
Anxiety disorders 18.7% of patients

Applicants most frequently reported using medical marijuana for pain relief (82.6%), improved sleep (70.6%), and relaxation (55.6%) . The next most frequently reported benefits included relief of muscle spasms (41.3%), headache (40.8%), relief of anxiety (38.1%) , improved appetite (38.0%), relief of nausea and vomiting (27.7%), and relief of depression (26.1%). Half the applicants (50.8%) reported using marijuana as a substitute for prescription medication and 13.2% reported using marijuana as a substitute for alcohol.

27. <https://doi.org/10.1176/appi.ajp.2007.07061016>

Hence, it can be speculated that the anti-obsessive effect observed in our patients may have been a consequence of the glutamate modulation of the cannabinoid dronabinol.

28. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4349825/>

The findings from the study indicate that cannabis use is associated with a subsequent change in positive affect, depressive symptoms and manic symptoms over the course of daily life. No evidence for the use of cannabis to self-

medicate minor fluctuations in negative affect or BD symptoms was revealed. Participants in the study were currently well and out of episode. Future research should explore whether the self-medication hypothesis is more relevant to individuals that are in the acute stages of depression or mania. This would be consistent with the broader self-medication hypothesis in BD where individuals have reported finding cannabis useful in the management of their symptoms.

29. <https://www.ncbi.nlm.nih.gov/pubmed/9692379>

The authors present case histories indicating that a number of patients find cannabis (marihuana) useful in the treatment of their bipolar disorder. Some used it to treat mania, depression, or both. They stated that it was more effective than conventional drugs, or helped relieve the side effects of those drugs. One woman found that cannabis curbed her manic rages; she and her husband have worked to make it legally available as a medicine.

Others described the use of cannabis as a supplement to lithium (allowing reduced consumption) or for relief of lithium's side effects. Another case illustrates the fact that medical cannabis users are in danger of arrest, especially when children are encouraged to inform on parents by some drug prevention programs. An analogy is drawn between the status of cannabis today and that of lithium in the early 1950s, when its effect on mania had been discovered but there were no controlled studies. In the case of cannabis, the law has made such studies almost impossible, and the only available evidence is anecdotal. The potential for cannabis as a treatment for bipolar disorder unfortunately can not be fully explored in the present social circumstances.

30. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4898690/>

Findings suggest that for some bipolar patients, marijuana may result in partial alleviation of clinical symptoms. Moreover, this improvement is not at the expense of additional cognitive impairment.

31. <https://www.ncbi.nlm.nih.gov/pubmed/17703715>

Subjective reports by patients suggest an overall positive effect, but these may be unreliable. We herein report a case in which mood data was prospectively collected over two years of total substance abstinence and two years of extreme marijuana use. Marijuana use did not alter the total number of days of abnormal mood, however, marijuana was associated with an increase in the number of hypomanic days and a decrease in the number of depressed days. While not conclusive, the data suggest that marijuana may indeed have an effect on mood in bipolar patients that needs to be systematically examined.

32. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5652027/>

Cannabis use diminishes some of the adverse effects of neurological and psychiatric disorders.

33. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4323143/>

These results suggest that cannabis use has clinical implications for the early course of BD (Bipolar Disorder) by increasing mood level.

34. <https://doi.org/10.1111/j.1368-5031.2005.00271.x>

Medicinal cannabis use was Reported by patients with chronic pain(25%), multiple sclerosis and depression (22% each), arthritis (21%) and neuropathy (19%).

(8) Provide any information, studies, or research reports regarding any beneficial or adverse effects from the use of cannabis in patients with the medical condition. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Minnesota has undertaken the most comprehensive research on the medical cannabis patients in its medical cannabis program in the United States. Including surveys by both the patients and their physicians. Tracking which medical cannabis products they purchase, use and continue using to treat each qualifying condition.

The Minnesota Department of Health publishes reports of the medical cannabis patients and how medical marijuana

helps them with anxiety.

In its first year of reports, the Minnesota DOH published patient comments about the beneficial effects of the medical marijuana.

(REF #98) <https://www.health.state.mn.us/people/cannabis/about/firstyearreport.html>

(REF #94) <https://www.health.state.mn.us/people/cannabis/docs/about/appendixa.pdf>

Many such comments are found within the above report.

Further reports in the following years also track which patients under each condition report benefits of medical marijuana on anxiety.

<https://www.health.state.mn.us/people/cannabis/about/omcreport.html>

<https://www.health.state.mn.us/people/cannabis/about/cohort.html>

(REF #93) https://www.health.state.mn.us/people/cannabis/docs/about/cohort/2015_2016_benefitspse.pdf

The patient self-evaluation is required for patients to complete prior to each medical cannabis purchase. It includes questions to assess symptom severity, some of which are administered to all patients (standard set of 8 symptom measures) and some of which are tailored to symptoms for a given condition (condition-specific symptom measures). Since symptom data is collected prior to each patient's first medical cannabis purchase, symptom changes can be assessed over time and compared to baseline (baseline = patient responses to symptom questions just prior to their first medical cannabis purchase)

These reports are useful to show that medical marijuana patients find a greater than 30% reduction in anxiety symptoms, and a large percentage of patients continue to maintain that reduction of anxiety for 4 months.

(REF #92) https://www.health.state.mn.us/people/cannabis/docs/about/cohort/2016_2017_benefitspse.pdf

(REF #91) https://www.health.state.mn.us/people/cannabis/docs/about/cohort/c2015_2017_benefitspse.pdf

MDOH publishes Adverse Side Effects reports which show a very small percentage of people experience a worsening of anxiety symptoms. I urge you to read them all as it shows how small the number of adverse anxiety reports are.

<https://www.health.state.mn.us/people/cannabis/about/cohort.html>

(REF #90)

https://www.health.state.mn.us/people/cannabis/docs/about/cohort/appendix_c_2015_2016_patientreportednegativeeffects.pdf

Although the comments mention anxiety as a side effect, sometimes it is not the cannabis's fault, but prohibition's fault, as this comment rated at score level 4 shows:

I have more anxiety that police may take me for a blood test of charge me with DUI if they know I'm a patient at dispensary. I also had a Warning of illegal drug use in a urine test from the so called pain clinic I'm required to go to by [CLINIC]By my now ex primary Dr of 20 years. I told the pain clinic when I signed contract not to use illegal drugs that I took cannabis by prescription in medical form thru Dept of Health etc. The Dr said OK, as long as it wasn't in organic form for smoking! He said I was the 1st patient at [CLINIC]to be on legal cannabis. I advised him, I maybe to 1st but surely not the last patient. They said this will be resolved ok but I still was warned for illegal THC drug use, which is upsetting but it will be straightened out. Thank u!

Massachusetts published a report on its medical marijuana patients and their benefits.

<https://www.mass.gov/report/massachusetts-department-of-public-health-marijuana-research>

(REF #77) <https://www.mass.gov/files/documents/2019/07/09/MBHS-full-report-final.pdf>

The Marijuana Baseline Health Study (MBHS)

A legislative mandate required the Massachusetts [Department of Public Health \(DPH\)](#) to conduct a baseline study to investigate marijuana use in Massachusetts. The report published confirms the consensus that marijuana use improves

mood and or mental health for a large percentage of people.

Page 10:

Among all respondents, **78% reported positive changes in their mood or mental health**, and 67% reported improved physical health. In addition, 83% of respondents reported no negative outcomes/consequences related to their marijuana use.

Page 148:

Results from this survey suggest that respondents appear to be treating a wide range of medical conditions, and often more than one at a time. **The top 5 medical conditions being treated were anxiety (60% or all respondents), chronic pain (46%), insomnia (43%), depression (42%), and stress (41%),** and the average number of conditions being treated by medical marijuana is 4.7.

(9) Attach letters of support from physicians or other licensed health care professionals knowledgeable about the medical condition.

Appendix A: Patient-Reported Benefits from Surveys

Note: Word choice and spellings have been retained as written by respondent to avoid inadvertent mischaracterization of intent. Brackets have been used to explain words redacted to prevent individual identification or for other reasons. Benefits are broken down by qualifying condition and by benefit score rating.

Severe and Persistent Muscle Spasms

1: No Benefit

- no benefits
- none yet

2

- Did not help control my son's seizures but we at least never seen any negativeside effects of the medication
- Don't recognize sublingual drops
Helps relaxing
- Improved sleep
- physical movement
- The "Patient Discontinuation Survey" didn't have a place to comment when choosing "won't buy again", so I want to be sure someone got this. What I get from the medical market in other states works much better for pain relief and spasm reduction, in both flower and concentrate. I think it's because the critically important terpenes (more important than THC/CBD) are removed in the processing at [MANUFACTURER] and not added back, like they are in other places. Without better processing (more expensive) or giving patients access to flower (least expensive), MN's processing is removing nearly all of what makes cannabis a medicine - terpenes.

3

- Less overall pain
- Mood may have been better slightly. Still not good, but better.
- More confidence in public
- Less tremors
- no nausea, It helped with spasms
- reduced pain and spasm
- Reduced tremors slightly

4

- upper spinal relief
- 1. Pain reduction
- 2. Sleep
 - Being able to buy my medicine legally and not being considered a criminal from law enforcement for using a plant as medicine!

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- Better sleep
- Better sleep some nights, some days I am able to be more active and I have a viable option for pain relieve.
- Calming my anxiety, sleeping a full night, waking feeling well rested
- Decrease in spasticity and pain.
- Has controlled arthritis and fibromyalgia.
- Helping relieve my muscle spasms
- I get more sleep.
- I am feeling better.
- It has reduced my muscle spasms, and is helping with nerve pain, and seems to have reduced the number of migraines I get.
- Less nausea
- Less symptoms
- Moderate relief from muscle spasms/cramps
- My spasticity has improved some with the medical cannabis, but I still experience at least three or four times a week, severe pain, cramping and spasticity in myhamstrings.
- nausea / pain / spasims
- nausea is slowing down.
- Nerve pain. I can actually ride in a car again without crying.
- pain relief
- Pain relief
- Reduction in pain.
- Relaxation which reduces nerve pain
- Relaxing of muscles in legs - better walking distance, less pain, more active
- Remediation of muscle spasm symptoms
- Rest
- Sleep better.
- spasticity reduction
- Spouse and PT think I am less stiff

5

- one benefit of taking medical cannabis for my condition symptoms is the effectiveness how it ease the pain of my spasticity.
- better appetite, less nausea less pain less anxiety
- Better sleep
Less anxious
Very little need for vicodin
- Better sleep, less spasms, less spasticity
- cears
- decrease in auras, muscle spasms and pain.
- decreased muscle spasms and pain, decreased abdominal discomfort, better mood, less anxiety

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- Eliminating muscle spasms, relaxed muscles, relief of pain, increased improvement of sleep
- Helps my sleep
- I can Manage my pain and muscle spasms to keep the pain at a tolerable level.
- I don't feel much pain, and not as severe as it always was before.
- I hope to greatly reduce the persistent pain in my lower extremities from my toes to mid thighs.
- I no longer get, AT ALL almost, or greatly reduced on the small occasion that I do, migraines and/or small seizures. (And there are so many other benefits!!)
- I use it for sleep and at the beginning of the day always. It has been very helpful in me getting restful sleep and also helpful in having help with pain relief during the day without the awful side effects of opioids (excessive drowsiness and constipation)
- improved nausea
- improved anxiety
- spasms- only a little better
- Improved nausea, improved appetite, less pain, less spasms, relaxed spasms.
- Increased help with muscle spasms and inflammation in lower back. Also lower back chronic pain.
- Increased sleep time - was between 2 - 3 hours a day, now 3 - 4 hours a day. Pain from knee nerve damage has been lowered to very manageable now.
- It has decreased my spasms, lessens some pain, and helps me sleep better.
- It has improved things a little, but because of the cost, not sure it's worth it.
- It has reduced my numbness and spasms
- knowing that it's legal and I don't have to worry about anything
- lack of chronic pain. Lack of twitches.
- Less aching in my joints and less all over body pain.
It has also helped my anxiety.
- Less pain and discomfort.
- Less spasms
- limits my muscle spasms
- little less depressed.
- lowered my pain so I could be up more during day , helped with anxiety from having pain for so long as well
- muscle spasm pain was greatly reduced.
- Muscles relax a great deal so I am in less pain so I can sleep and move around easier.
- My most important benefit has been discovering that my severe pain can be modified with the use of medical cannabis.
- Pain management
- Appetite
- pain reduction
- pain relief
- Pain relief and relaxation.

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- pain relief, muscle relaxer
- Relaxation of Muscle spasms...
- Relief of muscle spasms
- Relieves pressure.
Engages senses
Allows for easier sleep
- Restful and relaxed sleep.
- Sleep
- Slowed my spasms.
- The back spasms are better.
- Vape seemed to help the pain. Liquid not so much.

6

- The same dose each and every time consistent delivery
- A large reduction in symptoms, allowing me to participate in my daily life without a large number of limits my symptoms would place on me - stools decreased from over 8 a day to about 2 with much less blood and mucous in stools. Pain has reduced to a tolerable amount.
- Able to eat. In less pain. Don't need my depression meds any more.
- Almost immediate pain relief from vaping and help settling my leg spasms.
- An increase in appetite, and decrease of muscle spasms
- Appetite
- Calms the restless leg down quite a bit
- Decrease in severity of spasms
Decrease in duration of spasms
Notable decrease in pain
More so than other pain med and anti spasmotic meds
- decreased intensity of muscle spasms
- dramatic decline in seizures
- Elder of symptoms
- Fewer spasms and less pain when standing and less pain when walking
- First I have to say I replaced a decade of narcotics with only medical cannabis with no relapse. I had a failed back surgery and severe sciatic pain and back pain daily. I also suffer from a rare blood disorder called Acute Porphyria's. its nearly impossible to treat however i have found some relief in that as well with this medication. I found the products still to be weak compared to other staes. Also the selection is so very limited. Not to mention the price is three time higher then industrystandard.
I have had great improvements in pain, which has also allowed me to be much more active with my family. My muscle spasms although are still there I find most days the medication helps considerably, however my issues are serious and sometimes nothing helps at times. I also suffer from severe anxiety attacks and have seen less of those as well. over all not only myself but my family sees positive change and I feel healthier, happier and feel currently this is making a huge positive impact on my life.

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- Freedom from pain in the evenings and sleep
- Has allowed me to move forward in life
- Have slept better than I have in 14 years! Due to not worrying all night if I was going to have a seizure in the morning
- helps calm the spasms in my eye lids due to blepharospasm
- Helps to lower stress, my muscle spasms have been pretty much nulled! My stomach issues having been like before, cramps have been minimized, just feel quite a bit better!
- Helps with anxiety (better mood). Back, did help some! The pain is still there, caused of disks and ceribre needs operated on the back. But I do like the vapor medicalcannabis
- helps with leg spasms greatly.
- I am having less falling and in addition I have had a reduction in my OxyContin from three 40 MG tablets per day to three 20 MG tablets per day. That is half.
- I experience very little nausea when taking the medicine
- I have been able to cut out the pain pills and am down to one muscle relaxer per day. I am not as tired as much. I can't believe how much better I feel
- I have been able to delay needing shots for my blephrospasm
- I have been able to get a good nights rest using the [HIGH THC] pill. I have also gained clarity and energy from taking 1 [HIGH CBD PRODUCT] 2 times daily.
- I'm less in pain
I don't have spasm in my back and legs that much.
I'm less moody
- It calms the spasms and the vapor gives relief right away.
- It has decreased the pain level and increased stamina to exercise
- It has helped with my bladder issues and leg weakness greatly.
- It helps my spasms and helps me to "not pay attention" to the pain as much.
- It helps with pain the most then it helps with my muscle spasms and helps me sleep at night do to the burning of my legs
- legal access to medication
- Less pain and calmer
- Less pain, easier sleep
- less sharp back pain
- Less spasms and nausea.
- less stiffness in the muscles, joints, bones
- lessening spasms and muscle pain
- loosens muscles
- Medical cannabis is one of only a few treatments to help control symptoms of my neurological disorder
- Might save my life
- More comfortable and not as much guarding position of shoulders.
- more urinary control
- Muscle spasm/ pain reduction

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- My spasm's are less frequent, pain I have in my back is tolerable, relaxes me.
- My stomach (core) feels more normal (calm) and my bowel movements are less often - have more form - not as much liquid & gas.
- nausea control
- Nausea has improved
- Appetite
- no spasms at all
- Overall decrease in pain sensitivity
- Pain
- PAIN CONTROL
- pain management
- Pain reducton
- More mobility
- Pain relief
- Pain relief is the biggest benefit. Also less cramping.
- pain relief
- anxiety relief
- Pain relief,
- Peace of mind.

Worry is like PTSD. I only make arrangements I can back out of in case I have a flare. Anticipation of a new flare is always on my mind. I don't know how long a flare is going to last or how bad it will be. In the middle of a flare, I didn't have any form of relief so I'd panic because of severity of symptoms and no treatment.

Now, I still have MS PTSD because I've had problems for so long, but I know I have >something< that will help the problem. Though a flare may last a while, I know I'll be able to break through the mental barrier of panic because I have a treatment that works. It's very comforting after years of only suffering.

- Reduced pain. Able to eat. And spasm are less
- reduces muscle spasms
- Reducing tone and spasticity
- reduction in pain and muscle spasms as well as at least a 50% reduction of monthly use of prescription pain medications.
- Reduction of pain due to muscle spasms and less side effects compared to other medications
- Relaxes my muscles
- Relief from painful spasticity
- relieve anxiety
- sleep better
- Relieve the pain of Charlie horses in my legs. Tremors from MS less noticeable.
- Relieves pain, helps me relax, helps me sleep. I feel more comfortable and have more energy.
- Rigidity is so much better!

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- sleeping
- Sleeping/spasms
- Spasm relief and that leads ultimately to pain management.
- spasms decreased
sleep improved greatly
pain relief
less Xanax and opiates used
- Stopped my seizures, convulsions and shaking .
- The pain I feel in my lower half of my body cease to exist while taking medical marijuana. With that being said, it's difficult to take it during my work hours, because it makes me feel less attentive So, I'm between a rock and a hard place. NO pain or pain.
- The Spasms are less frequent as they were before.
- Using Medical Cannabis PRN for anxiety & irritability has replaced the need for PRN Ativan use completely.

7: Great Deal of Benefit

- Very few side effects, actually feel a lot better getting off the narcotics, Vicodin, methadone, and Valium . Did not have an appetite and did not want to leave the house before, I feel so much better it's like a miracle
- 1. Spasm and pain reduction.
2. I have stopped all pain meds and off two spasm meds. This is amazing for me. I've been on the spasm meds for over 10 years, now, when I feel tightness or a spasm starting, I take a small amount of high CBD cannabis and the spasm does not develop. It's been a life saver for me.
- 1. Being able to take my medicine legally, avoiding problems being evicted for use of cannabis.
2. Assistance with nausea
3. Help with muscle spasms - I have been able to work out in Physical therapy more intensely than before helping to reduce pain.
4. Reduction of narcotic pain medication.
- 1. Helps control Back Pain and Muscle Spasms without narcotic fears.
2. Relaxing and Sleep
3. Appetite
- 1. large decrease in pain
2. large decrease in back spasms
3. my depression isn't as bad
4. my panic-anxiety attacks have decreased and I am not anxious all the time
5. my foot drop is 95% better
6. I have been able to decrease my pill medications by FIVE!
- Ability to relax with decreased pain
- Able to stop taking all pain meds and stay off. Helps all of my symptoms to be better. Unfortunately too expensive to buy what I need to stay off pain pills and have better

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

quality of life. Need plant form, then medicine will cost less and last longer. I do not like smoking, vaping oils into my body.

If mn law had followed other states and not been stupid about this law people could get certified properly with insurance, and have access to Affordable medical cannabis. Instead many, many people are not benefiting or using program because of all the hoops you have put into place.

In 2016 I should be able to google doctors that are certifying for medical cannabis and make sure they take my insurance. Instead I had to take almost a year to find a clinic that certifies and takes insurance.

The way it is now is better than nothing at all but the way it is now is like dangling a bone for your dog that he just can't ever get a full bite of.

- Access to a good consistent medication that helps multiple problems.
- After 29 years I no longer have migraine headaches everyday.
- Almost all muscle spasms and pain associated with spasms are gone. I used to have constant nerve triggered pain that is minimal now. Results were almost immediate. I am sleeping way better now also.
- Although there is no proof that I directly benefited, I took a large dose of the oral suspension and was able to enjoy the holidays like a normal person for the first time in a long while. Pain hasn't returned as long as I continue to medicate with medicinal grade Cannabis.
- anti inflammatory
- Appetite stimulation
- Back seizures gone
arthritis gone
- Being able to cope with my daily pain, and reducing the amount of other medications I am prescribed is very important to me.
- being able to sleep without waking up in spasm
- Being able to treat my epilepsy with cannabis oil and not having to worry about breaking the law. I have been seizure free ever since I began using cannabis oil.
- Besides helping with my back issues, my general pain and soreness have been less, as well. Also, helps me just be in a better mood and think a little more clearly.
- Better quality of life, greatly reduced pain, greatly reduced spasms and exacerbations, less stiffness able to sleep through the night.
- Better sleep, appetite, pain reduction and sense of well being.
- Calming of my muscles n joints from spasms
Also helping with food intake
- calming of my spasms
- calmness
- calms my inner nerves & muscle pain & bad spasms & hand tremors & sleep
- Cannabis has helped my Crohn's in nearly every way. There's no way I can choose just one benefit that's the most important to me. The highlights of my experience have

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

been; no more abdominal pain, a 15 weight gain(I was underweight beforehand) and a reduction in my inflammation.

Thanks to cannabis crohns no longer controls my life.

- Cannabis has helped with keeping the chrons calm. I made it through the holidays with no flare ups.
- Clearer head since I have been using this program instead of pain pills.
- comfort, pain relief, hope.
- Cured my nonstop UTI
- Decrease in muscle spasms and increase in appetite with a reduction in my discomfort and pain.
- Don't have to take as many pain pills
- Ease of pain and consequently tension and the ability to be more active.
- Even though I have increased in number of muscle spasms each day due to my MS, when I take my meds both the pain and the spasms subside for a number of hours. My physical therapy sessions are more beneficial as well because I can actually bend my legs easier.
- Far less muscle spasms. A little less pain associated with muscle spasms.
- fewer muscle spasms in my neck. less pain than before I started the program.
- freedom to be excepted and relieve from mussel spasams
- Functionality. I am able to withstand more hours with out pain and muscle spasms. They are still there, but greatly reduced.
- Geneal improvement in quality of life
- Getting off all my narcotic pain medications, no more muscle relaxers, or sleeping pills.
- getting off pain meds
- Going from disabled to working again.. Having my life back. Being able to leave my house again.
- got ripped off for 450 dollars at [MANUFACTURER], they lied to me before i made my purchase, the oil was not consistant - hardly effective, bad consulting they should be shut down along with their grower. [MANUFACTURER] was ok, better quality, can't afford the prices i am poor and in pain.
- Greater mobility and less inflammation.
- Helped reduce swelling in my ankle a great deal, among other benefits
- helps reduce the pain associated with spasticity in me legs,
- Helps with my issues...
- I am able to sleep at night.
- I am in significantly less pain. I can function throughout the day so much better than I could before the cannabis program. It is like night and day.
I have less dizziness from vertigo with the cannabis
I have better mobility of my neck
- I am not on any narcotic pain meds anymore, and I am not having to reposition myself every 15 to 30 min, and am sleeping for longer periods at night.

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- I am registered under the condition of Tourette's Syndrome. I used to experience a great deal of muscle spasms and tics. Since starting the program I have had many comments from friends and family saying that they have hardly noticed any tics in the previous few months.
- I could walk better.
- I feel less stress resulting in fewer muscle spasms. I can sleep sometimes at night without using the Ambien which I have needed for over 15yrs. It allows me to have a better perspective of any given situation because I am not feeling stressed out or as if I were a criminal. I have been able to discontinue my opioid pain medicine that I took for over four years after my accident. I can remain calm in many situations that used to upset me emotionally. I can enjoy my grandchildren and family so much more now that both physical and emotion health are improved with medical cannabis.
- I have a great deal of relief from my muscle spasms. I get the relief without the anxiety I experience from cannabis I get off the street. I believe the medications work better than the stuff on the street.
- I have been able to manage my chronic migraine headaches much better. I have been able to decrease my use of abortive medications.
- I have been able to reduce my Parkinson's meds by about 70%. I sleep much better. I am less depressed.
- I have less pain in my body & less migraines
- I have periods of the day where i experience little to no pain.
- I have stopped taking two narcotic pain and one skeletal muscle relaxer RX's. And the VERY painful spasms are much more tolerable.
- I take less or smaller doses of other prescription meds.
I sleep better at night with less pain.
I move more freely
- I was quickly able to get off both Valium and Ambien Both were heavy duty drugs that I was dependent on, not because I wanted to take them, but had to. I was so glad to get off them and feel somewhat normal.
- I'm not kicking my wife while I'm asleep. The leg is still restless but not as bad as before. And I don't have as much pressure/dullness in the back of my neck/head area.
- Increased muscle coordination
Increased attentiveness
Increased cognitive function
Increased mobility
Increased positive moods
Decreased spasm severity
Decreased seizures
- It controls my mind grains and headaches caused by my condition.
- It has allowed me to reduce the number of medications I take; both type and quantity.
- It has caused a marked decrease in my essential tremor, severe muscle spasms in my osteoporosis ridden degenerative disc disease. Lower degree of pain and less in

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

frequency. I also have severe GI IBS and pancreatic issues, involving tumors that cause painful abdominal muscle spasms. The two pancreatic tumors are inoperable, and I need to have them scanned annually for any sign of malignancy. I also feel it helps a patient's attitude and sense of hope. I know that's not a medical concern, but it's a great side effect, "Hope"!!! Thank You!!!

- It has cut down my back spasms at least 50% or more and since I've been on medical program for Minnesota I haven't fallen over once which team is a great deal
- It has evened out my muscle spasms and made things both possible and more comfortable. It has slowed down the Dystonia storms.
- It has helped my sleep thru the night and a lot less spasms
- it has made my quality of life better to make it short and sweet
- It has reduced my muscle spasms by 90%. It helps me sleep at night. For example, it helps control my spasms so they don't wake up and I have less pain. The amazing thing it's also a nerve blocker like Neurontin or gabapentin. Here's another amazing fact. It helps control my autonomic dysreflexia. Out of every benefit this has undoubtedly given me my quality of life back. At night, if you understand autonomic dysreflexia, my blood pressure would shoot up to 150 or 180 before bedtime. This is dangerous as my normal range is 80 or 90 over something. My muscle spasms at night shoot my blood pressure up. I felt like I was going to have a stroke and could have if they are not controlled. My head would pound like it was going to explode with a severe headache, my face becomes extremely hot and flushed, my hands and fingers become numb (weird side effect), my heart starts to pound against my chest as it has to work harder to pump blood. So heart rate goes down as blood pressure goes up. It's helped the inflammation of my joints because they ache less. There is not "one" benefit in my case but many. All of them are important to my quality of life. I finally feel like I have that back now!!!
- It has replaced all opioid medications and allows me to function and participate in family and social activities again.
- it helps with my spasms to be less as well as not as painful
- It reduces the number of attacks and severity of the leg cramps at night.
- it relaxes my muscles in my body to help lower pain and allowing me to keep the narcotic medication down to the bare minimum. Without the program I would be unable to stay functioning because the narcotics make me tired and worn out and want to do nothing. With the use of Medical Marijuana and keeping the Narcotics down allows me to keep my day to a functioning day no matter how slow I may be, but I am not worn out because I can use the vaporizers to help the muscles so much. That in return makes me feel that my life is somewhat productive instead of dormant.
- It works on too many levels. I can eat better and I usually get nausea and it works great for that. My arthritis is much better. I am still dealing with the side effects of radiation my cancer Dr. says. I guess with no stomach and most intestines gone I don't usually eat as well or feel good (healthy) enough to even get up and go to my office.

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- I can afford to but have added the stock market to my ways to make additional money. I can puff and some days with in hours I may go to the office.
 - it works quickly to relieve muscle spasms,,helps control pain during physical work, controls pain to a certain extent,helps give you opportunity to quality of life.
 - [PATIENT]'s mobility has increased.
 - some pain relief
 - Less lower back pain, increased apatite.
 - Less muscle aches and better sleep.
 - Less muscle spasm's = body not being as fatigued allowing me to perform my physical therapy better.
 - Less muscle spasms!!
 - less mussel spasms and pain
 - less nerv pain
 - Less pain and inflammation in legs and ankles. Didn't feel so wore out at the end of the day. Was able to relax and sit for long periods with less stiffness and joint pain. Overall I had less pain
 - Less Pain
 - Less sleep issues
 - More hunger'
 - Less mood swings
 - All around better feeling of life
 - less petit mal seizures , better sleep at night and , reduced muscle spasms
 - less seizures
 - Less spasms helps me relax.
 - Many fewer spasms. I went from several per hour every day to several per day. Much improvement! I also have less anxiety. My confidence has increased from feeling more relaxed.
 - Much less pain, in my bowel and neurapathy pain. I can tell almost immediately if I forget to take the medication. Within one or two hours, the pain in the gut/bowel area is back. I never realized how terrible I have felt until after I started to feel better. I have had bowel pain as long as I can remember (pre-school) and I thought everyone felt like that. It is all I ever knew and it was getting worse each year.
 - much less weakness/pain
 - easier sleeping
 - not as many spasms in the morning
 - Muscle spasms stopped completely. I was able to walk much better and sleep better at night.
 - Muscle spasms, burning, pain, level of thing's would be a couple less for sure, but depending on affordability, and the level of it like I was doing great making real strides, I lost like a lot of weight and my body sores from other medicine went away a lot on my skin by using the cannibas, and I just had a fall recently that just is not normal but happens, an set me way back again now so or my numbers are effected cuz that just

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

happened... Takes time especially nerve pain, when a feather hurt's a nerve just a touch, and scar tissue rapping on them hurt's alot as it did me again now among other thing's! But the medicine help's me in my ailment struggles.

- My horrible chronic spasms have greatly diminished.
- My insomnia is so much better,my muscle spasms have calmed down some,I have an appetite now,my muscle pain has lowered quite a bit to the point I can get somethings down around the house,I was walking with a cane but I am no longer at this point...I believe my balance over all is better at this moment in time.
- My muscle spasms are getting easier to cope with on a daily basis
- My muscle spasms have decreased and my nausea and general pain decreased
- My muscles were spasm all day long , what this medicine is doing is helping them to relax more , at first I was scared because the spasms were so tight around my bone , when it relaxed more the bone started to hurt and pulse ate . After that went I new what was happening . I keep at a steady pace and the muscles are reacting good to it . I am so grateful for this medicine , and can't believe I was on the opposite side of this medicine . It truly is like a miracle !!!!
- My severe spasms of my neck, spine, legs, feet, arms, and hands become very mild, and almost absent when medicated with Cannabis treatment!
- Nausea, pain in my back
- No crohns disease flare ups since starting treatment
- No longer need Botox to control spasms in thighs
- No more street weed
- no spazims and sleeping well
- Off topic from my qualifying condition, my root disease is Mast Cell Disease that stemmed from Childhood Leukemia. I have always had a low WBC, and now I am in the normal WBC range, with my WBC having DOUBLED!!! Since the start of using MC regularly from [MANUFACTURER]. I use the 50/50 THC-CBD ratio. THIS IS A HUGE IMPACT and I am nothing that my Mast Cell Disease is becoming more calm, which is leading to less pain, reactions, inflammation and muscle spasms.
- One of the benefits that I did get it from medical cannabis is the ability to get up and walk take a shower take a drive and have an ability to cope with extreme muscle spasm and back pain daily and work with these problems and medical cannabis help me deal with all that not just a bunch of painkillers and other medications that I can't spell medical cannabis help me through my injury.
- Only usage of the oil helped! But it's much too expensive.
- Pain & Muscle Spasms
- Pain control
- pain control and relaxing of muscle spasms while allowing me to be coherent and continue to work.
- Pain goes away
- Pain is more manageable

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

Anxiety is way down (PTSD)

- pain relief
- Pain relief
- pain relief
- sleep completely through the night
not as moody because im in pain
- pain relief and nausea relief
- Pain relief has been a major benefit as I am able to control pain from my backspasms very well with medical cannabis. Not having to take opiods is great!!
- Pain relief nausea relief
- Pain relief, increased mood/motivation, less time in bed, more time enjoying life not focused on pain
- Pain relief.
- pain spasms
- Reduced pain and anxiety
- Reduced pain from muscle spasms, reduced headaches.
- Reduced seizures and spasms feel more normal on cannabis.
- Reduction in spasms
- reduction in spasms
reduction in pain
reduction in ""jibberish"" due to pain and spasms
better sleep
less anxiety
reduction of harmful pharmaceutical medications (side affects)
- reduction of interocular eye pressure; also reduction in muscle cramps and chronic pain
- Reduction of spasms
- Reduction or outright elimination of my intractable pain.
- Relaxation
- Relaxes me at the end of the day . Makes my pain go away.
- Relaxes me I don't have as many tremers and the pain is better than before.
- Relief from muscle spasms
- Relief from my syptoms
- Relief of muscle spasms with no side effects
- relief of severe pain
- RELIEF using an all natural method ... Cannabis is a holistic formula of balancing your condition and very-very little side effects compared to the Rx monopoly. If it works, keep in simple, keep it green. ㄟㄟㄟ
- Relieves muscle spasms
- Seizures are less intense
- Send starting medical cannabis my quality of life has increased dramatically. My my pain has subsided almost completely my energy level has taken a 360 turn for the better. I am a young woman and my late mid thirties and I would wake up every day feeling like I

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

was 90 years old. I would spend most my days in bed with no energy and the pain kept me from venturing out and enjoying my young children. Medical cannabis has also stimulated my appetite as well as help my anxiety and depression. I previously self medicating the street marijuana and even knowing the price difference and the cheaper I am able to get it from the streets I will never go back. I am also a cigarette smoker and the medical cannabis has reduced money smoking regular cigarettes in which in turn has increased my lung capacity and constant bronchitis feeling. My family and friends have seen a difference in me and the way I live my day-to-day life. Instead of denying the activities but I want to enjoy it I know have the ability to live my life the way I want to.

- Significantly decreased the pain/cramping in my lower legs and feet
- sleep, calmness
- Sleep well. Reduces pain
- Sleeping has improved! Mental health has improved! Pain control is optimal
- spasm control
- spasm relief
- spasm/pain lessened, reduced
- SPASMS AND NECK PAIN
- Starting to be able to slowly cut out other medications, noticing that I'm feeling healthier from the cannabis cause that's all natural and I haven't had as many attacks and when an attack does one on ice noticed just a couple of hits and the attack is under control.
- the ability to control my pain management without the groggy feeling I get when I use pain medication.
- the ability to move around more without having spasms and pain
- The ability to stop or juristically decrease my lower back spasms at any point in the day.
- The cancer-fighting effects from the cannabis oil.
- The medical cannabis has given me much more flexibility and an increased range of motion in my movement..
- The most important benefit to me is that this program has got my life moving again!! I cannot believe the favorite things I can now do thanks to the Minnesota Medical Cannabis Program, also the new things I can try, and still stay comfortable. Because of this program, I am getting so much time away from my Facio Scapulo Humeral Muscular Dystrophy, used to take away from me!! I can do more to care for myself, my home, my dog, my husband. I can get out and about, I can eat better, there are just so many benefits from this program I do NOT want to give back!
- the pain relief and it helps sleep
- The pain relief is great and my spasms are less and less
- The reduced muscle spasms in my legs has made it possible to take more steps than I thought would be possible again.
- The relief from pain
The feeling of well being

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- the Vape oil allows me to go to work without vomiting. also the pills help with inflammation and pain
- This is typed by his spouse. [PATIENT] has a TBI (traumatic brain injury). He says that it has had a major beneficial effect on his quality of life. One of the unexpected side effects has been a clarity of thought. He use to get confused doing some small tasks and some how it helps him to think clearer. He has been exceedingly more motivated and accomplishing more.
- This treatment has significantly reduced the frequency and intensity of cervical muscle spasms and the associated severe headaches.
- To be able to do things that I haven't been able to do for years because of pain and immobility.
- Vomiting control, tremor relief, ability to eat, went off antidepressants, can sleep.
- walking better
- We have seen a girl go from not interacting, to interacting. No appetite to appetite. Balance also seems better.
- When I use medication I can move. Without it I am in too much pain to move or engage with the world.
- Within 1 week of use, my tics disappeared and have stayed gone even with occasional use. This has never happened previously in my life, so it is very effective.
- Yes, It benefits me every day and my quality of life has greatly improved as a result, for the first time in my life i am neither under or over medicated.
- Reduced spasticity, reduced pain, improved Sleep, improved depression and anxiety.

Cancer

1: No Benefit

- Didn't like it and didn't use it
- None

2

- Increase appetite
- Some relaxation
- the first thing I discovered was the importance of taking time. second thing was taking things for granted!

4

- Appetite
- dull pain, sleep
- eating more,
- Facilitated my sleep
- helped with the nausea
- helps with pain
- Helps with sleep. Helps with pain.

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- I am feeling better.
- learning
- relaxation in the midst of pain, better appetite, some alleviation of pain.
- Relief from pain
- relief of stress
pain relief
- This survey was sent to [PATIENT], who died on [DATE].

5

- better sleep, less pain and fatigue, not as anxious, continued to have a appetite.
- [PATIENT] is dead. But it kept his potential nausea very low and help with any potential pain.
- Evening pain is eased with Cannabis before bed.
- Helping w/ pain management, sleep, reducing nausea
- It helped with my nausea.
- Keeping my appetite up and removing nausea symptoms.
- Little benefit to my cancer pain but a surprising improvement of at least 75% in my chronic arthritis pain.
- loosened up
- One benefit was it helped with my nausea and vomiting but not as well as I would have hoped. I had to puff on the vape pen consistantly to relieve me of the nauseated feeling instead of the 1 to 2 puff recommended dose.
- Pain
- Pain and nausea control
- pain management
- Pain relief
- Seems to have helped the neuropathy symptoms and also gives me an all over sense of well being - also helps with the nausea symptoms after chemotreatments.
- Seems to slow down pain rolls and eye strain.
- Sleep aid

6

- ability to eat
- An increase in appetite, and decrease of muscle spasms
- appetite enhancement
- Appetite, more relaxed
- Appetite
- Decrease in pain and imflammation
- help with pain
- I'm comfortable and able to eat and sleep
- Improved appetite, somewhat less pain
- improved pain load mood and sleep
- It has helped manage pain and anxiety.

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- leg cramps and nausea
- Less jabbing pain in feet from Neuropathy - better sleep
- less narcotic pain medicine
much better pain control
fewer breakout pain incidences
- Less pain, calmer about the situation
- Less spasms and nausea.
- Might save my life
- My stomach (core) feels more normal (calm) and my bowel movements are less often - have more form - not as much liquid & gas.
- nausea control
- Not feeling the pain in bones/muscles and good feelings for a terminal illness
- Pain control
- Pain Management
- pain reduction, better sleep, increased appetite
- pain relief and help with sleep
- Really helps with pain from cancer treatments as well as resulting anxiety from multiple surgeries and permanent scars, etc.
- Reduction of Nausea and pain, and increase in appetite.
- reduction of side effects or neg. effective of other forms of treatment I have been on.
- relieve anxiety
sleep better
- Sleep and being able to eat, and reduced nausea
- Spasm relief and that leads ultimately to pain management.
- Stomach cramps gone
Anxiety relief
Nausea relief
Sleep

7: Great Deal of Benefit

- Because of the THC, I feel like getting up and doing things. Prior to having the cannabis, I just laid on the couch. I felt like I was just waiting to die. 2. I do not use the percocet. I do not want to have to take pain pills. Period. To many people are getting addicted to these things. 3. I do not get the dry mouth or canker soars since I hardly use the anti nausea drugs.
- Ability to create appetite and relieve pain
- ABLE TO EAT AND MAINTAIN MY WEIGHT PLUS MY NAUSEA HAS DECREASE TREMENDOUSLY .
- able to eat food. helps keep nausea down.
- Appetite, was losing weight fast! Didn't have one! Now got it back! And gained 20 pounds! From this.
- Appetite. During chemo weeks I can barely eat and the THC helps a lot.
- Being able to start weaning myself from opiates I've been on for ten years.

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- controlling nausea
- Controlling nausea
- Coping with nausea, being able to eat and maintain weight
- [PATIENT] has passed away. I am her daughter and was her care giver. She was open to trying medical cannabis and we got the liquid form. It was a saving grace. She was in a lot of pain and when prescribed medications did NOT work - we started this and it kept her calm and relaxed. I am very thankful that we were able to have this option available. It helped to make her last months more bearable and truly it would have been miserable without it.
- Eating
- general overall feeling of well-being...pain relief
- Getting appetite back, and attitude adjustment.
- Greater mobility and less inflammation.
- Help with sleeping
- Helped ease pain. Calmness and appetite. Have no appetite on chemo without it
- helped with nausea
- I am able to sleep pain free for 7 to 8 hours a night
- I have not had issues with nausea at night and my PSA counts are going down.
- I used cannabis to treat my constant nausea during chemotherapy. This option seemed to be a very effective option after I was unable to take pills orally. Later on during treatment I used the medical cannabis to see for myself how it would treat the pain I was in. I wouldn't say medical cannabis a great painkiller, however the cannabis seemed to break my focus on the pain better than the oxycodone alone. I really feel that my quality of life was better using the cannabis.
- I was able to discontinue the use of multiple dangerous drugs.
- I was able to get off all my anti nausea medication which allowed me to
Get off all the anti constipation medication. Prior to being in the cannabis program I had no appetite and had lost 35 lbs I have been able to put back on 15 lbs. My quality of life after chemotherapy treatments turned around substantial. An added bonus was the pain relief from a chronic back pain, it has helped significantly with my pain management.
- Improved quality of sleep.
- Increased appetite and motivation.
- Instead of sleeping all day [PATIENT] was social and wanting to be with family and friends.
- It helps a lot with my pain level. Since I started this program I have not needed to increase my opioid medication to control my pain. I many times use the vaporizer in place of oxycodone for breakthrough pain. When my anxiety is very hi I use the vaporizer. It has made a very positive difference in my quality of life at this point.
- less bowel urgency, less pain, less anxiety
- Makes me eat/ help me sleep relax pain is not as bad

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- Medical cannabis has almost completely relieved my pain and nausea associated with my cancer and the effects of treating my cancer with chemo (I have chemo every three weeks for the rest of my life due to metastatic colon cancer).
- Mitigation of nausea and sleeping assistance.
- My inflammation from chemo and radiation completely went away! My pain and suffering has really decreased because of this oil it is a miracle!!!
- my nausea after chemo is gone in less than a minute after one inhalation from my vaporizer
- nausea control makes me hungry with my condition helps with the lulls in life
- Nausea and Pain
- Pain and sleeping
- Pain control while still allowing me to live. I can not handle opiates.
- Pain control
 - Appetite
 - Anxiety reduction
- Pain reduced: 70% - 80%,
 - Better sleep
- pain relief
- Pain relief
- Pain relief
- Pain relief
 - Sleep
 - Nausea
- reduced vomiting.
- Reduction in pain, muscle tension, and anxiety. Sleep has also improved.
- Relaxing, peaceful sleep and wake up relaxed... less anxiety..
- relief from Nausea, gave me appetite
- Relief of breakthrough pain
- Relief of nausea
 - increased appetite
 - relief of anxiety
 - better sleep
- Relief of pain
 - Ability to Sleep
 - Restoration of Appetite
 - Gaining of strength
 - Increased Mobility
 - Restoration of concentration
- Relief of the nausea that I have all day with the chemo drug I am on.
- Relieves anxiety and nausea
- Relieves anxiety, depression and pain and is a natural solution as opposed to a man made pill.

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- since I've started using the oil my brain cancer has maintained its size, it isn't getting any bigger and it isn't getting any smaller.
- Sleep aid. Anxiety decrease.
- The cancer-fighting effects from the cannabis oil.
- the cannabis takes away the upset stomach feeling instantly. it also is a great sleep aid. it helps me with my apatite and takes away the pain. and i don't have to worry about addiction.
- With my cancer diagnoses and treatment, I've found relief while taking the cannabis!!! I get relief from pain, relief from nausea, relief from insomnia.
- Without the medical cannabis I am not able to eat at all. With the cannabis I have been able to maintain a healthy weight and get the nutrition I need during my treatment.
- I died

Seizures

1: No Benefit

- At first thought seemed to be more aware but not we are off it he is still more aware
- None - lives in a group home and group home can not store or administer or risk lose fed. funding
- Nothing really
- Other health issues occurred and I stopped the cannabis before the dose was at a high enough level to do anything. So we are not a fair representation of effectiveness of cannabis for seizure control

2

- "possible" slight decrease in seizure activity
- Being able to legally get marijuana in MN.
- I believe it has reduced seizures. It's difficult to fully know without my epilepsy dr. not involved.
I've tried approximately 13 different seizure medications over the past decade, non of which has helped a great deal.
I'm trying to follow the process that the Dr. used for other medication.
Take a small amount look for side effects and or change to the seizures.
If side effects try to lower the amount.
If no side effects try to find an amount that works.
I'm trying to do this on my own but a Dr. is needed.
It's not clear if it's working or not, so keep that in mind when looking at my answers to the questions.
- I was experiencing relief from stress and anxiety the first two months but I am no longer
- more present cognitively
-Also, being able to try it and stop wondering if it was going to help.
- slight seizure reduction, but too many side effects

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

▪ Speech Development

3

- Decrease the amount of seizures and seizure meds
- fewer seizures
- knowing we have had the option to try medical cannabis when other treatments have failed
- [PATIENT] was having clonic seizures. All muscle tone would leave body and she would drop. She no longer has those seizures
- More aware of my surroundings; thinking more clearly.
- Reduction of seizures

4

- A slight decrease in seizures, though still not enough control. Also, improved cognitive skills.
- Breathing thru seizures more?
- comfort, has a tethered spine seems to feel less irritability.
- Cognitive thinking. More alert.
- Helps with diaphragmatic flutters
- I have less seizures
- It may have lessened seizure activity.
- Less muscle twitching and sleeping better..
- less seizure activity
- lessening of pain
- Limiting seizures
- Local
- My daughter is the patient and I have seen more cognitive improvements on CBD oil.
- seeing [PATIENT]'s seizures reduce overall.
- seizure reduction
- Seizures respond quicker to emergency med
- Thinks clearer talks more

5

- Anxiety/Depression
- Calmed my muscles and seemed to help my seizure
Also helped me sleep all night, not waking up 5-6 times a night
- tears
- Controlling his seizures as well as I'm probing cognitive functioning!
- decrease in auras, muscle spasms and pain.
- decrease in seizures
- decreased seizures

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- Developmental Growth: Using hands more, fine and gross motor skill improvement within the first couple weeks! More verbal, smiles more, babbles and talks more, reaches for toys more, overall has enhanced his quality of life in a very short time.
- Fewer seizures, more cognitively aware/focused/alert, improved sleep
- He seems so much happier since we've switched to the [HIGH CBD PRODUCT].
- I know for a fact that this med is helping me
- Less aching in my joints and less all over body pain.
It has also helped my anxiety.
- Less Seizures (Four patient reports)
- less seizures, more mental clarity, overall improved wellness
- limits my muscle spasms
- Medical cannabis has been amazing for my son. No harmful side effects or lifelong medical problems from taking it. Such as Risperdal, ect. I would however remove the MCT from all cannabis products. It is not a good thing for people with stomach or neurological issues. Which is usually why a person would need this or desire relief from dealing with these issues. MCT is for people with none of those problems.
- Mood
- More alert or aware
- My daughter went for the full month of September with NO seizures when she first started on cannabis. October and November were not so good. This past month we tried a different formula to see if we can get better control. Still more adjustments are needed.
- Pain and seizure relief. Finally off oxycodone after 1.5 years
- reduction in seizures with no side effects and no mood problems
- reduction of seizures
- Reduction of seizures.
- [PATIENT]'s spasms and twitching have significantly decreased
- Seizures are more under control even when other med levels are low.
- The first 2 days, very sleepy. After that the first week, her small seizures were gone, the second week her mobility increased and her verbal language increased. 3rd week, she got her cycle, so everything went out the window with that. 4th week she got a cold. We had dosage changes but did not see the 2 week awesome things again.
- [PATIENT] more alert and vocal than ever before

6

- Better cognition and less seizures
- Decrease in seizures overall, especially tonic-clonic seizures, & few rescue meds.
- Decreased seizure activity
- dramatic decline in seizures
- Feel better. More energy.
- Fewer seizures
- fewer startle seizures

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- Have slept better than I have in 14 years! Due to not worrying all night if I was going to have a seizure in the morning
- Helps eliminate or reduce certain side effects from the other epileptic medication.
- [PATIENT] began babbling and made new sounds! His synapses seemed to be firing faster.
- Increased alertness, increased development, less seizures,
- Large decrease seizures. Caregivers have not had to rescue him since beginning medication.
- Less convulsions, dizziness, auras, confusion during everyday moments which are signs of possibly losing consciousness, or are very problematic to function at work.
- Less seizures
- less seizures,
- managing pain
- Marked reduction in frequency of seizures, their duration and severity
- My postictal state after a seizure went from 4-5 days down to 1-2 days.
- Reduced seizures (Two patient reports)
- Reduction of number of intractable seizures plus reduction of length of seizures and a quicker recovery time from seizures.
- Reduction of seizures quality and quantity
- responsiveness. core strength.
- Sara is much more alert and cognitively connected in her conversation.
- Less severe seizures
- Seizure control
- Seizure reduction was the main goal, and we have seen seizure reduction. In addition, [PATIENT] has a better quality of life. We are taking him off all other pharmaceuticals. He is eating better, sleeping better and is a happier child.
- Seizures are weaker and less
- seizures have decreased
- Seizures have decreased in amount and intensity.
- seizures have reduced in frequency and there are no negative side-effects to the medication
- Stopped my seizures, convulsions and shaking .
- The seizures are stopping and the dizziness is going away. [PATIENT] is more controllable and is able to control himself better as well. He's still autistic 😊

7: Great Deal of Benefit

- 75% reduction in seizures
- 95% reduction in uncontrolled seizures
- 98% seizure reduction, elimination of persistent headaches, and we were able to wean 75% of child's benzodiazepines, meaning that her Quality of Life has significantly improved, as have all of her abilities.

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- Being able to treat my epilepsy with cannabis oil and not having to worry about breaking the law. I have been seizure free ever since I began using cannabis oil.
- Better cognition
 - Better focus
 - Less anxiety
 - Better mood
- Better sleeping, less muscle cramping, less periods of seizure-like activity.
- Control of seizures, FINALLY!!! :) = Quality of life for my little boy!!!
- Decreased # of seizures.
- [PATIENT] is still on anti seizure meds, but he has not had any seizures from forgetting to take them (Keppra) on several occasions...normally he would have.
- [PATIENT] has been seizure free since Sept 21, 2015!!!
- Epilepsy, helping me stay seizure free, and also helps anxiety, calm down
- Fewer Seizures Better Calmer Communicating Ability
- Grand mal seizure free
 - Sleep duration has dramatically increased
 - Better quality of life (only one side effect compared to the horrendous side effects from the pharmaceutical medications he was on)
- Having no more seizures is the biggest reason.
- his ability to come off some of his other meds and be more "present", calm, and content.
- I am in significantly less pain. I can function throughout the day so much better than I could before the cannabis program. It is like night and day.
 - I have less dizziness from vertigo with the cannabis
 - I have better mobility of my neck
- I am not having any seizures at all
- I feel more alive, less depressed, outgoing, functional, pain relief from my headaches and eye twitches, also just overall life has improved since this has come available to me.
- I started out on a normal dose of antiseizure meds and was still experiencing seizures that lasted over 3 minutes in duration. I then increased my antiseizure meds to the maximum recommended dose however I still was having seizures lasting over 3 minutes. I had my last seizure 4 days after starting the cbd cannabis medicine. It lasted less than 1 minute. I can happily say that I am over 4 months seizure free.
- Increased focus, ability to calm self more easily, able to be present in the moment, engaging more with others, better sleep, increased verbalization. (averaging 5-10 words each day, prior to CBD oil >3) better digestion
- Increased muscle coordination
 - Increased attentiveness
 - Increased cognitive function
 - Increased mobility
 - Increased positive moods
 - Decreased spasm severity

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

Decreased seizures

- It has greatly helped with the seizures and quality of life has improved very much. The quality of life has improved so much that much more is possible than was not before, such as community outings without extreme behavior outbursts.
- I've only had a seizure when I increased the cannabis and that's normal. Otherwise, I haven't had any seizures randomly in my sleep or out running since I've started the cannabis.
- Less frequency of seizures. 20/day to 2-5/day
- less headaches less anxiety
- less petit mal seizures, better sleep at night and, reduced muscle spasms
- less seizures
- less seizures
- More alert. Less myoclonic seizures.
- More seizure control and more energy
- My daughter has had an over 95% reduction in seizures and gotten off many harmful medicines since starting the Medical Cannabis program.
- No grand mal seizures
- No seizures since beginning treatment. Sleep is continuous and more restful.
- No seizures since I started taking the [HIGH CBD] Medical Marijuana formula!!!! It's amazing!!! :-)
- One month without seizures!!!
- Only usage of the oil helped! But it's much too expensive.
- Pain reduction and now able to sleep 6-7 hours per night vs 2 before using medicinal marijuana.
- Pain relief has been a major benefit as I am able to control pain from my back spasms very well with medical cannabis. Not having to take opioids is great!!
- Quality of life
- QUALITY OF LIFE & WAY LESS SEIZURES!!!!!! 90% LESS!!!!!!!!!!!!!!
- Reduced seizure activity & sense of "neurological calm" on good days; also mental clarity and sharpness
- Reduced seizure frequency, anxiety reduced, less partial seizures, mood booster
- reduction in seizure frequency for my son
- reduction in seizures
- reduction of seizures
- Seizure control. [PATIENT] (4 yr. old) was having 5-10 seizures a week before Medical Cannabis. She is down to a 7 week period seizure free- and if she has one it is every couple of weeks and very small.
- Seizure control is my greatest benefit but it also helps with the migraines from a lit of broken skull.
- seizure free
- Seizures and anxiety, depression, and better sleep better

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- Seizures anxiety depression bi-polar
- Seizures are less intense
- -Stopped shaking hands (side effect from epilepsy meds).
-FEWER SEIZURES. ***If this was more affordable I am very confident they would stop all together because I would be able to use more.
-Helps w/nausea (side effect from epilepsy meds).
-Reduces an
- the ability to control my pain management without the groggy feeling I get when I use pain medication.
- The decrease in the number of daily seizures
- The treatment stops my seizure from being so frequent it helps my eating and gives me great relief thank you for finding something that really helps me thank you all for supporting other epileptic patients
- This is typed by his spouse. [PATIENT] has a TBI (traumatic brain injury). He says that it has had a major beneficial effect on his quality of life. One of the unexpected side effects has been a clarity of thought. He use to get confused doing some small tasks and some how it helps him to think clearer. He has been exceedingly more motivated and accomplishing more.
- We have seen a great deal of improvement on our daughters ability to focus and attend to tasks. if this improvement is due to a reduction in subclinical seizures or other factors is yet to be seen. We will have a follow up EEG in a few months to see if we are getting subclinical seizure control.
- We haven't noticed any new seizures.
- [PATIENT] is no longer on cannabis - sorry

Crohn's Disease

3

- It helps me with sleep

4

- Helping calm my intestines.
- rest and more solid stools
- slightly improved mood, moderate pain relief

5

- 1. Decrease in Anxiety
- 2. Increase in Appetite
- 3. Decrease in Pain
- 4. Decrease in Nausea
- A recent blood test showed C Reactive Protein at 2.2, in Nov 2015 it was greater than 20. Also helps with anxiety.
- less bowel pain and bowel movement pain

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- Medical cannabis has allowed me to sleep well at night. I was up 3-4x/night- now I sleep through the night. This allows me to feel significantly better during the day. less fatigue and less arthritic pain and so I've been able to significantly cut back on opiate pain meds.
- Pain Management
- Pain relief.
- Sleeping better , allowing for more energy. Lower anxiety.
- The cannabis has allow me to maintain my weight more effectively. Pain relief from cramping would also be a benefit.

6

- A large reduction in symptoms, allowing me to participate in my daily life without a large number of limits my symptoms would place on me - stools decreased from over 8 a day to about 2 with much less blood and mucous in stools. Pain has reduced to a tolerable amount.
- Being able to sleep.
- Decrease in pain, reduced symptoms, completely able to avoid having to use narcotics for pain relief
- decreased anxiety, decreased pain
- Helps to lower stress, my muscle spasms have been pretty much nulled! My stomach issues having been like before, cramps have been minimized, just feel quite a bit better!
- I have gained an amount of weight that I have not been able to in the past. I have been very pleased with this result.
- Increased stool firmness
- My stomach (core) feels more normal (calm) and my bowel movements are less often - have more form - not as much liquid & gas.
- nausea control
- Pain relief in low back
- Pain relief is the biggest benefit. Also less cramping.
- pain/appetite management
- Reduction in the use of pain medications

7: Great Deal of Benefit

- abdominal pain relief
- Better Health
- Can digest better so im not scared to eat giving me more energy allowing me to accomplish more in a day sleep better at night joint pain relief cramping relief clears up mental fogginess less agitation eases anxiety
- Cannabis has helped with keeping the chrons calm. I made it through the holidays with no flare ups.
- Helped reduce swelling in my ankle a great deal, among other benefits

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- Helps in overall feeling much better, reduces abdominal cramping tremendously, helps w/ nausea. I also use the medication after my Remicade treatments as usually after those treatments I don't feel well. I use the cannabis and it's almost instant relief. The medical cannabis over all makes me feel much better than when not using the medication.
- I am in significantly less pain. I can function throughout the day so much better than I could before the cannabis program. It is like night and day.
I have less dizziness from vertigo with the cannabis
I have better mobility of my neck
- I have gone from having diarrhea daily, to having it once a month. That's a huge quality of life improvement for me.
- It stops vomiting almost as quickly as IV drugs for nausea
- Just a general improvement of quality of life with the symptoms of my Crohn's disease. I have extremely benefited from cannabis.
- Less nausea
- Lessens the amount of stools per day. Increases my appetite so that I can maintain my weight. Allows me to digest my food slower increasing the amount of nutrition absorbed.
- My overall inflammation has dropped significantly thanks to medical cannabis. this has resulted in me having to drop my daily amount of background (Lantus) insulin throughout the day by 10 units. with my diabetes, I am less insulin resistant and probably use 15 units less per day on top of the 10 units less per day from my Lantus. I also have been sleeping much better and am have been able to completely remove opiates from my life which is a huge accomplishment for me.
- No crohns disease flare ups since starting treatment
- Not having to live with daily pain since starting treatment!!!!!! :-)
- pain killers have been eliminated from my routine because pain has been reduced
- Pain relief
- Pain relief
- reduced diarrhea - reduced stomach pain, gas and bloating
- Re-established my ability to partake in physical activity.
- Relief from pain and nausea. Help with sleeping.
- Suppression of most of my Crohn's symptoms with very few side effects
- That the pain was pretty much non-existent.
- The medicine has helped me not feel as sick all the time.
- the Vape oil allows me to go to work without vomiting. also the pills help with inflammation and pain
- When I was on it the quality of life it gave me back

Terminal Illness

4

- helps with pain

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- Helps with sleep. Helps with pain.
- Nausea and vomiting

5

- [PATIENT] is dead. But it kept his potential nausea very low and help with any potential pain.
- Pain relief, distraction from pain

6

- I'm comfortable and able to eat and sleep
- it really helpful with my anxiety and rib pain
- Might save my life
- Reduction of Nausea and pain, and increase in appetite.
- Seizures have dissipated
Somewhat calmer behavior

7: Great Deal of Benefit

- Ability to create appetite and relieve pain
- Anti nausea, it's a miracle worker for nausea.
- Coping with nausea, being able to eat and maintain weight
- [PATIENT] has passed away. I am her daughter and was her care giver. She was open to trying medical cannabis and we got the liquid form. It was a saving grace. She was in a lot of pain and when prescribed medications did NOT work - we started this and it kept her calm and relaxed. I am very thankful that we were able to have this option available. It helped to make her last months more bearable and truly it would have been miserable without it.
- Eating
- general overall feeling of well-being...pain relief
- Getting appetite back, and attitude adjustment.
- Helps a lot with pain and relaxing from stress also helps a lot with upset stomach.
- Improved quality of sleep.
- It helps a lot with my pain level. Since I started this program I have not needed to increase my opioid medication to control my pain. I many times use the vaporizer in place of oxycodone for breakthrough pain. When my anxiety is very hi I use the vaporizer. It has made a very positive difference in my quality of life at this point.
- my nausea after chemo is gone in less than a minute after one inhalation from my vaporizer
- No nausea from Chemotherapy. Much more energy and appetite along with a more positive outlook on life.
- Pain relief
- reduced vomiting.
- Relaxing, peaceful sleep and wake up relaxed... less anxiety..
- Relief from nausea

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- since I've started using the oil my brain cancer has maintained its size, it isn't getting any bigger and it isn't getting any smaller.
- the relief of pain.
- We have seen a girl go from not interacting, to interacting. No appetite to appetite. Balance also seems better.

HIV/AIDS

3

- Eating
- That the medicine does increase the ability to tolerate my intense pain, or at least takes some of the edge off.

4

- Takes the edge off of the worst pain, not quite as sharp on most days.

6

- It has significantly helped reduced the physical pain related to my chronic pain, fibromyalgia, and systemic exertion intolerance disease. It has helped make my days more bearable and easy.
- Less pain, better sleep and I experience less anxiety.
- Pain management

7: Great Deal of Benefit

- Relief that my other pain medication does not remedy.
- A significant reduction in after-medication nausea. There has also been relief of neuropathic pain in my extremities.
- able to sleep at night. I have been living with Neuropathy pain since 1990
- Appetite, was losing weight fast! Didn't have one! Now got it back! And gained 20 pounds! From this.
- calmness
- Cannabis has been a helpful tool in finding relief from pain and fatigue; so that I'm able to exercise and do yoga. I'm able to eat and I have gained back healthy weight. I have found cannabis to be beneficial in relieving anxiety and depression, also. Although, I think there are medicinal qualities in the whole flower that are missed in the current extractions available.
- Finally putting on weight again due to underlying health reasons that he has trying to overcome for 20+ years, finally gaining fat mass back, started as a skeptic, no effect from leaf form tries
- Help with nausea
- Immediate relief of nausea and the ability to sleep at night.
- Reduction in spasms
- relaxed no anxiety stomach better neuropathy better
- stress/mental stability, medication toxicity dampening (less effect on stomach), better quality sleep, longer sleeping time, pain decreased, food consumption increase.

APPENDIX A: PATIENT REPORTED BENEFITS FROM SURVEYS

- The constant pain in my feet is really diminished and only have occasional time that I feel like I am having hot nails slammed into them

Tourette Syndrome

4

- calmer in general
tics have reduced some
doesn't get upset as easily by noise
more regular BM's
gained some weight - more hungry
- The normalization of cannabis, cannabis's new legal status and increased social acceptance.

5

- The cannabis has calmed both physical and verbal tics. It has not completely suppressed the tics.

6

- elimination of tic behaviors
- [PATIENT] has experienced decreased anxiety and rigidity related to his autism. He is better able to focus and pay attention. His mood is more positive and he is more flexible.
- My tourettes has calmed down.
- Quiets the tourette symptoms.
- Reduced ticks, better cognition, calmer in public places, Reduced stress over all.

7: Great Deal of Benefit

- [PATIENT] has greatly reduced tics and anxiety which has improved every aspect of his life.
- less ticks, no depression, focus at work
- No longer injuring herself. Such as banging head and kicking walls and etc. Does not seem to be uncomfortable.
- Reduced motor and vocal tics tremendously. I am off 6 medications including morphine.
- The removal of my disability, Tourette Syndrome. And it's almost all gone, when medicated.
- Within 1 week of use, my tics disappeared and have stayed gone even with occasional use. This has never happened previously in my life, so it is very effective.

Glaucoma

6

- Less eye pressure headaches
Increased appetite
Less anxiety

7: Great Deal of Benefit

- reduction of interocular eye pressure; also reduction in muscle cramps and chronic pain
- spasm relief
- Reduced eye pressure especially during pressure attacks and quick climbs, pain relief and addresses the migraines associated with my glaucoma (brain injury related)....I also remain seizure free
- Better quality of life, greatly reduced pain, greatly reduced spasms and exacerbations, less stiffness able to sleep through the night.
- Pain and encumbered vision from Iritis Uvitis completely eliminated - Have been able to discontinue use of Pred Forte steroids which had terrible side effects but was prior to medical cannabis the thing drug available for managing the pain and inflammation and white cell production associated with my disease.
- The reduction of symptoms of my glaucoma. Less frequent eye pain attributed from lower IOP.
- verification that cannabis can treat my qualifying conditions.

ALS

4

- It helps alleviate my stress.

5

- help with sleep, anxiety and regularity

6

- helps calm mind/nerves, this lowers stress which caused muscle twitching
- Less pain
- Spasticity relief

7: Great Deal of Benefit

- anxiety is greatly reduced
- I can sleep at night, all night long.
- Pain control (back pain) and no leg cramps
- The relief from pain
The feeling of well being

DESCRIPTORS

Cannabidiol;
Cannabis sativa;
Anxiolytics;
Anxiety disorders.

Abstract

Objectives: To review and describe studies of the non-psychotomimetic constituent of *Cannabis sativa*, cannabidiol (CBD), as an anxiolytic drug and discuss its possible mechanisms of action. **Method:** The articles selected for the review were identified through searches in English, Portuguese, and Spanish in the electronic databases ISI Web of Knowledge, SciELO, PubMed, and PsycINFO, combining the search terms “cannabidiol and anxiolytic”, “cannabidiol and anxiolytic-like”, and “cannabidiol and anxiety”. The reference lists of the publications included, review articles, and book chapters were handsearched for additional references. Experimental animal and human studies were included, with no time restraints. **Results:** Studies using animal models of anxiety and involving healthy volunteers clearly suggest an anxiolytic-like effect of CBD. Moreover, CBD was shown to reduce anxiety in patients with social anxiety disorder. **Conclusion:** Future clinical trials involving patients with different anxiety disorders are warranted, especially of panic disorder, obsessive-compulsive disorder, social anxiety disorder, and post-traumatic stress disorders. The adequate therapeutic window of CBD and the precise mechanisms involved in its anxiolytic action remain to be determined.

Introduction

Cannabis sativa is the most used drug of abuse worldwide and around 20% of youth use it heavily and regularly around the globe.¹ The main psychoactive component of the plant is Δ 9-tetrahydrocannabinol (Δ 9-THC), one of the substances responsible for the psychoactive effects of Cannabis.²⁻⁴

Cannabidiol (CBD) is another abundant compound in *Cannabis sativa*, constituting around 40% of the plant's active substances.⁵ The pharmacological effects of CBD are different and often opposite to those of Δ 9-THC.⁶ The number of publications on CBD has increased remarkably over the last years and support the view that CBD has a vast array of possible therapeutic effects. Among these possibilities, the anxiolytic and antipsychotic properties of CBD stand out.⁷⁻¹⁰ CBD's anxiolytic effects are apparently similar to those of approved drugs to treat anxiety,¹¹ although its effective doses have not been clearly established and the mechanisms underlying these effects are not fully understood. The low affinity of CBD for cannabinoid neuroreceptors^{12,13} and its agonist properties at 5-HT_{1A} receptors^{14,15} have been repeatedly demonstrated.

Most studies on CBD have been conducted with rodents, but studies with human samples have also provided promising results.^{16,17} Therefore, the aim of this paper is to review the scientific literature on the anxiolytic properties of CBD in animal and in humans.

Method

The articles selected for this review were identified by searches in English, Portuguese, and Spanish in the electronic databases ISI Web of Knowledge, SciELO, PubMed, and PsycINFO combining the search terms "cannabidiol and anxiolytic", "cannabidiol and anxiolytic-like", and "cannabidiol and anxiety". In addition, the reference lists of the selected articles and relevant literature reviews and book chapters were handsearched for additional references. We included experimental studies with human and animal samples with no time limits. We sought to exclude studies that used smoked Cannabis, as it is not possible to establish the dose, composition, and proportion of the different cannabinoids in this case, besides the great individual variations in the samples enrolled. Finally, we did not include studies using extracts containing both THC and CBD in oral (Cannador®) or oromucosal spray (Sativex®) forms due to the difficulty to establish the effects of CBD alone (Table 1).

Animal studies

The two first articles about the effects of CBD on experimental anxiety were published in journals that were not indexed in the databases used for this review but were located through handsearch in the reference lists of relevant literature. These two investigations showed contradictory results. In one study, no significant effects of high doses of CBD (100 mg/kg) were seen in rats in the Geller-Seifter conflict test.¹⁸ In the other, a low dose of CBD (10 mg/kg) had anxiolytic effects in rats submitted to the conditioned emotional response test.¹⁹

Later studies using the elevated plus maze (EPM) helped to elucidate this contradiction.⁹ The EPM consists of two opposing open arms (50 x 10 cm) and two closed arms

(50 x 10 x 40 cm) that intersect in their central portion. The arms are made of wood and stand 50 cm above the ground. In this study, mice injected with CBD, diazepam or vehicle (no active substances) were placed in the center of the maze facing the closed arms. The time spent and the numbers of entries in the open and closed arms were measured for 10 minutes. The frequency of entries in the open arms of animals receiving CBD presented an inverted U-shaped curve, with significantly higher rates than those observed in animals treated with vehicle, at the doses of 2.5, 5, and 10 mg/kg. The measures of mice treated with CBD 20 mg/kg did not differ from those of controls, suggesting that anxiolytic effects are only present at low doses, which explains the absence of effects with CBD 100 mg/kg reported in 1981.¹⁸ The same inverted U-shaped dose-response curve was obtained with a wider range of doses of CBD in the EPM (Onaivi et al.).²⁰ Furthermore, the same pattern was observed with the direct infusion of CBD in the periaqueductal gray (PAG) of rats tested in the EPM,^{15,21} confirming that anxiolytic effects should only be expected with low doses of CBD.

The mechanisms through which CBD acts to diminish anxiety have been studied in a number of animal models of anxiety using rodents. One of these studies used Vogel's conflict test,²² in which the animal is water-deprived from and placed in a cage with an electrified grid at the bottom through which the animal receives a shock after licking water for a predetermined number of times. Three substances were tested in rats using the following procedure: CBD (2.5, 5 and 10 mg/kg), diazepam, and flumazenil (an antagonist of benzodiazepine receptors), in addition to vehicle (placebo). The tests showed that CBD produced effects consistent with those of diazepam by increasing the number of licks, even if they resulted in punishment. Flumazenil antagonized the anxiolytic effect of diazepam, but not that of CBD, suggesting that the effects of CBD are not mediated by the activation of benzodiazepine receptors.

There is strong evidence showing that the serotonergic system is involved in the anxiolytic action of CBD. The injection of the 5-HT_{1A} receptor antagonist WAY-100635 (WAY) directly into the dorsolateral portion of the PAG (dIPAG) in rats antagonized the anxiolytic effects of CBD in the EPM and in Vogel's conflict test.¹⁵ The participation of 5-HT_{1A} receptors in the anxiolytic action of CBD was also derived from behavioral and cardiovascular responses to restraint stress in rats.¹¹ In this study, animals were intraperitoneally injected with vehicle or CBD (1, 10 and 20 mg/kg) and, after 30 minutes, they were restrained for 60 minutes. Immobilization increased blood pressure, heart rate, and anxiety responses in the EPM 24 hours later, and these effects were attenuated by CBD. Pretreatment with WAY blocked the anxiolytic action of CBD. The injection of CBD into the intra-dorsal PAG also blocked panic-like responses in the elevated T-maze (ETM) and flight responses to the electrical stimulation of this area.²³ The ETM has three arms with the same dimensions, two open and one closed, and allows the measure of entrance avoidance in the open arms when the animal is placed in the closed arm, as well as of escape when the animal is placed in the open arm. The panic-like response seen with CBD in the two procedures was antagonized by the previous intra-dIPAG administration of WAY.²² Chronic oral administration of CBD also had anti-panic effects in the ETM that were neutralized

by intra-dlPAG injection of WAY. However, chronic administration of CBD did not change the extracellular concentration of serotonin in the dlPAG or the expression of 5-HT1A or 5-HT2C, indicating that CBD directly activates 5-HT1A receptors.²⁴ CBD was also found to activate the vanilloid receptor type 1 (TRPV1)²⁵ and there is evidence that this activation could explain the inverted U-shaped dose-response curve of CBD's anxiolytic effect seen in the EPM. TRPV1 receptors regulate the release of glutamate in the dlPAG and the increased activation of this system would result in increased anxiety. Thus, it has been suggested that elevated doses of CBD in the dlPAG could activate local TRPV1 receptors facilitating the glutamatergic neurotransmission and increasing anxiety.

To test this hypothesis, rats pre-treated with the TRPV1 antagonist capsazepine in the dlPAG were injected with CBD (30 and 60 mg/kg) in the same region and tested in the EPM. The dose of 60 mg/kg CBD, which had no anxiolytic action before, was able to reduce anxiety after pre-treatment with capsazepine, suggesting that the activation of TRPV1 receptors by the higher dose of CBD would counterbalance the anxiolytic effect of CBD produced by the activation of 5-HT1A receptors.²¹

Because serotonin has also been implicated in obsessive-compulsive disorder (OCD), the effects of CBD were tested in mice submitted to the marble-burying test (MBT), an animal model of compulsive behavior. CBD induced a significant reduction in the number of buried marbles at different doses (15, 30, and 60 mg/kg) compared to controls in a dose-dependent pattern. The same was found with the administration of the ISRS paroxetine (10 mg/kg) and diazepam (2.5 mg/kg). However, the effects of CBD 30 mg/kg persisted even after seven days of repeated daily administration, whereas the effects of diazepam disappeared. Pre-treatment with WAY (3 mg/kg) counteracted the effects of paroxetine, but did not affect the action of CBD, which was prevented by pre-treatment with the CB1 receptor antagonist AM251 (1 mg/kg).²⁶ This action of CBD in the MBT was recently replicated by another group using a higher dose (120 mg/kg).²⁷

The participation of specific cannabinoid receptors (CB1) in the anxiolytic action of CBD has also been investigated using animal models. In the study with the EPM that reported the antagonism of the anxiolytic effect of intra-dlPAG CBD by WAY, the CB1 receptor antagonist AM251 was unable to avoid this effect.¹⁵ However, this receptor system seems to be involved in another anxiolytic-like action of CBD, according to tests using a procedure known as contextual fear conditioning. In this procedure, animals are pre-conditioned to a hostile environment (foot shocks) and later exposed to the same environment, when they normally present freezing, the duration of which can be monitored as a measure of anxiety. Both CBD and diazepam are successful in attenuating freezing in rats, as well as the increased heart rate and blood pressure induced by re-exposure to the contextually feared environment.¹⁰ This effect of CBD on contextual memory is also produced by the endocannabinoid reuptake inhibitor AM404, which increases the availability of cannabinoids in the synaptic cleft.²⁸ In this study, the two drugs were injected into the ventricles and their effects were counteracted by the CB1 receptor antagonist SR141716A, suggesting the involvement of the endocannabinoid system in the anxiolytic action of CBD in this model. The pre-limbic region of the prefrontal cortex

appears to underlie this effect of CBD, as the reduction in contextual fear produced by systemic administration of CBD (10 mg/kg) is associated with reduced c-Fos expression in this area. In addition, the microinjection of CBD (30 nmol) in the pre-limbic region of the frontal cortex reduced freezing induced by re-exposure to the aversive context.²⁹ The effects of CBD on contextual fear indicate a possible therapeutic action of this cannabinoid in post-traumatic stress disorder.

Another area that is apparently involved in the anxiolytic-like effects of CBD is the bed nucleus of the stria terminalis (BNST). The intra-BNST injection of CBD (15, 30, and 60 nmol) increased the number of punished licks in Vogel's conflict test and the number of open arm entries in the EPM. These effects were blocked in rats pre-treated with WAY.³⁰

CBD was also effective in an ethologic model that investigates behaviors induced by innate fear, the predator-prey paradigm.³¹ This procedure was performed using a semi-transparent plexiglass box in the shape of a quadrangular arena (154x72x64 cm) with walls covered with a light-reflecting film and floor in transparent plexiglass over a board of stainless steel divided in 20 equal rectangles. One of the corners of the arena has a shelter box with black walls and a complex maze inside. Three days prior to the experiment, the mice were placed and kept in this arena, with free access to food and water until the day of the trial. The "no threat" group had its behaviors recorded for five minutes. Animals exposed to the predator (snake) were divided into four groups (n = 12/11 per group) and pre-treated with intraperitoneal injections of CBD (0.3, 3 and 30 mg/kg) or vehicle (control group). The group of animals that were not confronted with the predator presented no defensive behaviors. Animals pre-treated with CBD had significant reductions in explosive flight and defensive immobility, responses related to panic models. Risk assessment and defensive attention were unaltered in animals treated with CBD. These results suggest that CBD can be effective in the control of panic attacks.

Human studies

The first evidence of CBD's anxiolytic effects in humans, documented with assessment scales, was published in 1982 in a study on the interaction between CBD and THC.⁷ The study sample consisted of eight volunteers with a mean age of 27 years, no health problems and who had not used *Cannabis sativa* in the previous 15 days. In a double-blind procedure, the volunteers received CBD, THC, THC + CBD, diazepam, and placebo in different sequences and days. The results showed that the increased anxiety following the administration of THC was significantly attenuated with the simultaneous administration of CBD (THC + CBD).

Based on this preliminary evidence, researchers decided to investigate a possible anxiolytic action of CBD in experimentally induced anxiety in healthy volunteers using the simulated public speaking (SPS) model.³² The procedure consists of asking a subject to speak in front of a video camera for a few minutes, while subjective anxiety is measured with self-rated scales and physiological correlates of anxiety are recorded (heart rate, blood pressure, skin conductance). CBD (300 mg), as well as the anxiolytic drugs diazepam (10 mg) and ipsapirone (5 mg), administered in a double-blind design, significantly attenuated SPS-induced anxiety.

The SPS test may be regarded as a good model of anxiety and has apparent validity for social anxiety disorder (SAD), as the fear of speaking in public is considered a central feature in this condition. Therefore, the anxiolytic effect of CBD in healthy volunteers observed in this test led to the hypothesis that this cannabinoid could be effective to treat SAD. This hypothesis was recently tested in 24 patients with SAD who had their performance in the SPS test compared to that of a group of 12 healthy controls.³³ The patients with SAD were divided into two groups of 12, one of which received CBD 600 mg and the other placebo, in a double-blind procedure. The results showed that the levels of anxiety, somatic symptoms, and negative self-assessment were higher in patients who took placebo than in those of the CBD group who performed similarly to healthy controls in some measures.

In another study that investigated the effects of CBD on regional cerebral blood flow (rCBF) in healthy volunteers using single photon emission computed tomography (SPECT), SPS-induced anxiety was reduced in patients receiving CBD.³⁴ In that study, patients received either CBD (400 mg) or placebo, in a crossed double-blind design, in two experimental sessions with an interval of one week. CBD significantly reduced subjective anxiety as measured by rating scales, while brain activity was increased in the left parahippocampal gyrus and decreased in the left amygdala-hippocampus complex, including the fusiform gyrus. This pattern of SPECT results is compatible with an anxiolytic action.

SPECT was also used later to investigate the neural correlates of CBD's anxiolytic effects in a sample of patients with SAD.¹⁷ A single dose of CBD 400 mg was able to reduce subjective anxiety measures and SPECT showed changes in the same regions previously identified in healthy volunteers.

Functional magnetic resonance imaging (fMRI), which allows the acquisition of larger series of images with better temporal and spatial resolution, was used to investigate the neural correlates of the anxiolytic effects of CBD in 15 healthy volunteers.³⁵ This experiment showed that CBD (600 mg) attenuated fMRI responses during the recognition of fearful facial expressions in the amygdala and the anterior cingulate, and that this attenuation pattern correlated with skin conductance responses to the stimuli. The same group also reported that the anxiolytic action of CBD occurs by altering the subcortical prefrontal connectivity via amygdala and anterior cingulate.¹⁶

Conclusion

Together, the results from laboratory animals, healthy volunteers, and patients with anxiety disorders support the proposition of CBD as a new drug with anxiolytic properties. Because it has no psychoactive effects and does not affect cognition; has an adequate safety profile, good tolerability, positive results in trials with humans, and a broad spectrum of pharmacological actions,³⁶ CBD appears to be the cannabinoid compound that is closer to have its preliminary findings in anxiety translated into clinical practice.³⁷ Future studies should test this possibility in clinical trials involving patients with different anxiety disorders, especially panic disorder, obsessive-compulsive disorder, social anxiety disorder, and post-traumatic stress disorder. In addition, because the actions of CBD are biphasic, the adequate therapeutic window for each anxiety disorder remains to be determined.

Regarding the mechanism underlying the anxiolytic effects of CBD, the most consistent evidence points to the involvement of the serotonergic system, probably through direct action on 5-HT_{1A} receptors, although other systems, as the endocannabinoid system itself, may also be implicated. Further investigation is warranted to clarify these issues, especially if we consider that CBD is a drug with a variety of effects in the nervous system.³⁸⁻⁴⁰

Nabilone for the Treatment of Pain in Fibromyalgia

Ryan Quinlan Skrabek, Lena Galimova, Karen Ethans, and Daryl Perry

Section of Physical Medicine and Rehabilitation, University of Manitoba, Rehabilitation Hospital, Health Sciences Centre, Winnipeg, Manitoba, Canada.

Abstract: A randomized, double-blind, placebo-controlled trial was conducted to determine the benefit of nabilone in pain management and quality of life improvement in 40 patients with fibromyalgia. After a baseline assessment, subjects were titrated up on nabilone, from 0.5 mg PO at bedtime to 1 mg BID over 4 weeks or received a corresponding placebo. At the 2- and 4-week visits, the primary outcome measure, visual analog scale (VAS) for pain, and the secondary outcome measures, number of tender points, the average tender point pain threshold, and the Fibromyalgia Impact Questionnaire (FIQ), were evaluated. After a 4-week washout period, subjects returned for reassessment of the outcome measures. There were no significant differences in population demographics between groups at baseline. There were significant decreases in the VAS (-2.04 , $P < .02$), FIQ (-12.07 , $P < .02$), and anxiety (-1.67 , $P < .02$) in the nabilone treated group at 4 weeks. There were no significant improvements in the placebo group. The treatment group experienced more side effects per person at 2 and 4 weeks (1.58 , $P < .02$ and 1.54 , $P < .05$), respectively. Nabilone appears to be a beneficial, well-tolerated treatment option for fibromyalgia patients, with significant benefits in pain relief and functional improvement.

Perspective: To our knowledge, this is the first randomized, controlled trial to assess the benefit of nabilone, a synthetic cannabinoid, on pain reduction and quality of life improvement in patients with fibromyalgia. As nabilone improved symptoms and was well-tolerated, it may be a useful adjunct for pain management in fibromyalgia.

Key words: Nabilone, cannabinoid, fibromyalgia, pain.

Fibromyalgia is a syndrome of unknown etiology, characterized by diffuse musculoskeletal pain, fatigue, and sleep disturbance.³⁸ It affects 2% to 4% of the general population^{35,36,37} and is 4 to 7 times more common in women, with symptoms usually arising between 20 and 55 years of age.¹⁵

The diagnostic criteria for fibromyalgia, established in 1990 by the American College of Rheumatology, includes widespread pain for at least 3 months and point tenderness with 4 kg of pressure at 11 or more of 18 characteristic tender points.³⁸ These criteria allow for the

differentiation of fibromyalgia from other chronic musculoskeletal pain with a sensitivity and specificity of almost 85%.¹⁶

Patients with fibromyalgia have lower pain thresholds to both mechanical and thermal insults, give higher pain ratings, and experience an altered temporal summation to painful stimuli.¹⁶ The sensitization of pain perception that is present in these patients can occur both peripherally and centrally after tissue damage but may also be present in patients with no obvious tissue damage.²⁰ Sensitization occurs in the dorsal horn of patients with fibromyalgia, as activity of both unmyelinated C fibers and A- δ fibers is increased^{14,21}; however, it is unknown whether sensitization is due to increased pain fiber facilitation, or decreased inhibition.²⁰

Given the lack of understanding in the pathophysiology of fibromyalgia, it is not surprising that until recently, with the approval of pregabalin, no medical treatment had been specifically approved by the United States Food and Drug Administration for its management.¹³ There is also evidence that tricyclic antidepressants, cardiovascular exercise, cognitive behavioral therapy and patient

doi:10.1016/j.jpain.2007.09.002

education are effective in reducing the pain experienced by fibromyalgia patients.¹⁶ A recent case series of 4 patients has suggested the possible benefit of nabilone, a synthetic cannabinoid, in the treatment of fibromyalgia, however more studies are required.¹⁸

Two types of cannabinoid receptors have been isolated: CB1 and CB2. The CB1 receptor is found predominantly in the central and peripheral nervous system,²⁵ whereas CB2 receptors are found principally in the immune system.²⁷ Endogenous cannabinoids have been isolated that interact with these receptors.¹⁰ CB1 agonists have been shown to have an analgesic effect in acute and chronic pain models.¹⁰ The CB1 agonists act at many sites along pain transmission pathways including activation of peripheral, spinal, and supraspinal CB1 receptors, each independently decreasing nociception.¹⁰

The endocannabinoid system shares several similarities with the opioid system.⁹ CB1 and opioid receptors are both found in similar areas of the nervous system involved in pain control, including the periaqueductal gray matter, rostral ventromedial medulla, and the spinal cord.²⁹ Besides the similarities with the opioid system, cannabinoids have also been shown to inhibit prostaglandin E-2 synthesis,⁸ reduce platelet aggregation,³¹ and have an anti-inflammatory effect twice as great as hydrocortisone and 20 times that of aspirin.¹²

Nabilone is 1 of 2 orally administered cannabinoids available in Canada and is currently approved for the management of nausea and vomiting during chemotherapy. Research into oral cannabinoid use in the management of chronic and neuropathic pain has been encouraging.^{18,32} As no treatment has been specifically approved for management of fibromyalgia, further research into treatment strategies is important. To date, no randomized, controlled trials have been conducted to assess the efficacy of a synthetic cannabinoid on pain and quality of life in patients with fibromyalgia.

Our hypothesis was that nabilone will significantly reduce the pain and improve quality of life in fibromyalgia patients compared with placebo, as evidenced by significant improvements in visual analog scale pain scores (VAS), number of tender points, average tender point pain threshold, and scores on the Fibromyalgia Impact Questionnaire (FIQ).

Materials and Methods

Setting

The study was conducted in the Outpatient Musculoskeletal Clinic at the Rehabilitation Hospital, Health Sciences Centre (HSC), Department of Physical Medicine and Rehabilitation, in Winnipeg, Manitoba, Canada, from April 2006 to November 2006. Patients were recruited from the musculoskeletal practices of attending Physiatrists and Rheumatologists at the Rehabilitation Hospital.

Inclusion Criteria

Inclusion criteria for the study included the subject meeting The American College of Rheumatology (1990)

criteria for the classification of fibromyalgia³⁸; patients between 18 and 70 years of age; having continued pain despite the use of other oral medications; and no previous use of oral cannabinoids for pain management.

Exclusion Criteria

Subjects were excluded from participating in the study if their pain was better explained by a diagnosis other than fibromyalgia; for abnormalities on routine baseline blood work including electrolytes, urea and creatinine, a complete blood count, and liver function tests; heart disease; schizophrenia or other psychotic disorder; severe liver dysfunction; history of untreated nonpsychotic emotional disorders; cognitive impairment; major illness in another organ system; pregnancy; nursing mothers; a history of drug dependency; or a known sensitivity to marijuana or other cannabinoid agents.

Protocol

Subjects met the eligibility criteria through a structured interview process, and participants provided informed consent. HSC Research ethics board, HSC Impact Committee and Health Canada approval was obtained prior to proceeding with the study.

Subjects were randomly assigned by the HSC pharmacy into treatment and control groups, each consisting of 20 participants (Fig 1). The examining physicians and the subjects were blinded to the randomization process. All of the study medication was provided by Valeant Canada Limited (Montreal, Quebec, Canada) and was identical to placebo. Subjects in both groups were seen at baseline, after 2 weeks and 4 weeks of treatment and after a 4-week washout period. Subjects in the treatment group received 0.5 mg nabilone PO at bedtime for a 1-week period, with instructions to increase to 0.5 mg BID after 7 days. At the 2-week visit, subjects were evaluated for the presence of side effects and drug tolerance, and if they consented to continue, had the prescription increased to nabilone 0.5 mg PO in the morning and 1 mg PO at bedtime, with instructions to increase to 1 mg BID after 7 days. Subjects in the control group received a corresponding placebo. Subjects were assessed for the safety and efficacy of their prescription based on the outcome measures at the 2-, 4-, and 8-week follow-up visits. Subjects were asked to continue any current treatment for fibromyalgia, including breakthrough pain medications, but not to begin any new therapies.

Outcome Measures

The primary outcome measure was a 10 cm VAS for pain. The secondary outcome measures included the number of positive tender points; the average tender point pain threshold; and the subject's score on the FIQ.

At each visit, subjects were asked to rate their current level of pain on the 10 cm VAS, (0 = no pain; 10 = worst pain imaginable), a valid and reliable scale for rating pain intensity.²⁶ Subjects then filled out the FIQ, which is a validated, self-administered test, scored out of 100, that evaluates physical function, work status, depression,

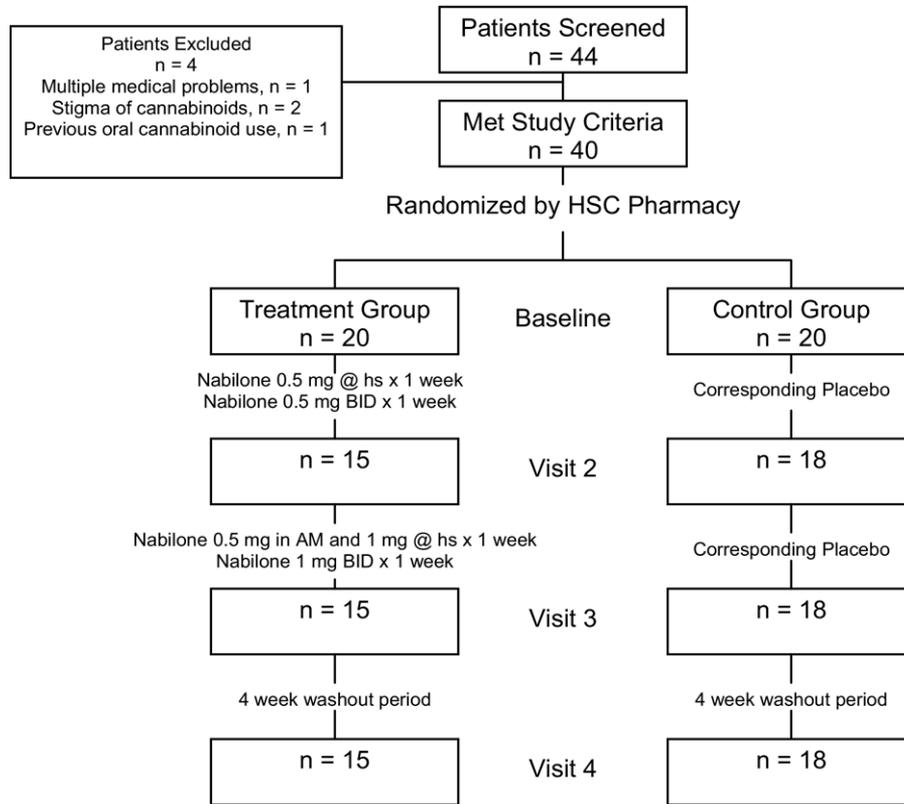

Figure 1. Study design. A randomized, double-blind, placebo-controlled trial.

anxiety, sleep, pain, stiffness, fatigue, and well-being in patients with fibromyalgia.^{7,23} The higher the score on the FIQ, the greater the impact of fibromyalgia on the subject's quality of life.⁷ Subjects were then assessed for the number of positive tender points by digital palpation over the 18 characteristic tender point sites in the ACR criteria for the diagnosis of fibromyalgia,³⁸ which has been previously shown to have both good intrarater and interrater reliability.³³ The subjects were asked to identify if a given point was painful as slow steady digital pressure was applied. The same evaluation of the tender points was then repeated with a hand-held Fischer algometer. This test has also demonstrated good interrater and test-retest reliability.³³ Pressure was applied over each tender point at a rate of 1 kilogram per square centimeter per second, and subjects were asked to identify the moment the pressure became painful. The pain threshold at each of the 18 tender points was recorded and an average tender point pain threshold for each visit was calculated. During each visit, any reported side effects as well as weight, blood pressure, and heart rate were recorded.

Statistical Analysis

Based on the previous case series investigating nabilone use in fibromyalgia,¹⁸ we calculated that 16 patients would be necessary in each group to detect a change of 2 cm on the 10 cm VAS, using an α of <0.05 and a power of 80%. Allowing for dropouts, our aim was

to have 20 subjects in each group start the study. Statistical analysis was conducted, and we considered $P < .05$ to be statistically significant for all of our outcome measures. The mean and standard deviation was calculated for each outcome measure at each visit and a Student's *t* test was performed to compare the change in the mean from baseline within and between groups.

Results

Forty-four subjects were screened to participate in the study between April and November of 2006. Four subjects did not meet the entrance requirements for the study. Reasons for their exclusion included a history of multiple medical problems ($n = 1$); subjects did not like the stigma associated with the use of cannabinoids ($n = 2$); and previous oral cannabinoid use ($n = 1$).

The remaining 40 subjects were randomly assigned by the HSC pharmacy into either the nabilone or placebo group (Fig 1). The examining physicians and patients were blinded to the randomization process. The baseline demographic data and baseline outcome measures are presented for both groups (Table 1). No significant differences in baseline demographic data or primary and secondary outcome measures were present. The percentage of subjects employed and the use of opioid medications for pain were not significantly different between the 2 groups.

A total of 5 subjects from the treatment group and 2

Abbreviations: FIQ, Fibromyalgia Impact Questionnaire; VAS, visual analog score.

from the placebo group dropped out of the study before its completion. All of the subjects who withdrew from the study did so at or before the first follow-up visit. In the control group, one subject discontinued the medication after 4 days because of headaches; the other withdrew at the first follow-up visit, after 2 weeks, although no side effects or reason for dropping out was stated. Of the subjects in the treatment group, 3 withdrew before the first follow-up visit. Two of these subjects did not state a reason for withdrawal and listed no side effects, whereas the other subject experienced dizziness, disorientation, and nausea. The remaining 2 subjects in the treatment group to withdraw did so at the first follow-up visit, after 2 weeks. One subject stated poor coordination, dizziness, headache, and nausea as the reasons for withdrawing from the study, whereas the other experienced drowsiness and fatigue. All patients in the treatment group that continued with the study achieved a nabilone dose of 1 mg BID.

There was a significant increase in the weight of subjects treated with nabilone for 2 weeks, (1.13 kg, $P < .01$).

This effect, however, was transient, as there was no significant difference in weight change observed between the 2 groups during the 4-week and 8-week visits.

When compared with baseline, at the 2-, 4-, and 8-week visits, no statistically significant differences were observed in any of the outcome measures in the placebo group.

There were no statistically significant differences from baseline in the outcome measures in the nabilone treated subjects, at a dose of 0.5 mg BID, after 2 weeks of treatment. However, at the 4-week follow-up visit, at a nabilone dose of 1 mg BID, statistically significant improvements were seen in the VAS, FIQ, and FIQ anxiety scale. The VAS scores for pain decreased from baseline at 4 weeks (-2.04 , $P < .02$) (Fig 2). Fibromyalgia Impact Questionnaire scores also significantly decreased (-12.07 , $P < .02$) (Fig 3). The 10-point anxiety scale within the FIQ was the final outcome to be statistically improved from baseline after 4 weeks of treatment (-1.67 , $P < .02$) (Fig 4). The remaining outcomes we assessed including number of tender points, tender point pain threshold, and

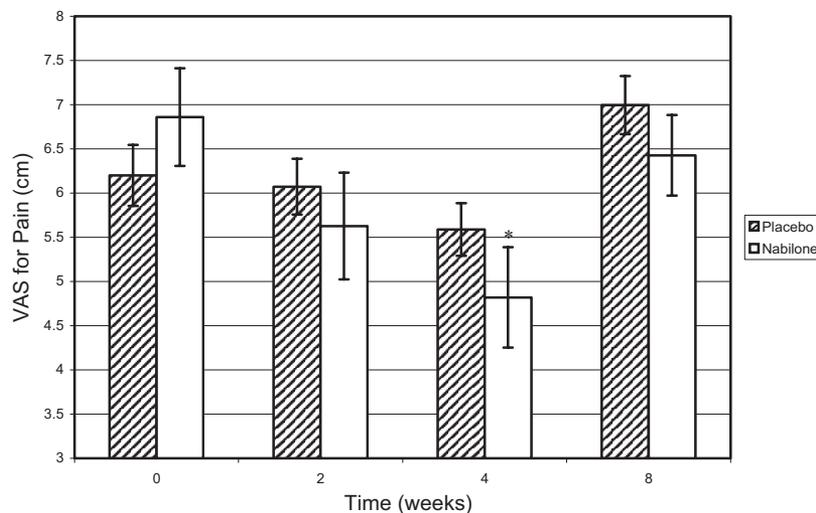

Figure 2. VAS scores, nabilone vs placebo, mean \pm SE. When compared with baseline, nabilone-treated patients had significantly improved VAS scores at 4 weeks (-2.04 , $P < .02^*$).

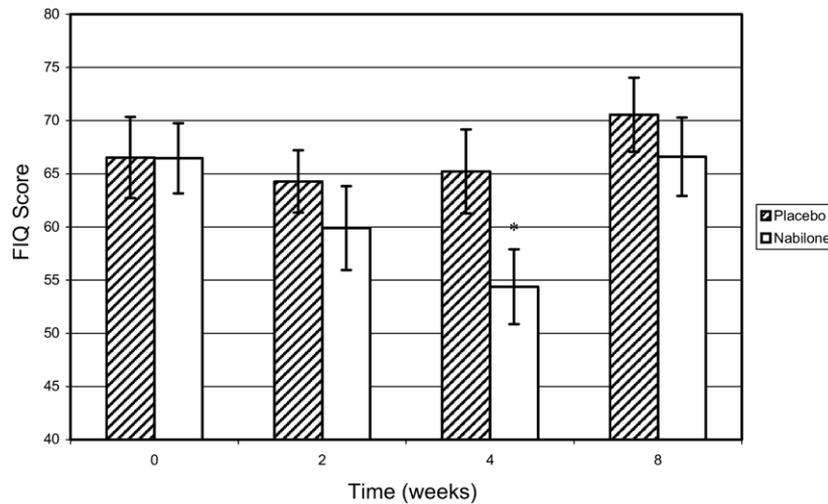

Figure 3. FIQ scores, nabilone vs placebo, mean \pm SE. When compared with baseline, nabilone-treated patients had significantly improved FIQ scores at 4 weeks (-12.07 , $P < .02^*$).

the depression and fatigue scales on the FIQ were not significantly different from baseline values.

Comparing the treatment and placebo groups at 2 weeks of treatment, no significant differences were seen in VAS, number of tender points, tender point pain threshold, or FIQ. Of the 3 separately analyzed questions in the FIQ concerning anxiety, depression, and fatigue, only anxiety was significantly less at the 2-week visit in the nabilone group. The score on the 10-point scale for anxiety decreased in the treatment group at a nabilone dose of 0.5 mg BID (-1.92 , $P < .025$).

At the 4-week visit, statistically significant differences between the treatment and placebo groups were also present. The change from baseline in visual analogue scale pain scores (-1.43 , $P < .05$) (Fig 5), FIQ scores (-10.76 , $P < .01$) (Fig 6), and the FIQ anxiety scale (-2.20 , $P < .01$) (Fig 7) all showed significant improvement when compared with the placebo group.

No significant differences were seen between the treatment and placebo groups after the 4-week washout period at the 8-week visit.

Side effects were more common in the nabilone-treated subjects compared with placebo controls at both 2 and 4 weeks of treatment, (1.58, $P < .02$ and 1.54, $P < .05$), respectively. The frequency of the most common side effects for both groups is listed in Table 2. The most common side effects reported by subjects in the nabilone group include drowsiness (7/15), dry mouth (5/15), vertigo (4/15), and ataxia (3/15). No serious adverse events occurred during the study.

Discussion

Our study was conducted to investigate the possible benefits of the synthetic cannabinoid nabilone on pain reduction and quality of life improvement in patients

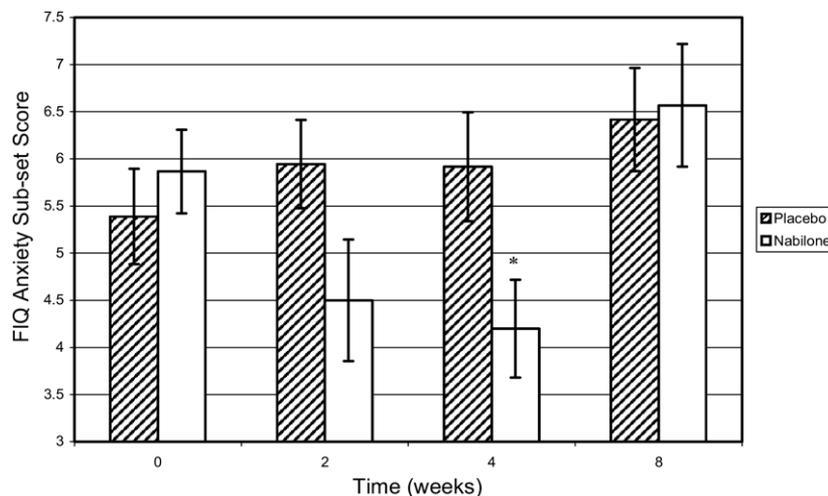

Figure 4. FIQ anxiety subset scores, nabilone vs placebo, mean \pm SE. When compared with baseline, nabilone-treated patients had significantly improved FIQ scores at 4 weeks (-1.67 , $P < .02^*$).

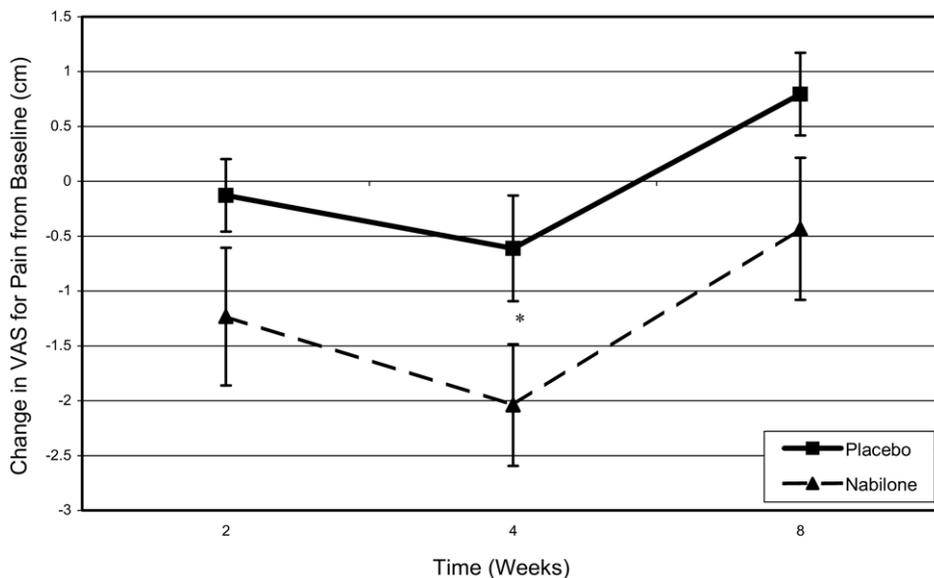

Figure 5. Change in VAS score, nabilone vs placebo, mean ± SE. There was a significant improvement in the change in VAS score in the nabilone group compared with placebo at 4 weeks ($-1.43, P < .05^*$).

with fibromyalgia. Significant reductions in VAS score for pain, FIQ score, and FIQ anxiety score were seen in the treatment group at the 4-week visit. These significant reductions are found both when comparing the treatment group with their baseline values and when comparing the change from baseline to the placebo group at 4 weeks. None of the study participants achieved a total remission of their fibromyalgia symptoms.

Although improvements in VAS and FIQ scores were present after 4 weeks of treatment, there was no significant change in the number of tender points or tender point pain threshold, which is supported by other studies.^{2,23}

Subjects in the placebo group did not obtain any significant benefit in the outcome measures at any time during the study. After a 4-week washout period, out-

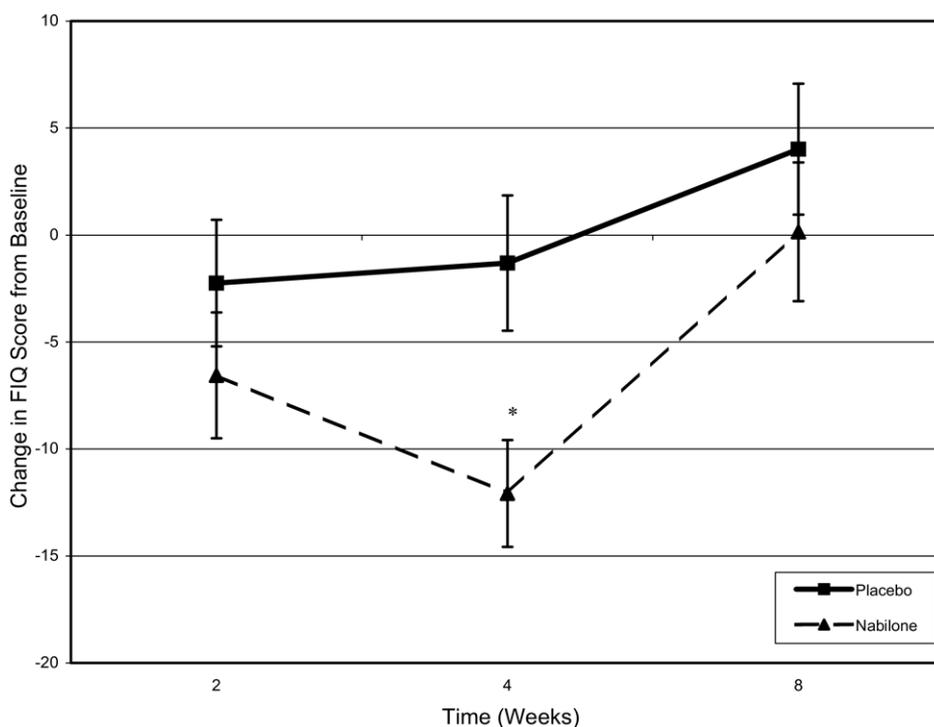

Figure 6. Change in FIQ score, nabilone vs placebo, mean ± SE. There was a significant improvement in the change in FIQ score in the nabilone group compared with placebo at 4 weeks ($-10.76, P < .01^*$).

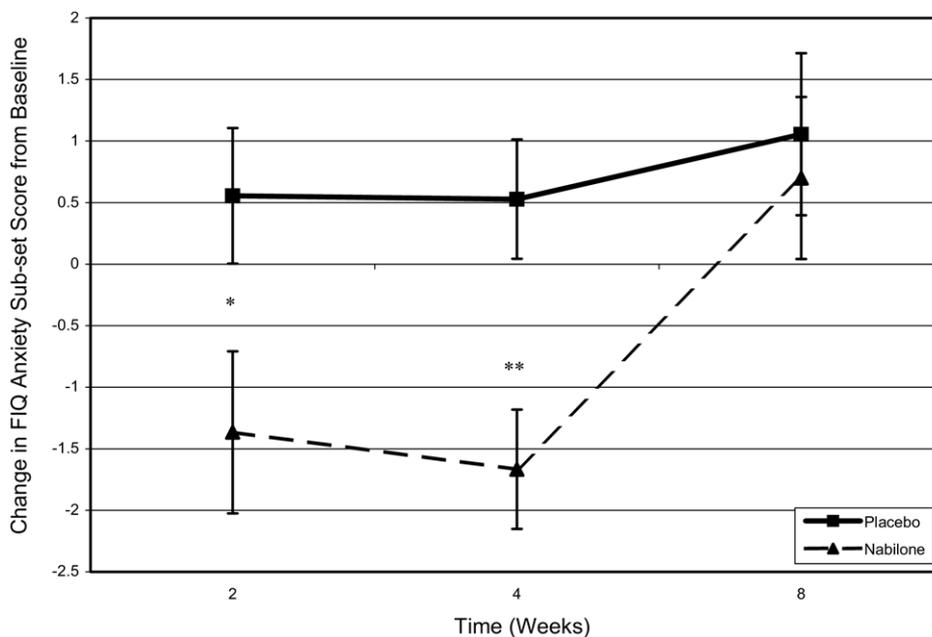

Figure 7. Change in FIQ anxiety subset scores, nabilone vs placebo, mean ± SE. There was a significant improvement in the change in anxiety score in the nabilone group when compared with placebo at 2 and 4 weeks of treatment, with differences of (−1.92, $P < .025^*$) and (−2.20, $P < .01^{**}$), respectively.

come measures were not significantly different from baseline in both groups. Nabilone does not appear to have any lasting benefit in subjects when treatment is discontinued.

Comparing the baseline FIQ scores in our study to some recent studies that used the FIQ, our subjects scored on average 12 to 22 points higher,^{2,5,30} indicating their quality of life was more severely affected by fibromyalgia.²³ As our recruitment practices were similar, the reason for the disparity in the baseline FIQ scores and its effect on our results is unclear.

The significant drop in the VAS (−2.04, $P < .02$) in our treatment group was similar to those of other drug trials, which ranged from 1.2 to 2.2.^{2,5,17} Our finding of a significant drop in the FIQ score (−12.07, $P < .02$) was also similar to other drug trials whose drop in FIQ score ranged from 5.53 to 15.8.^{2,3,5,17,30} Despite the poorer

baseline quality of life of our subjects, they still managed a significant improvement in FIQ scores on par with other studies. This suggests that nabilone is an effective treatment even for those with severe cases of fibromyalgia with marked functional impairment.

Although statistically significant reductions in VAS score for pain, FIQ score, and FIQ anxiety score were observed in this study, the question remains whether these findings are clinically significant? With the current lack of understanding of the pathophysiology of fibromyalgia, and options in its medical management,¹³ the statistically significant benefits obtained in this study are promising and require consideration as an adjunct to the current medical management of fibromyalgia.

The analgesic benefits of cannabinoids in the treatment of acute and chronic pain have already been estab-

Table 2. Side Effects Reported in the Treatment and Placebo Groups at 2 and 4 Weeks

SIDE EFFECT	PLACEBO		NABILONE		SIDE EFFECT	PLACEBO		NABILONE

Anorexia	0/20	1/18	1/18	2/15	Tachycardia	0/20	1/18	0/18	0/15
Headache	2/20	3/18	3/18	1/15	Hallucination	0/20	0/18	0/18	0/15

lished,¹⁰ so their benefit in fibromyalgia patients is not surprising. Whether this benefit is secondary to a clinical endocannabinoid deficiency in fibromyalgia patients as has been suggested²⁸ or the synergistic relationship with endogenous opioids,²⁷ it is clear from previous studies that cannabinoids act at many sites along pain transmission pathways.

Other known actions of cannabinoids including inhibition of prostaglandin E-2 synthesis,⁸ its anti-inflammatory effect,¹² experimental increases in β -endorphins,³⁴ and the regulation of substance P and enkephalin mRNA levels in the basal ganglia²² could all contribute to less pain experienced in the nabilone-treated patients.

Anxiety on the FIQ was also decreased in the treatment group at the 4-week visit, which is not exclusive to our study. A trial assessing the effects of tramadol and acetaminophen on patients with fibromyalgia found similar improvements in VAS, FIQ, and anxiety, without significant improvements in depression or fatigue.⁵ Although part of the benefit obtained in pain reduction and quality-of-life improvement in these patients may be secondary to reduced anxiety, other studies have not shown a change in anxiety despite significant functional improvements.³⁰ Further studies with validated scales for anxiety need to be conducted to explore this issue.

Nabilone was generally well tolerated by participants throughout the study. This is reassuring, as it is well known that patients with fibromyalgia are sensitive to most medications and have difficulty tolerating medication side effects.¹⁵ Although there were significantly more side effects per person in the treatment group at 2 and 4 weeks (1.58, $P < .02$ and 1.54, $P < .05$), respectively, no serious adverse effects were seen in the nabilone-treated subjects during the study. Three-quarters of the subjects in the treatment group tolerated the medication well and completed the study. Those who withdrew from the study did so at or before the first follow-up visit at 2 weeks. The reported side effects of nabilone were generally mild, and nabilone did not appear to have adverse interactions with any of the concomitant medications patients were taking, including antidepressants, muscle relaxants, nonsteroidal anti-inflammatories, and opioids. This supports the findings from the previously conducted case series with nabilone and fibromyalgia patients.¹⁸ Slowing the titration of the medication in longer studies may further reduce treatment side effects.

When prescribing nabilone, cost must be taken into consideration. Participants using nabilone at the dose we found to be effective in the study should expect to pay over four thousand dollars for a year's supply of the medication in Canada. Patients must weigh these costs against the potential benefits of pain reduction and improved quality of life. As the medication's cost may be prohibitive to some patients, nabilone probably would not be the first line therapy prescribed to patients with fibromyalgia but should be considered if other treatments have been ineffective.

The current study is not without its limitations. Participants in both groups were allowed to continue any treatments for pain, with the use of nabilone as an adjunctive therapy. Despite the benefit in pain and anxiety reduction and quality of life improvement in the treatment group, it cannot be definitively concluded that the benefit was not a result of the combination of therapies. We thought that allowing both groups to continue their ongoing pain therapies controlled for this variable, and as fibromyalgia patients using complementary therapies ranges in studies from 60 to 90 percent,⁴ the use of nabilone as an adjunct is clinically relevant. Future studies could be done using nabilone as a single agent to determine its effect on pain and quality of life alone.

Given the fluctuating nature of fibromyalgia symptoms,¹⁵ our study was limited by its short duration and limited number of visits. To control for the fluctuating nature of fibromyalgia symptoms a pain journal could be given to subjects; however, this requires more effort on their behalf and may lead to decreased adherence to the protocol.

Subjects were only trialed on nabilone for a total of 4 weeks, of which only the last week of treatment was at 1 mg BID. The long-term effect of nabilone in alleviating pain and improving quality of life in patients with fibromyalgia cannot be determined based on the short duration of the study. As this study was the first randomized, controlled trial to assess the benefits of nabilone in subjects with fibromyalgia, it was reasonable to conduct this study for a shorter duration. Now that our study has shown significant improvements for fibromyalgia patients, future studies should involve a longer duration of the treatment, at a stable dose.

Although anxiety, depression, and fatigue were assessed in this study with single questions on the FIQ, these single questions are not validated scales for the respective symptoms. As the outcome measures in our study focused on pain and quality of life, the VAS for pain and FIQ were the scales used to assess them. Reports exist for^{19,24} and against¹ the incidence of depression and anxiety being higher in the fibromyalgia population, and this area is still up for debate. Chronic fatigue syndrome is associated with fibromyalgia,⁶ and it has been reported that patients with fibromyalgia have less restorative sleep.¹¹ Future studies to evaluate the effect of nabilone on anxiety, depression, and fatigue in patients with fibromyalgia should use validated scales for each.

To our knowledge, this is the first randomized, controlled trial to demonstrate the benefit of nabilone on pain and quality of life in subjects with fibromyalgia. The significant reductions in VAS, FIQ, and anxiety seen in the treatment group, coupled with minimal side effects, suggest that nabilone may be a beneficial, well-tolerated, treatment option in patients with fibromyalgia. Future studies are still necessary to assess the long-term benefit of nabilone on pain and quality of life, and secondary outcome measures such as anxiety, depression, and

fatigue should be further explored with validated assessment tools.

Acknowledgments

The authors would like to thank the RR1 Musculoskeletal Clinic staff at the Rehabilitation Hospital, Nella Chlopecki, the study's nurse coordinator, the Health

Sciences Centre Pharmacy, and the referring physicians for their support in completing this study. The authors would also like to thank Sue Skrabek, B(Ed), BMR (OT), for her editorial assistance and the HSC Medical Staff Council Fellowship Fund for their financial support. A thank you is also extended to the study participants.

Abstract

Background: The New South Wales State Government recently proposed a trial of the medical use of cannabis. Australians who currently use cannabis medicinally do so illegally and without assurances of quality control. Given the dearth of local information on this issue, this study explored the experiences of medical cannabis users.

Methods: Australian adults who had used cannabis for medical purposes were recruited using media stories. A total of 147 respondents were screened by phone and anonymous questionnaires were mailed, to be returned by postage paid envelope.

Results: Data were available for 128 participants. Long term and regular medical cannabis use was frequently reported for multiple medical conditions including chronic pain (57%), depression (56%), arthritis (35%), persistent nausea (27%) and weight loss (26%). Cannabis was perceived to provide "great relief" overall (86%), and substantial relief of specific symptoms such as pain, nausea and insomnia. It was also typically perceived as superior to other medications in terms of undesirable effects, and the extent of relief provided. However, nearly one half (41%) experienced conditions or symptoms that were not helped by its use. The most prevalent concerns related to its illegality. Participants reported strong support for their use from clinicians and family. There was almost universal interest (89%) in participating in a clinical trial of medical cannabis, and strong support (79%) for investigating alternative delivery methods.

Conclusion: Australian medical cannabis users are risking legal ramifications, but consistent with users elsewhere, claim moderate to substantial benefits from its use in the management of their medical condition. In addition to strong public support, medical cannabis users show strong interest in clinical cannabis research, including the investigation of alternative delivery methods.

Background

While cannabis has long been part of folk pharmacopeia, there is a burgeoning body of research on its therapeutic potential. This has largely drawn on scientific advances in our understanding of the pharmacology of cannabis, and its complex interactions with the central nervous system, particularly endogenous brain reward pathways [1]. In addition to basic experimental research, case reports, sur-

veys of people using cannabis for medical conditions and prospective clinical trials of cannabis-based medicines are consolidating the evidence that cannabis may play a role in the management of some medical conditions. Authoritative reviews of this evidence indicate that cannabis has therapeutic potential for conditions such as HIV- and cancer-related wasting, nausea and vomiting resulting from

chemotherapy, neurological disorders such as multiple sclerosis and chronic pain [1-4].

While current research reveals exciting therapeutic opportunities, there is an ongoing debate about the virtues of obtaining such benefits from the complex chemical cocktail contained in the whole plant or from one or more components isolated and developed into a synthetic pharmaceutical product. This debate cross-cuts important issues such as the difficulties of reliable dosing when using the natural product, whether the potential harms of smoking cannabis due to its ease of titration overshadow its therapeutic benefits, and whether different medical conditions will respond more favourably to the whole plant or to different constituents in isolation or combination. However, underlying these issues is the reality that most people who use cannabis medicinally do so by using black market supplies of an illicit drug.

As with the opiates, evaluations of the therapeutic potential of cannabis occur in the context of a vigorous political debate on the use of an illicit drug with dependence potential for medicinal purposes. This situation is clearly evident in the United States, where there is an ongoing legal challenge by the Federal Government over the States' rights to allow cannabis to be used by registered medical users. Despite Canada's recent decision to provide a controlled supply of natural cannabis to registered users, and approvals for the marketing of Sativex, a pharmaceutical cannabis extract, in some countries, currently most users would rely on home-grown cannabis, or supplies obtained from friends, families, dealers and medical compassion clubs.

To date, there has been little interest in Australia in formally investigating the therapeutic potential of cannabis or investigating the practices of current medical users. In 1999 the NSW State Government commissioned a Working Party to investigate the issue and recommend research and legislative options. Among their recommendations were: controlled clinical trials of cannabis, investigations into delivery methods other than smoking, surveys of current medical cannabis users and legislative amendments to allow compassionate use [4]. Subsequently, in 2003 the NSW Government announced it would conduct clinical trials, but despite generating significant publicity, there has been no further commitment by the NSW Government on this issue. The 2004 National Drug Strategy Household Survey found widespread public support for medical cannabis use, with 68% supporting a change in legislation to permit use for medical purposes and 74% supporting a clinical trial of medicinal cannabis use [5]. It is not known how many people use cannabis for medicinal purposes in Australia. Those who do use it engage in an illegal behaviour and risk arrest. Those that rely on

black market supplies use a product of unknown source and quality.

Several surveys in the US, UK, Germany and Canada [6-12] have reported perceived improvements in a variety of medical conditions following cannabis use. However, we know very little about the experiences of Australian users, and how they compare to findings in other studies. These authors are aware of only two unpublished Australian studies conducted in northern NSW; in 1998 a survey of 202 users recruited at the Nimbin HEMP Embassy [13], and in 2003 a survey of 48 members of a medical cannabis information service [14].

This paper presents the results of a study of 128 users, which aimed to learn more about their patterns of use, experiences and concerns, and interest in participating in a medical cannabis trial.

Methods

Sample

The sample comprised 128 people who used cannabis for medical purposes. To be eligible for the study, participants had to be living in Australia and to be currently using/have previously used cannabis for medical purposes. While the study targeted residents of Australia's most populous state, NSW (pop: approximately 6.7 million), we did not exclude participants from other parts of Australia (total pop: approximately 20 million).

As it is not known how many Australians use cannabis for medical purposes it was not possible to obtain a representative sample of such users. As this was an exploratory study to see who responded to a general call for participation in the survey, we did not target groups representing people with specific medical conditions (e.g., HIV/AIDS, multiple sclerosis) or hospital departments known to treat patients who may benefit (e.g., oncology, chronic pain clinics). Participants were primarily recruited from opportunistic media stories between November 2003 and August 2004, in newspapers, on radio and television. In addition, the Medical Cannabis Information Service (MCIS) in Nimbin, NSW, offered to tell its members about the survey and the International Association for Cannabis as Medicine (IACM), in Germany, placed the questionnaire on its website.

A total of 147 enquiries were received between December 2003 and August 2004 by telephone and email and approximately 170 questionnaires distributed (some people requested multiple copies to distribute). For example, the media stories generated enquiries from several GPs who said they would inform certain patients of the study. Of the 131 questionnaires returned, 128 were used for analysis (75% of questionnaires sent out). Of the three

Table 1: Conditions/symptoms experienced, duration, and conditions/symptoms requiring cannabis relief (n = 128).

Condition	(%) with condition	Median duration (yrs)	% used cannabis for relief of..*
Depression	60	10	56
Chronic pain	53	10	57
Arthritis	38	9	35
Migraine	22	18	17
Weight loss	21	4	26
Persistent nausea	20	6	27
Spinal cord injury	14	11	13
Spasms (spasticity)	13	8	16
Fibromyalgia	13	13	13
Wasting	13	5	11
ME (chronic fatigue)	13	16	13
Neuralgia/neuropathy	12	8	12
HIV/AIDS	9	15	8
Multiple sclerosis	7	9	7
Cancer	6	10	4
Other neurological disorder	6	5	6
PTSD	5	13	1 person
Irritable bowel syndrome	4	10	1 person
Glaucoma	3	29	2

*These figures do not necessarily equate with the % reporting a particular condition because some people reported using cannabis to relieve the particular symptoms (e.g., chronic pain, nausea) associated with a condition, rather than citing they used cannabis to relieve the condition itself (e.g., arthritis, cancer).

discarded questionnaires, one respondent was a recreational cannabis user and two had never used cannabis.

Questionnaire

The survey comprised an anonymous mail-out questionnaire, adapted from one developed by the MCIS in a recent study of its members [14]. Several issues were covered, including medical conditions/symptoms experienced, patterns of medical cannabis use, symptom relief and effects of use, comparison of cannabis to other medications, source and legal concerns (e.g., arrest), other concerns over use, opinion of family, friends and medical personnel, and interest in participating in a cannabis trial. The final version incorporated comments from researchers and clinicians interested in this issue.

Procedure

The study received ethics approval from the University of New South Wales Social/Health Human Research Ethics Advisory (HREA) Panel. Interested persons were screened for eligibility over the phone and informed of the purpose of the survey; assurances of anonymity and confidentiality were provided. Questionnaires were mailed to participants, completed anonymously and returned in a stamped, self-addressed envelope. Addresses were destroyed when the questionnaire was posted.

Analyses

Data were entered into SPSS (Version 12.0.1). As this was an exploratory study with a small sample size, this paper reports descriptive statistics only. Percentages are presented for categorical data; means (for normally distributed) and medians (for skewed data) are presented for continuous data. While data are usually presented on the overall sample, gender and age differences are presented for some variables, where they are of interest.

Results

Demographics

The sample was 63% male. Participants had a median age of 45 yrs (range 24–88), with almost one third (31%) aged 50 years or over, and one in ten (9%) aged 60 years plus. While the study targeted NSW residents (who represented 58% of participants), responses came from across Australia, especially Queensland (15%) and Victoria (12%). Residents of other States and Territories each comprised less than 3% of participants.

Participants reported a wide range of medical conditions and symptoms associated in the literature with the use of medicinal cannabis (Table 1), most commonly chronic pain (53%) and arthritis (38%). Approximately one in five reported migraine (22%), weight loss (21%) and persistent nausea (20%). However, depression was the most commonly reported condition/symptom (60%). Up to 35 other conditions/symptoms were listed, most commonly

post traumatic stress disorder (PTSD) (5%) and irritable bowel syndrome (4%). It is important to note that we did not ask participants to distinguish between primary symptoms/conditions for which they sought treatment (e.g., cancer) and conditions which may have been secondary to this (e.g., depression) or consequent to treatment (e.g., chronic nausea). Multiple conditions (mean = 3.7, SD = 2.1, range = 1–10), of lengthy duration, were the norm, with three quarters (84%) reporting more than one condition and two thirds (67%) at least three conditions. Congruent with this picture, cannabis was used to relieve multiple symptoms (median = 3, range = 1–12), especially chronic pain (57%), depression (56%), arthritis (35%), persistent nausea (27%) and weight loss (26%).

Patterns of medical cannabis use

Participants had first tried cannabis for medical purposes at a median age of 31 years (range = 14–77). More than one quarter (29%) had discovered its therapeutic benefits as a spin-off from recreational use; others had tried it following concerns about the side-effects of their medications (14%), or a belief their medications or treatment were ineffective (13%), or had acted on the recommendation of a medical practitioner (10%) or friend (10%).

Table 2 presents data on patterns of medical use. Most (85%) were currently using cannabis therapeutically, even if sporadically. For those who had stopped, the main reasons were: their inability to obtain a regular supply (9/19 people), its illegality (7/19), cost (7/19) and disliking the side effects or route of use (each 3/19). Of those using intermittently, many reported their use would be more regular if it were more readily availability and cheaper.

Medical use was typically long-term and regular. Use of less than one year was uncommon (12%), with more than half (61%) having used it for at least six years; one in five reported very long-term use (more than 20 years). Most used at least weekly (75%), and more than half (59%) used almost daily or daily. Approximately one in five (22%) specified they used it "as required" for their condition (e.g., when pain was severe). Women tended to report shorter term use than men (52% vs. 31% citing use of 5 years or less).

It was most common for participants' medical use to be stable (22%) or largely unchanged since they started (17%), although it was most common for the amount used to vary according to their condition (35%). About one in ten indicated some increase in dose had been required (12%), while few reported a decrease (5%). Women tended to report more variable (44% vs. 29% of men) or short term use (15% vs. 6% of men); men tended to report an increase in the amount needed (17% vs. 4% of women).

In addition to medical use, three quarters (80%) of participants had used cannabis recreationally. Recreational use was less common among older participants (75% and 97% of recreational users were aged less than 50 years and 65 years, respectively). For almost half (46%), use in the past year had been solely medicinal, but the remainder reported recent recreational use – 29% in the past week, 19% in the past month and a further 6% in the past year.

Route of use

While most people had tried multiple routes for relief, overall smoking was the route most commonly reported (91%). Approximately half the sample (49%) also

smoked tobacco, and two thirds (64.1%) mixed their cannabis with tobacco.

Eating cannabis in cooked recipes was also very prevalent (49%). While vaporisers are not readily available in Australia, 8% had used them. In addition, four people had used tinctures and one used it topically in the bath or as a cream for a skin condition. Overall, smoking was also considered to be the most *helpful* route of use for symptom relief (74%), although concerns about this route of use were widespread. Consistent with Australian research on preferred route of use and age [15], older users (aged 50 years +) typically found joints the most helpful method of use (41% vs. 26% of younger users), while younger users preferred the use of waterpipes (43% vs. 13% of older users).

When asked to comment on the good and bad points of different methods of ingestion the most consistent response was that smoking of any form, particularly with tobacco, was detrimental to respiratory function (and health). This was of particular concern to non-smokers, some of whom did not know how to cook cannabis recipes. Despite attracting the bulk of negative comments, its popularity seemed to lie with its instant effect, its ease of titration and cost-effectiveness compared to the oral route. It seemed to "do the job". Eating was seen to be a much healthier option – it was "safer", tasty when cooked in a recipe, less obvious than smoking and could be done virtually anywhere. Some people liked its slow onset and long-lasting effects, but others claimed difficulties with titration and slow onset made it expensive and ineffective for rapid symptom relief.

Effects of cannabis use

When asked to rate the overall effects of cannabis on a Likert scale ranging from "I feel a lot worse" to "gives me great relief", cannabis was perceived to provide "great relief" (86%) or a little relief (14%). No one believed it had been detrimental to their condition or symptoms.

Positive ratings were ("great" or "good" relief) were also typical for its ability to relieve specific symptoms (Table 3). In addition, several other symptoms were noted, primarily insomnia (13% used for insomnia; of these 82% derived "great" relief).

Approximately three quarters of participants (71%) claimed to have experienced a return of their symptoms or condition on stopping cannabis, especially: pain (53% of those who claimed a return of symptoms), depression or anxiety (30%), insomnia (11%), spasm (10%) and nausea/vomiting or lack of appetite (9%).

Table 3: Symptom relief (n = 128)

Symptom relief required...*	Total (%)	Male (%)	Female (%)

great relief	72	69	78
good relief	28	31	22
no effect	0	0	0

* No-one reported their condition was made worse

Only one in ten (11%) participants reported symptoms they believed were unrelated to their medical condition upon stopping cannabis, citing symptoms congruent with cannabis withdrawal such as anxiety or mood disturbance (including paranoia), insomnia, loss of appetite, restlessness and vivid dreams.

Comparison with other medicines

Almost two thirds (62%) of respondents claimed that they decreased or discontinued their use of other medicines when they started using cannabis medicinally. This was more common in males (65% vs. 58% of females) and older participants (aged 50 years +) (70% vs. 59% among younger participants). For some people this was a

Table 4: Comparison of cannabis with other medications (n = 128 unless specified).

	Total	Male	Female
Decreased or discontinued use of other medicines (n = 117*)	62%	65	58
Comparison of undesirable effects (n = 125)			
Cannabis produced much worse effects than other medicines	1	0	2
Cannabis produced somewhat worse effects	2	4	0
Undesired effects about the same	8	8	9
Other meds produced somewhat worse effects than cannabis	16	14	19
Other medicines produced much worse effects than cannabis	41	40	43
I have no undesirable effects from cannabis	31	33	28
Other medicines work differently	1	1	0
Comparison of relief provided (n = 118*)			
Other medicines work much better than cannabis	3	0	7
Other medicines work a bit better than cannabis	3	4	0
Other medicines work about the same as cannabis	9	8	9
Cannabis works a bit better than other medicines	13	11	15
Cannabis works much better than others medication	54	58	48
Only cannabis gives me relief from my condition	15	15	15
Other medicines work differently	2	0	4
Can't distinguish – use them together	1	1	2
Use cannabis to relieve side effects of other medicines	1	1	0

*Some people did not use other medications concurrently

substantial change, representing a shift away from chronic, high-dose medication use.

Perhaps not surprisingly, cannabis was typically perceived as superior to other medications in terms of undesirable effects, and the extent of relief provided (Table 4). Thus, cannabis was rated to produce equivalent (8%) or worse side effects (3%) by a minority of therapeutic users. It was considered to work "a bit" or "much better" than other medicines, or to be the only source of relief, by more than three quarters (82%). Two participants made the interesting comment that cannabis worked *differently* to other medicines, so could not be directly compared.

Despite the very positive response to the use of cannabis, nearly one half (41%; 36% of men and 50% of women) found it did not help certain conditions/symptoms. Almost one third (29%) said cannabis was less effective for certain types of pain, or extreme pain, with a further 12% specifying migraine or headache pain. Nearly one in ten (8%) reported no effect on depression or anxiety. More than one in ten (14%) specified that while cannabis could ease their symptoms and enabled them to cope, they realised that it could not cure their underlying condition. Younger participants were more likely than older participants to claim a condition not helped by cannabis (45% vs. 32% of those aged 50 years +).

Supply issues

Participants obtained medical cannabis from multiple sources (median = 1, range = 1–6; 44% had two or more sources), especially friends or family (58%) and dealers (42%). A substantial proportion grew their own (38%) while few (6%) obtained it from a compassion club or cooperative. Among those who purchased cannabis, the median weekly outlay was \$50 (range = \$1–\$500, n = 95).

When asked to comment on the variability of the cannabis they used, those who could obtain a consistent supply of high quality cannabis that suited their needs were in the minority. Typically, participants noticed variability along a number of lines, such as potency, effectiveness, intoxication and side-effects, which made titration difficult. While some noted the importance of factors such as the part of the plant used (e.g., leaf versus head/buds), strain (e.g., *sativa* versus *indica*), soil and climate, the overwhelming responses focussed on hydroponic versus soil-grown cannabis ("bush bud" or home grown cannabis), and home grown cannabis versus purchased cannabis.

Hydroponic cannabis was almost universally unpopular and was avoided where possible – despite its greater potency, it was also considered shorter acting, produced greater tolerance and worse side-effects than other cannabis. By comparison, soil-grown cannabis was perceived to

be less unpleasantly potent, natural ("organic"), less chemically treated, and with fewer side-effects. However, it was also perceived as harder to get. Home grown cannabis was seen as the best method of obtaining a consistent, safe supply of medicinal quality. A common response was that purchased cannabis was not to be trusted, and that unscrupulous growers who were more concerned with yield and greed compromised the quality of their crop with chemicals such as growth hormone and pesticides.

Concerns

A minority (13%) had no concerns over their medical cannabis use. Concerns over potential health effects (32%) or the risk of dependence (21%) were overshadowed by those relating to its illegal status (76%), the fear of being arrested (60%) and cost (51%). Indeed, one quarter (27%) claimed to have been arrested, cautioned or convicted in relation to their medical cannabis use, with this outcome more commonly reported by men (31% vs. 19% of women) and younger users (30% vs. 16% of users aged 50 years +). Other concerns mentioned (15%) were: the stigma of using, issues around parenting, pregnancy and relationships, availability, quality and difficulties in dose adjustment.

Support from others and interest in clinical trial

Most participants had a regular doctor (90%) and about a half had a regular specialist (55%). Virtually all (90%) had informed a clinician of their therapeutic use, typically reporting a supportive response from GPs (75% of those told), specialists (74%) and nurses (81%). Family and friends were largely considered supportive of the participant's use (71%).

Not surprisingly, there was widespread support for Government provision of cannabis to patients in a variety of circumstances. At least three quarters supported the supply of cannabis to any patient who was permitted to use it by being registered under a Government scheme (82%); more specifically, those patients who: could not afford to buy it on a regular basis (82%), could only purchase it on the black market (81%), couldn't ensure a consistent supply (75%), or were worried about quality control issues (77%). More than half endorsed the supply of patients who did not know anyone capable of growing it (72%), were concerned about hydroponically grown cannabis (72%), or who needed a supply quickly (66%).

Although not all participants were NSW residents, there was almost universal interest (89%) in participating in a clinical trial, in which a controlled supply of cannabis was grown and provided to registered medical cannabis users. There was also strong, although lesser, interest in trying alternative delivery methods such as a spray or tablet (79%).

While for some people, the availability of any cannabis-derived product that worked was their prime concern, alternative delivery methods were considered attractive as they obviated the necessity to smoke, removed concern about engaging in illegal behaviour and having to access the black market, and were more portable and acceptable than smoking. The main caveats on an alternative were that it was easy to titrate, quick, efficient, reliable and natural or safe – sprays and vaporisers were mentioned specifically by some as preferable to pills in this regard. A clear theme was the desire to keep the holistic, natural properties of cannabis rather than produce a chemical/synthetic drug with numerous binding and carrying agents. Nevertheless, there was recognition that different medical conditions may require different approaches, such as different active agents (e.g., THC versus other cannabinoids), strains or methods (e.g., slow release pill versus fast-acting spray).

The main reason for not supporting alternatives appeared to be that using the whole plant in its natural state was perceived to be the best method. In addition, for some the ritual of cannabis use was perceived as part of its medicinal benefit. There was also concern at political interference and its potential for exploitation and corruption in a trial.

Discussion

This exploratory study examined the patterns of medicinal cannabis use among a sample of 128 Australian adults who responded to media stories about this issue. Firstly, we need to acknowledge its limitations. As we do not know how many Australians use cannabis medicinally or their characteristics, we relied on the recruitment of volunteers through purposive sampling. Instead of targeting a particular group we used media stories disseminated widely on the radio, television and in newspapers to attract a cross-section of people. Thus, these results may not be representative of the experiences of all medicinal users, and may be affected by selection bias by excluding those who did not have access to these media, who did not wish to or could not contact us or did not return the questionnaire. We also attracted participants whose experiences with medical cannabis were typically positive, so they have little to tell us about people who have not found cannabis helpful or pleasant therapeutically. However, they still provide important information on these people's experiences, and raise important issues regarding the use of black market supplies of the cannabis plant and the development of cannabis-based pharmaceuticals. As the questionnaire was self-completed, there was potential for misunderstanding of the questions. However, the wording was straightforward, contact details were provided in the event of misunderstanding, and the results were remarkably consistent across participants, which encour-

ages us that the questions were understood. Despite being anonymous, several participants provided us with contact details in case further information was needed, and wrote additional comments about their experiences and attitudes. In addition, many of the findings are remarkably consistent with the findings of other local and international studies, as indicated below.

People in this study reported regular, ongoing medical use over quite long periods – with 61% using for more than five years and 20% reporting very long-term use of more than 20 years. However, as Ware and colleagues noted in their study of almost 1000 medical users [10], this was a group of chronically ill people with multiple long-standing conditions. The perceived need for alternative or additional symptom relief may reflect the fact that we recruited a sample of particularly entrenched medicinal cannabis users who were dissatisfied with conventional treatments, that medicinal cannabis use is more likely to be considered an option by people who find conventional treatments and medications unsatisfactory, or that many had been exposed to its perceived medical benefits quite early due to their recreational use. Larger studies addressing a broad cross-section of users may better answer this question.

Consistent with the literature on the conditions for which cannabis has been indicated, chronic pain, arthritis, persistent nausea and weight loss were among the most common conditions for which cannabis relief was sought. However, depression was the most common condition: more than half (56%) used cannabis to relieve depression, and two thirds (66%) used it to cope emotionally, universally obtaining great or good relief. Other studies have also reported cannabis use for the relief of depression, although not at this level [8-10,14]. The relationship between depression and cannabis use is controversial, with recent literature indicating that cannabis use may be implicated in depression and suicidal thoughts and behaviours. This would suggest that regular medicinal use may be contraindicated by placing people at risk of depression or self-harm. However, we do not know the type or aetiology of the depression cited by our participants. Many may have experienced depression and stress associated with their physical condition, which may have been alleviated along with any physical relief. The risk may also be greatest among heavy, younger users and those who may already be vulnerable to mental ill health due to their life circumstances [16-18]. Medical cannabis use patterns may not typically be regular enough to pose a great risk. Regardless, it is important that people considering the use of medical cannabis are aware of the risks of use [19]. A recent paper [20] has suggested that THC and cannabidiol, two major components of cannabis, may help alleviate bipolar disorder, recommending a pharmaceutical

product would be a safer option than crude cannabis, in which the balance of components is variable.

Consistent with local and international research on people with a variety of medical conditions [8-12,14], most participants claimed moderate to substantial benefits from cannabis, both in terms of their overall condition and management of individual symptoms. It was typically considered more effective and less aversive than other medications in managing their condition(s), the symptoms of which commonly re-emerged upon stopping (71%). While their use was often complementary to other medications and treatment, 62% had decreased or discontinued use of other medications when they commenced medicinal cannabis use. Nevertheless, cannabis was not a panacea – it did not help all conditions, particularly certain types of pain, and there was recognition that while it substantially improved quality of life it was not a cure. This is not necessarily surprising, as overall well-being and specific symptoms have multiple causes and can be affected by several factors, and is borne out by recent controlled clinical trials, for example, on chronic pain [21].

As others have reported (e.g., [8-10]) we also found that in addition to medical use, recreational use was common: most (80%) had used cannabis recreationally, with about one half (54%) of these reporting some recent use. Indeed, 29% had discovered its therapeutic potential through their recreational use. One participant raised the issue that part of the therapeutic effect for them was the ritual of use and the "high" experienced [6]. This demonstrates the difficulty of precisely identifying the therapeutic component when people are using the natural plant matter, and will continue to present a challenge for the development of cannabis pharmaceuticals. While some people may find the illegality, route of use and psychoactive effects of natural cannabis undesirable and prefer a manufactured pharmaceutical product, several in this survey claimed to prefer the holistic delivery of all the compounds present when using the natural plant. We need to know more about the effect of the different active chemicals on medical conditions and how their therapeutic potential is mediated by the context of use.

Nonetheless, this was not simply a sample of recreational users, especially as we attracted many older users who used exclusively for medical reasons (75% of those aged 50 years+). They did not fit the recreational user stereotype, were willing to take the risk of using an illicit drug, exposure to the illicit drug market and the possibility of arrest to gain symptom relief. Indeed, the most common concern over medicinal use was its illegality, fear of arrest and cost (all >50%). One quarter (27%) of participants had experienced legal ramifications due to their use. Several people commented that they had no alternative than

using an illegal drug, claiming that other medicines with negative and toxic effects (e.g., opiates) were legally prescribed, and that if nothing else worked for them they had the right to access cannabis without fear or stigma. Several made pleas for medical cannabis use to be treated as a medical, rather than a legal, issue, as their health and quality of life were at stake.

Smoking was the most common method of use; in addition, many were tobacco smokers or mixed cannabis with tobacco. Given the similarities between cannabis and tobacco smoke this is of particular concern for people who are ill, especially those with compromised immune systems. Despite acknowledgement of the risks of smoking and concerns expressed over its effects, it was considered the most helpful route of use. While eating was perceived as much healthier, until satisfactory solutions are achieved on titration and dosing issues, smoking will no doubt continue to be a popular method of obtaining relief.

Cannabis dependence was a concern for one in five participants (21%). This study provided indirect evidence that participants were unlikely to experience withdrawal symptoms on ceasing medical use, but this was only a crude measure. While the risk of dependence is probably low when used medicinally, this risk needs to be weighed up with the other concerns of the patient – for example, it may be low on the list of concerns for those with terminal illness [19].

Finally, participants reported that family and friends were likely to know about and support their medical cannabis use. These data also indicate that the medical profession is encountering, and frequently supporting, patients who use cannabis for symptom relief. Given their central role in the management of illness, it is important that clinicians are educated about the effects of cannabis, in order to assist patients in making informed decisions about their treatment. There was also clearly great interest among participants in a clinical trial and scope to investigate methods of delivery that avoid the health concerns associated with smoking cannabis, keeping in mind that some participants were reluctant to use a pharmaceutical product. In addition to distrust of unscrupulous participants in the black market, some were also distrustful of Government's motives and role in therapeutic research. It is therefore vital that any clinical trials are conducted in a rigorous, independent manner.

Conclusion

Overall, these findings are consistent with those of other surveys, in revealing the perceived effectiveness of cannabis for the relief of symptoms associated with several medical conditions. While a small study, it has several

implications. Firstly, people are risking the use of an illicit drug for its perceived therapeutic effects, and in some cases being arrested. Secondly, they are informing their clinicians about their medical use and frequently receiving support, highlighting the importance of ensuring clinicians are informed about cannabis. Finally, in addition to strong public support, medical cannabis users show strong interest in clinical cannabis research, including the investigation of alternative delivery methods.

Who Are Medical Marijuana Patients? Population Characteristics from Nine California Assessment Clinics[†]

Craig Reinerman, Ph.D.*; Helen Nunberg, M.D., M.P.H.**;
Fran Lanthier, M.A.*** & Tom Heddleston, M.A.***

Abstract—Marijuana is a currently illegal psychoactive drug that many physicians believe has substantial therapeutic uses. The medical literature contains a growing number of studies on cannabinoids as well as case studies and anecdotal reports suggesting therapeutic potential. Fifteen states have passed medical marijuana laws, but little is known about the growing population of patients who use marijuana medicinally. This article reports on a sample of 1,746 patients from a network of nine medical marijuana evaluation clinics in California. Patients completed a standardized medical history form; evaluating physicians completed standardized evaluation forms. From this data we describe patient characteristics, self-reported presenting symptoms, physician evaluations, other treatments tried, other drug use, and medical marijuana use practices. Pain, insomnia, and anxiety were the most common conditions for which evaluating physicians recommended medical marijuana. Shifts in the medical marijuana patient population over time, the need for further research, and the issue of diversion are discussed.

Keywords—anxiety, cannabis therapeutics, insomnia, medical marijuana, pain

Medicinal preparations containing marijuana (cannabis) were widely used in many societies for centuries. Dr. William O'Shaughnessy introduced it as a modern medicine in Europe in 1839. Marijuana was

prescribed for therapeutic use in American medical practice for a variety of conditions from the mid-nineteenth century into the twentieth. Marijuana was admitted to the *United States Pharmacopoeia* in 1850 and listed in the *National Formulary* and the *US Dispensatory*. Major pharmaceutical companies including Lilly, Burroughs-Wellcome, and Parke-Davis produced cannabis-based therapeutic agents (Brecher et al. 1972).

In 1936, the Federal Bureau of Narcotics advocated a law prohibiting its use, which Congress passed in 1937, against the advice of the American Medical Association (Grinspoon & Bakalar 1993:9–11). This law, along with increased prescribing of aspirin and barbiturates, pushed cannabis out of the *United States Pharmacopoeia* and common medical practice by 1942.

After nonmedical cannabis use spread in the 1960s, the number of Americans reporting lifetime prevalence

increased sharply. Recent estimates from the National Survey on Drug Use and Health show that 102,404,000 Americans have used this drug, 41% of the population aged 12 and over, or about half the adult population (SAMHSA 2010). This widespread use led to a gradual rediscovery of the therapeutic uses of cannabis, albeit largely without physician involvement.

Alongside the spread of nonmedical use, in 1964 scientists determined the precise chemical structure of delta-9 tetrahydrocannabinol (THC), thought to be the most significant psychoactive ingredient in cannabis (Gaoni & Mechoulam 1964). This stimulated research in the clinical pharmacology of cannabinoids. Many physicians in clinical practice also recognized the therapeutic potential of cannabis (Irvine 2006; Charuvastra, Freidmann & Stein 2005), specifically, for example, for pain (Woolridge et al. 2005), as an antiemetic for chemotherapy patients (Doblin & Kleiman 1991), or for symptoms of AIDS (Abrams et al. 2003). More recently a broader medical literature documenting the therapeutic properties of endogenous cannabinoids has developed (e.g., Nicoll & Alger 2004; Lehmann et al. 2002; Hall, Degenhart & Currow 2001). Numerous case reports in the medical literature also have suggested that cannabis has therapeutic potential for a variety of conditions. But rigorous experimental research that might determine more precisely the therapeutic efficacy of cannabis for specific conditions has been blocked by the Drug Enforcement Administration (see Zeese 1999; *Alliance for Cannabis Therapeutics v. Drug Enforcement Administration* 1994).

This combination of increasing therapeutic use and federal government opposition ultimately led to passage of new state laws providing for the medical use of cannabis upon physician recommendation. Since 1996, 15 U.S. states and the District of Columbia have passed such laws: California, Alaska, Oregon, Washington, Nevada, Colorado, Maine, Montana, Michigan, and Washington, DC by ballot initiative; Rhode Island, New Mexico, Vermont, Hawaii, and New Jersey by state legislation.

The first of these laws was California's Proposition 215, the Compassionate Use Act, passed in 1996 (*San Francisco Chronicle* 1996). This act made it legal under state law for patients to possess and use cannabis if recommended by their physicians. Numerous medical and scientific associations endorsed medical use of cannabis and/or supported further research into its therapeutic potential. These included the American College of Physicians (2008), the American Public Health Association (1995), the British Medical Association (1997), the Canadian Medical Association (2005), and the Institute of Medicine of the National Academy of Sciences (1999).

Such elections and endorsements notwithstanding, the Bush Administration's Office of National Drug Control Policy threatened to revoke the licenses of physicians who recommended cannabis to patients. One physician

challenged this policy and the U.S. Court of Appeals ruled (in *Conant v. Walters*) in 2002 that it unconstitutionally infringed physicians' First Amendment rights to freedom of speech with their patients (McCarthy 2004). Subsequent legislation and case law have left medical marijuana (MM) patients and their physicians in legal limbo:

- In 2003, the California legislature passed SB 420 to provide specific implementation guidelines for Proposition 215, including how counties should handle MM patient ID cards.
- Most drug law enforcement is done by local police who enforce state, not federal, drug laws. In 2005, The California Attorney General ruled that Proposition 215 is the legitimate will of the voters and is therefore valid under the California Constitution for purposes of *state* law enforcement. He advised the Highway Patrol and other state law enforcement agencies that under California law MM patients were legally entitled to possess and use cannabis for therapeutic purposes (Hoge 2005).
- In 2006, Bush administration Attorney General Gonzales sought to invalidate state MM laws, and the U.S. Supreme Court ruled (*Gonzales v. Raich* 2006) that the Compassionate Use Act—its legitimate electoral provenance notwithstanding—neither supersedes nor invalidates federal laws that prohibit marijuana use (see Mikos 2009 for a legal analysis of the states' neglected power to legalize behavior that is criminalized under federal law).
- In 2008 the Supreme Court denied without comment an appeal by two California counties that had refused to implement Proposition 215 (*County of San Diego v. San Diego NORML* 2008), thereby letting stand a lower court ruling that upheld SB 420's provisions regarding counties issuing MM identification cards.
- In 2009, Attorney General Eric Holder issued a policy stating that federal drug control agencies would no longer raid MM dispensaries if they operated within state and local laws (Moore 2009).
- That policy notwithstanding, the DEA has continued to raid MM dispensaries in California into 2011 (e.g., Blankstein 2009).

Within this grey area between conflicting state and federal laws, the number of patients who have received recommendations for medical marijuana from physicians has continued to grow, albeit by how much remains unknown. Over 1,000 MM dispensaries, delivery services, and cooperatives are said to be operating in California to meet the demand (NORML 2007). A rough estimate of the number of MM patients in California can be extrapolated from Oregon figures. Unlike California's Compassionate Use Act, Oregon's MM law set up an Oregon Medical Marijuana Program that requires centralized record keeping. As of July, 2009, some 2,983 Oregon-licensed physicians had approved 20,307 applications for MM (Oregon

Department of Human Services 2008). The population of California is 9.7 times that of Oregon (U.S. Census 2007), which yields a crude estimate of 196,978 MM patients in California. This is likely an underestimate because the California statute affords greater latitude to physicians regarding the conditions for which they can recommend MM (“... any other illness for which marijuana provides relief”). Americans for Safe Access (2008), a MM patient advocacy group, has estimated that there are well over 200,000 physician-sanctioned MM patients in California.

Despite their growing numbers, however, the ambiguous legal status of MM patients renders them a half-hidden population whose characteristics are not well documented, with the partial exception of the San Francisco Bay Area (O’Connell & Bou-Matar 2007; Reiman 2007a). Medical marijuana will likely continue to be a contentious issue, but across fifteen states and the District of Columbia several hundred thousand people are using marijuana as a medicine recommended by physicians, and yet little is known about them as a patient population.

We intend this study as a modest contribution toward filling this gap. It presents data on the demographic characteristics, presenting symptoms, physician evaluations, conventional treatments tried, and MM use practices of patients from a network of MM assessment clinics in California.

METHODS

These data were drawn from 1,746 consecutive admissions to nine MM assessment clinics operating in California in July, August, and September 2006. These assessment clinics are not dispensaries and are not connected to dispensaries. They were located throughout the state—in the north and south, coast and central valley, and large and small cities: Modesto, Oakland, Sacramento, Hollywood, San Diego, Santa Cruz, Ukiah, San Francisco, and Santa Rosa. They charged \$100 to \$125 for an assessment. At the time our sample was drawn, these assessment clinics had evaluated over 54,000 MM patients. Without a comprehensive patient database or representative household surveys, there is no way to determine precisely how representative this sample is of the overall population of MM patients. Moreover, there is a large albeit unknown number of people who use marijuana medicinally but who have not sought physician recommendations or official patient ID cards, perhaps because of the expense of the assessment.¹

Evaluating physicians interviewed potential patients and evaluated their patient medical histories for purposes of recommending MM and issuing patient identification cards under the Compassionate Use Act and SB 420. The evaluation instruments were (1) a basic patient-administered medical history questionnaire covering demographics, presenting symptoms or conditions, brief medical history,

conventional and alternative medical treatments tried, drug use history, and MM use practices; and (2) a physician evaluation form using International Classification of Diseases codes (ICD-9). Each patient received and signed an extensive informed consent form noting confidentiality, which was approved by the clinics’ IRB.

Most prior studies of MM patients are based on small, symptom-specific samples. Initially, the population of MM patients in the San Francisco Bay Area were people with HIV/AIDS and cancer (e.g., Harris, Mendelson & Jones 1998). Later, physicians began to recommend cannabis to patients with chronic pain, mood disorders and other psychiatric conditions (Gieringer 2002). The data reported here describe what is among the largest and most symptomatically and demographically diverse samples of medical cannabis patients to date (cf., O’Connell & Bou-Matar 2007).

RESULTS

As Table 1 indicates, the MM patients are three-fourths male and three-fifths White. Compared to the US Census of California, the patients in this sample are on average somewhat younger, report slightly more years of formal education, and are more often employed. The comparison also indicates that women, Latinos, and Asian Americans are underrepresented. Given the limitations of our data, we can offer only informed speculation as to why.

The underrepresentation of women may be in part an epidemiological artifact of the gender distribution of certain kinds of injuries (e.g., workplace, sports, and motorcycle accidents). It may also have to do with the double stigma women face in seeking MM—for using an illicit drug and for violating gender-specific norms against illegal behavior in general. Moreover, as with alcohol use, pregnant women and women considering pregnancy are likely to have health concerns and many may fear that MM could put them in jeopardy if discovered by child protection agencies.

Given the high poverty rate among Latinos and their concentration in the manual labor end of the occupational structure, Latinos are exposed to equal or greater risks of work-related injuries and to no less epidemiologic risk of other conditions for which MM is sometimes used. It seems likely that their under-representation has to do with the undocumented status of many Latinos in California. The undocumented often avoid contact with government agencies for fear of apprehension by law enforcement, for beyond arrest and incarceration this carries the risk of deportation. Such fears reduce the likelihood of Latinos accessing health care in general and MM in particular. Asian Americans are also underrepresented, but this may be because they have lower prevalence of marijuana use than other racial/ethnic groups and/or because they have their own venerable traditions of herbal medicine.

TABLE 1
Demographic Characteristics of California Medical Marijuana Patients Compared to California Census 2000, Age 18 and Over {n = 1746}

	MM Patients	U.S. Census 2000 – California
Female	27.1%	50.7%
Male	72.9%	49.3%
White	61.5%	59.5%
Latino	14.4%	32.4%

*Data not available in California Census.

African-Americans, conversely, are over-represented in this sample. This does not appear to stem from their prevalence of marijuana use, for representative national surveys show that Blacks generally do not have significantly higher prevalence of marijuana use than Whites (SAMHSA 2005). African-Americans may be more likely to seek MM for any of several reasons: because they are disproportionately poor, more often lack health insurance, are significantly less likely to be prescribed other medication for pain (Pletcher et al. 2008) or to receive treatment for cancer (Gross et al. 2008), and because African-Americans are a growing proportion of HIV/AIDS cases. Some of these same reasons may help to explain why Native Americans are also overrepresented, although their proportion of both this sample and the general population is too small to judge representativeness accurately.

In their medical history questionnaires, patients were asked “Which of the following best describe the therapeutic benefit you receive from medicinal cannabis? (Check the most important).” Patients typically reported more than one therapeutic benefit (mean = 3). Early studies showed most patients used MM to relieve symptoms of HIV/AIDS (Woolridge et al. 2005) or cancer, and it is likely that the majority of patients in our sample who reported “nausea” were cancer patients receiving chemotherapy. However, Table 2 suggests that cancer and AIDS patients are now a

TABLE 2
Patient Self-Reports of Therapeutic Benefits from Medicinal Marijuana*

	Percent
To Relieve:	
Pain	82.6
Muscle Spasms	41.1
Headaches	40.7
Anxiety	37.8
Nausea/Vomiting	27.7
Depression	26.1
Cramps	19.0

To Prevent:	
Medication Side Effects	22.5
Anger	22.4
Involuntary Movements	6.2
Seizures	3.2
As Substitute for:	
Prescription Medication	50.9
Alcohol	13.0

*N = 1,745; patients could report more than one benefit in more than one category.

significantly smaller proportion of the total (e.g., “to relieve nausea/vomiting” 27.7%, “to improve appetite” 37.7%) and that the MM patient population has become more diverse since the Compassionate Use Act was passed in 1996 (cf. Ware, Adams & Guy 2005, on MM use in the UK, and Grotenherman 2002 on MM use in Germany).

Instead, relief of pain, muscle spasms, headache, and anxiety, as well as to improve sleep and relaxation were the most common reasons patients cited for using MM. Chronic pain also topped the list of maladies for which MM was used in another California clinical sample (Reiman 2007b).

Table 3 shows the ICD-9 diagnostic codes most frequently recorded by evaluating physicians. Pain from back and neck injuries was the most frequently coded. This appears consistent with a nationally representative Medical Expenditure Panel Survey, which found a 19.3% increase in the prevalence of spine problems between 1997 and 2005 (Martin et al. 2008). Back and neck pain was followed in frequency by sleep disorders (also increasing), anxiety/depression, muscle spasms, and arthritis. Fully half of this sample reported using MM as a substitute

TABLE 3
Conditions Most Frequently Recorded by Physicians As Reasons for Approving Medical Marijuana Patient Identification Cards*

	Percent	ICD-9 Codes
Back/Spine/Neck Pain	30.6%	[722.1–724.2]
Sleep Disorders	15.7%	[307.42, 327.0]
Anxiety/Depression	13.0%	[300.0, 311.0]
Muscle Spasms	9.5%	[728.85]
Arthritis	8.5%	[715.0, 721.2, 721.2]
Injuries (Knee, Ankle, Foot)	4.5%	[959.7]
Joint Disease/Disorders	4.4%	[716.1–719.49]
Narcolepsy	3.7%	[347.0]
Nausea	3.4%	[787.02]
Inflammation (Spine, Nerve)	2.9%	[724.4]
Headaches/Migraines	2.7%	[784.0, 346.0, 346.2]
Eating Disorders	1.1%	[783.0]

*N = 1746; some patients reported multiple symptoms and/or conditions.

TABLE 4
Other Treatment Modalities Tried for the Medical Condition(s) for Which Patients Seek Medical Marijuana*

	%	N
Prescription Medication	79.3%	1383

Homeopathy	12.0	209
Other Types of Treatment	11.9	208

*N = 1746; patients could report multiple other treatments.

for prescription drugs, consistent with other studies (e.g., Reiman 2007a).

Table 4 indicates that the MM patients in the sample had tried a variety of other treatments, conventional and alternative, for the conditions for which they were seeking a MM identification card. Four in five (79.3%) reported having tried other medications prescribed by their physicians (almost half were opiates); about half (48.7%) had tried physical therapy; over a third (36.3%) had tried chiropractic; nearly one-fourth (22.3%) reported having had surgery for their condition.

Table 5 compares patient responses to the drug use questions to those in the 2006 National Survey on Drug Use and Health (SAMHSA 2007). Prevalence of tobacco

TABLE 5
Medical Marijuana Patients' Self-Reported Current Nonmedical Drug Use, Compared to 2006 National Survey on Drug Use And Health (SAMHSA 2007)

	MM Patients	NSDUH*
Tobacco	29.4%	25.0%
Alcohol	47.5	61.9
Cocaine	0.3	1.9
Methamphetamine	0.4	0.5
Heroin	0.1	0.3
Other Opiates	1.2	**

Note: Participants were asked "Do you currently use . . ."; answers are percent responding "yes." N = 1745; patients could report more than one drug. Of smokers, 65.5% used ten or less cigarettes/day; of drinkers, 58.7% used <= one or less drinks/day.

*NSDUH figures for "past month" prevalence used as a proxy for "current use".

**Data not available in comparable form.

use was somewhat higher than in the general population, but prevalence of alcohol use was significantly lower. Many patients reported that they valued MM because it allowed them to reduce their alcohol use. It is possible that self-reports on a self-administered instrument will underestimate illicit drug use, particularly if patients felt that admitting illicit drug use could reduce their chances of obtaining a MM identification card. Rigorous assessments of the reliability of such data must await further research, but limitations aside, these data suggest low prevalence of other illicit drug use among MM patients. While it is true that the great majority of our respondents had used marijuana recreationally, in response to a separate question over two-fifths (41.2%) reported that they had *not* been using it recreationally prior to trying it for medicinal purposes.

Table 6 presents data on patients' medical marijuana use practices. Amounts used per week varied from three grams or less (40.1%) to seven or more grams (23.3%). Two-thirds (67%) reported using MM daily while one-fourth (26%) reported using less than once a week. Half (52.9%) reported using one or two times per day while one in ten (10%) reported using three or more times per day. Patients consumed MM primarily in the evenings (52.3%) or prior to sleep (56.1%). More than two in five (42.3%) reported that when they used depended on their medical symptoms. Patients ingested MM predominantly by smoking (86.1%), although one-fourth (24.4%) reported ingesting orally and nearly a fourth (21.8%) reported using a vaporizer. These latter figures suggest that at least some of the time, many MM patients are choosing modes of ingestion that reduce the perceived risk of harms from smoking (Tan et al. 2009; Hashibe et al. 2006).

TABLE 6
Medical Marijuana Use Practices

Frequency of Medical Marijuana Use (N = 1583)*	
Daily	67.0% (1065)
<Once A Week	26.0% (409)
<Once A Month	7.0% (109)
On Days Used, Frequency per Day (N = 1574)	
1 To 2 Times Per Day	52.9% (833)
2 To 3 Times Per Day	29.0% (457)
>3 Times Per Day	10.0% (284)
Time Of Day Typically Used (N = 1745)

0–3 Grams	40.1% (574)
4–7 Grams	36.5% (523)
>7 Grams	23.3% (334)

*Total n = 1745, but N's vary across questions because patients could choose more than one response and because not all responded to each question.

DISCUSSION

Rediscovery of Medicinal Utility and Diversifying Patient Population

Compared to earlier studies of MM patients, these data suggest that the patient population has evolved from mostly HIV/AIDS and cancer patients to a significantly more diverse array. The diffusion of marijuana as a medicine may have been slower than that of other medicines in conventional clinical practice because the flow of information from physician to patient is impeded by MM's ambiguous legal status. Thus, information about the potential therapeutic utility of cannabis is spread mostly via word of mouth and other informal means. This suggests that the patient population is likely to continue evolving as new patients and physicians discover the therapeutic uses of cannabis. Ironically, this trend toward increasing therapeutic uses is bringing marijuana back to the position it held in the U.S. Pharmacopeia prior to its prohibition in 1937.

Further Research

Like other medicines, marijuana's therapeutic efficacy varies across conditions and patient groups. This variation seems more likely when supplies remain illicit because standardized dosages or other quality controls are more difficult to achieve. To gain maximum therapeutic potential across the growing range of conditions for which MM is being recommended, more systematic research is needed. Longitudinal, case control, and double-blind studies are required to rigorously assess marijuana's therapeutic efficacy for specific patient groups, conditions, and diseases. With regard to shifts in the patient population, it also would be very useful to have follow-up studies of patients accessing the assessment clinics in our sample and others drawn from similar assessment clinics.

Diversion

Critics have argued that some MM patients are "gaming the system" to get marijuana for nonmedical use. Neither our data nor any other data we are aware of allow any clear-cut, empirical estimate of the scale of such diversion. Given the widespread nonmedical use marijuana in the general population (102,404,000 Americans report lifetime prevalence; see SAMHSA 2010) and the risk of arrest (847,864 Americans were arrested for marijuana offenses in 2008, 754,224 or 88.96% of them for possession alone; FBI 2009), it seems likely that at least some MM patients use MM dispensaries as sources of supply for nonmedical use.

Defining and measuring such diversion, however, is complicated at best. Given the high prevalence of nonmedical use, it is not surprising that most MM patients in our sample reported having used it recreationally before using it therapeutically. But as noted above, two-fifths had *not* been using marijuana recreationally prior to trying it for medicinal purposes. Their self-reported rates of other illicit drug use are slightly lower than those found among the general population, and their levels of educational attainment and rate of employment are comparable to the California population. Our data have clear limitations, but they contain no obvious signs that MM patients differ from the general population.

Nor is drug diversion unique to medical marijuana. A significant albeit unknown proportion of other patients obtain prescriptions for numerous drugs through legal medical channels that they then use for nonmedical purposes, for example, Valium and other benzodiazepines (Haafkens 1997), Ritalin and other stimulants prescribed for ADHD, and Oxycontin and other opiates prescribed for pain.

The diversion issue will likely become more important as the line between medical and nonmedical drug use is increasingly blurred (Murray, Gaylin & Macklin 1984). Beyond the spread of MM, Prozac and other SSRI-type antidepressants, for example, are often prescribed

for patients who do not meet DSM criteria for clinical depression but who simply feel better when taking it. Such “cosmetic psychopharmacology” (Kramer 1993) is likely to grow as new psychiatric medications come to market. The line between medical and nonmedical drug use has also been blurred by performance enhancing drugs such as steroids, so-called “smart drugs” that combine vitamins with psychoactive ingredients, and herbal remedies like *ma huang* (ephedra) available in health food stores (Burros & Jay 1996).

These examples suggest that despite the best intentions of physicians and law makers, much drug use does not fit into two neat boxes, medical and nonmedical, but rather exists on a continuum where one shades into the other as

patients’ purposes shift to suit situational exigencies in their health and their daily lives. It is not clear where a border line between medical and nonmedical marijuana or other drug use might be drawn nor how it might be effectively policed (see Reinarman & Levine 1997: 334–44).

NOTE

1. We are grateful to one anonymous reviewer for pointing out that the cost of these assessments may well have prevented some potential MM patients—including many impoverished HIV/AIDS patients—from obtaining ID cards, which may have affected the demographics of this sample.

NOTICE: The project that is the subject of this report was approved by the Governing Board of the National Research Council, whose members are drawn from the councils of the National Academy of Sciences, the National Academy of Engineering, and the Institute of Medicine. The principal investigators responsible for the report were chosen for their special competences and with regard for appropriate balance.

The Institute of Medicine was chartered in 1970 by the National Academy of Sciences to enlist distinguished members of the appropriate professions in the examination of policy matters pertaining to the health of the public. In this, the Institute acts under both the Academy's 1863 congressional charter responsibility to be an adviser to the federal government and its own initiative in identifying issues of medical care, research, and education. Dr. Kenneth I. Shine is president of the Institute of Medicine.

This study was supported under Contract No. DC7C02 from the Executive Office of the President, Office of National Drug Control Policy.

CARLOS GABRIEL, Financial Associate

Reviewers

This report has been reviewed in draft form by individuals chosen for their diverse perspectives and technical expertise, in accordance with procedures approved by the National Research Council's Report Review Committee. The purpose of this independent review is to provide candid and critical comments that will assist the Institute of Medicine in making the published report as sound as possible and to ensure that the report meets institutional standards for objectivity, evidence, and responsiveness to the study charge. The review comments and draft manuscript remain confidential to protect the integrity of the deliberative process. The committee wishes to thank the following individuals for their participation in the review of this report:

JAMES C. ANTHONY, Johns Hopkins University
JACK D. BARCHAS, Cornell University Medical College
SUMNER H. BURSTEIN, University of Massachusetts Medical School
AVRAM GOLDSTEIN, Stanford University
LESTER GRINSPOON, Harvard Medical School
MILES HERKENHAM, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland
HERBERT D. KLEBER, Columbia University
GEOFFREY M. LEVITT, Venable Attorneys at Law, Washington, D.C.
KENNETH P. MACKIE, University of Washington
RAPHAEL MECHOULAM, The Hebrew University of Jerusalem
CHARLES P. O'BRIEN, University of Pennsylvania
JUDITH G. RABKIN, Columbia University

ERIC G. VOTH, International Drug Strategy Institute, Topeka, Kansas
VIRGINIA V. WELDON, Washington University

While the individuals listed above provided constructive comments and suggestions, it must be emphasized that responsibility for the final content of this report rests entirely with the authoring committee and the Institute of Medicine.

Preface

Public opinion on the medical value of marijuana has been sharply divided. Some dismiss medical marijuana as a hoax that exploits our natural compassion for the sick; others claim it is a uniquely soothing medicine that has been withheld from patients through regulations based on false claims. Proponents of both views cite “scientific evidence” to support their views and have expressed those views at the ballot box in recent state elections. In January 1997, the White House Office of National Drug Control Policy (ONDCP) asked the Institute of Medicine to conduct a review of the scientific evidence to assess the potential health benefits and risks of marijuana and its constituent cannabinoids. That review began in August 1997 and culminates with this report.

The ONDCP request came in the wake of state “medical marijuana” initiatives. In November 1996, voters in California and Arizona passed referenda designed to permit the use of marijuana as medicine. Although Arizona’s referendum was invalidated five months later, the referenda galvanized a national response. In November 1998, voters in six states (Alaska, Arizona, Colorado, Nevada, Oregon, and Washington) passed ballot initiatives in support of medical marijuana. (The Colorado vote will not count, however, because after the vote was taken a court ruling determined there had not been enough valid signatures to place the initiative on the ballot.)

Information for this study was gathered through scientific workshops, site visits to cannabis buyers' clubs and HIV/AIDS clinics, analysis of the relevant scientific literature, and extensive consultation with biomedical and social scientists. The three 2-day workshops—in Irvine, California; New Orleans, Louisiana; and Washington, D.C.—were open to the public and included scientific presentations and individual reports, mostly from patients and their families, about experiences with and perspectives on the medical use of marijuana. Scientific experts in various fields were selected to talk about the latest research on marijuana, cannabinoids, and related topics. (Cannabinoids are drugs with actions similar to THC, the primary psychoactive ingredient in marijuana.) In addition, advocates for and against the medical use of marijuana were invited to present scientific evidence in support of their positions. Finally, the Institute of Medicine appointed a panel of nine experts to advise the study team on technical issues.

Public outreach included setting up a Web site that provided information about the study and asked for input from the public. The Web site was open for comment from November 1997 until November 1998. Some 130 organizations were invited to participate in the public workshops. Many people in the organizations—particularly those opposed to the medical use of marijuana—felt that a public forum was not conducive to expressing their views; they were invited to communicate their opinions (and reasons for holding them) by mail or telephone. As a result, roughly equal numbers of persons and organizations opposed to and in favor of the medical use of marijuana were heard from.

Advances in cannabinoid science over the past 16 years have given rise to a wealth of new opportunities for the development of medically useful cannabinoid-based drugs. The accumulated data suggest a variety of indications, particularly for pain relief, antiemesis, and appetite stimulation. For patients who suffer simultaneously from severe pain, nausea, and appetite loss, such as those with AIDS or who are undergoing chemotherapy, cannabinoid drugs might offer broad-spectrum relief not found in any other single medication.

Marijuana is not a completely benign substance. It is a powerful drug with a variety of effects. However, the harmful effects to individuals from the perspective of possible medical use of marijuana are not necessarily the same as the harmful physical effects of drug abuse.

Although marijuana smoke delivers THC and other cannabinoids to the body, it also delivers harmful substances, including most of those found in tobacco smoke. In addition, plants contain a variable mixture of biologically active compounds and cannot be expected to provide a pre-

cisely defined drug effect. For those reasons, the report concludes that the future of cannabinoid drugs lies not in smoked marijuana but in chemically defined drugs that act on the cannabinoid systems that are a natural component of human physiology. Until such drugs can be developed and made available for medical use, the report recommends interim solutions.

Co-Principal Investigators

Acknowledgments

This report covers such a broad range of disciplines—neuroscience, pharmacology, immunology, drug abuse, drug laws, and a variety of medical specialties, including neurology, oncology, infectious diseases, and ophthalmology—that it would not have been complete without the generous support of many people. Our goal in preparing this report was to identify the solid ground of scientific consensus and to steer clear of the muddy distractions of opinions that are inconsistent with careful scientific analysis. To this end we consulted extensively with experts in each of the disciplines covered in this report. We are deeply indebted to each of them.

Members of the Advisory Panel, selected because each is recognized as among the most accomplished in their respective disciplines (see page iii), provided guidance to the study team throughout the study—from helping to lay the intellectual framework to reviewing early drafts of the report.

The following people wrote invaluable background papers for the report: Steven R. Childers, Paul Consroe, Howard Fields, Richard J. Gralla, Norbert Kaminski, Paul Kaufman, Thomas Klein, Donald Kotler, Richard Musty, Clara Sanudo-Peña, C. Robert Schuster, Stephen Sidney, Donald P. Tashkin, and J. Michael Walker. Others provided expert technical commentary on draft sections of the report: Richard Bonnie, Keith Green, Frederick Fraunfelder, Andrea Hohmann, John McAnulty, Craig Nichols, John Nutt, and Robert Pandina. Still others responded to many inquiries, provided expert counsel, or shared their unpublished data: Paul Consroe, Geoffrey Levitt, Raphael Mechoulam, Richard Musty, David Pate, Roger

Pertwee, Clara Sanudo-Peña, Carl Soderstrom, J. Michael Walker, and Scott Yarnell. Miriam Davis, consultant to the study team, provided excellent written material for the chapter on cannabinoid drug development.

The reviewers for the report (see page iv) provided extensive, constructive suggestions for improving the report. It was greatly enhanced by their thoughtful attention. Many of these people assisted us through many iterations of the report. All of them made contributions that were essential to the strength of the report. At the same time, it must be emphasized that responsibility for the final content of report rests entirely with the authors and the Institute of Medicine.

We would also like to thank the people who hosted our visits to their organizations. They were unfailingly helpful and generous with their time. Jeffrey Jones and members of the Oakland Cannabis Buyers' Cooperative, Denis Peron of the San Francisco Cannabis Cultivators Club, Scott Imler and staff at the Los Angeles Cannabis Resource Center, Victor Hernandez and members of Californians Helping Alleviate Medical Problems (CHAMPS), Michael Weinstein of the AIDS Health Care Foundation, and Marsha Bennett of the Louisiana State University Medical Center. We also appreciate the many people who spoke at the public workshops or wrote to share their views on the medical use of marijuana (see Appendix A).

Jane Sanville, project officer for the study sponsor, was consistently helpful during the many negotiations and discussion held throughout the study process. Many Institute of Medicine staff members provided greatly appreciated administrative, research, and intellectual support during the study. Robert Cook-Deegan, Marilyn Field, Constance Pechura, Daniel Quinn, and Michael Stoto provided thoughtful and insightful comments on draft sections of the report. Others provided advice and consultation on many other aspects of the study process: Clyde Behney, Susan Fourt, Carolyn Fulco, Carlos Gabriel, Linda Kilroy, Catharyn Liverman, Dev Mani, and Kathleen Stratton. As project assistant throughout the study, Amelia Mathis was tireless, gracious, and reliable.

Deborah Yarnell's contribution as research associate for this study was outstanding. She organized site visits, researched and drafted technical material for the report, and consulted extensively with relevant experts to ensure the technical accuracy of the text. The quality of her contributions throughout this study was exemplary.

Finally, the principal investigators on this study wish to personally thank Janet Joy for her deep commitment to the science and shape of this report. In addition, her help in integrating the entire data gathering and information organization of this report was nothing short of essential. Her knowledge of neurobiology, her sense of quality control, and her unflinching spirit over the 18 months illuminated the subjects and were indispensable to the study's successful completion.

MARIJUANA AND MEDICINE

Executive Summary

Public opinion on the medical value of marijuana has been sharply divided. Some dismiss medical marijuana as a hoax that exploits our natural compassion for the sick; others claim it is a uniquely soothing medicine that has been withheld from patients through regulations based on false claims. Proponents of both views cite “scientific evidence” to support their views and have expressed those views at the ballot box in recent state elections. In January 1997, the White House Office of National Drug Control Policy (ONDCP) asked the Institute of Medicine (IOM) to conduct a review of the scientific evidence to assess the potential health benefits and risks of marijuana and its constituent cannabinoids (see the Statement of Task on page 9). That review began in August 1997 and culminates with this report.

The ONDCP request came in the wake of state “medical marijuana” initiatives. In November 1996, voters in California and Arizona passed referenda designed to permit the use of marijuana as medicine. Although Arizona’s referendum was invalidated five months later, the referenda galvanized a national response. In November 1998, voters in six states (Alaska, Arizona, Colorado, Nevada, Oregon, and Washington) passed ballot initiatives in support of medical marijuana. (The Colorado vote will not count, however, because after the vote was taken a court ruling determined there had not been enough valid signatures to place the initiative on the ballot.)

Can marijuana relieve health problems? Is it safe for medical use?

Those straightforward questions are embedded in a web of social concerns, most of which lie outside the scope of this report. Controversies concerning the nonmedical use of marijuana spill over into the medical marijuana debate and obscure the real state of scientific knowledge. In contrast with the many disagreements bearing on social issues, the study team found substantial consensus among experts in the relevant disciplines on the scientific evidence about potential medical uses of marijuana.

This report summarizes and analyzes what is known about the medical use of marijuana; it emphasizes evidence-based medicine (derived from knowledge and experience informed by rigorous scientific analysis), as opposed to belief-based medicine (derived from judgment, intuition, and beliefs untested by rigorous science).

Throughout this report, *marijuana* refers to unpurified plant substances, including leaves or flower tops whether consumed by ingestion or smoking. References to the “effects of marijuana” should be understood to include the composite effects of its various components; that is, the effects of tetrahydrocannabinol (THC), which is the primary psychoactive ingredient in marijuana, are included among its effects, but not all the effects of marijuana are necessarily due to THC. *Cannabinoids* are the group of compounds related to THC, whether found in the marijuana plant, in animals, or synthesized in chemistry laboratories.

Three focal concerns in evaluating the medical use of marijuana are:

1. Evaluation of the effects of isolated cannabinoids;
2. Evaluation of the risks associated with the medical use of marijuana; and
3. Evaluation of the use of smoked marijuana.

EFFECTS OF ISOLATED CANNABINOIDS

Cannabinoid Biology

Much has been learned since the 1982 IOM report *Marijuana and Health*. Although it was clear then that most of the effects of marijuana were due to its actions on the brain, there was little information about how THC acted on brain cells (neurons), which cells were affected by THC, or even what general areas of the brain were most affected by THC. In addition, too little was known about cannabinoid physiology to offer any scientific insights into the harmful or therapeutic effects of marijuana. That all changed with the identification and characterization of cannabinoid receptors in the 1980s and 1990s. During the past 16 years, science has advanced greatly and can tell us much more about the potential medical benefits of cannabinoids.

CONCLUSION: At this point, our knowledge about the biology of marijuana and cannabinoids allows us to make some general conclusions:

- Cannabinoids likely have a natural role in pain modulation, control of movement, and memory.
- The natural role of cannabinoids in immune systems is likely multi-faceted and remains unclear.
- The brain develops tolerance to cannabinoids.
- Animal research demonstrates the potential for dependence, but this potential is observed under a narrower range of conditions than with benzodiazepines, opiates, cocaine, or nicotine.
- Withdrawal symptoms can be observed in animals but appear to be mild compared to opiates or benzodiazepines, such as diazepam (Valium).

CONCLUSION: The different cannabinoid receptor types found in the body appear to play different roles in normal human physiology. In addition, some effects of cannabinoids appear to be independent of those receptors. The variety of mechanisms through which cannabinoids can influence human physiology underlies the variety of potential therapeutic uses for drugs that might act selectively on different cannabinoid systems.

RECOMMENDATION 1: Research should continue into the physiological effects of synthetic and plant-derived cannabinoids and the natural function of cannabinoids found in the body. Because different cannabinoids appear to have different effects, cannabinoid research should include, but not be restricted to, effects attributable to THC alone.

Efficacy of Cannabinoid Drugs

The accumulated data indicate a potential therapeutic value for cannabinoid drugs, particularly for symptoms such as pain relief, control of nausea and vomiting, and appetite stimulation. The therapeutic effects of cannabinoids are best established for THC, which is generally one of the two most abundant of the cannabinoids in marijuana. (Cannabidiol is generally the other most abundant cannabinoid.)

The effects of cannabinoids on the symptoms studied are generally modest, and in most cases there are more effective medications. However, people vary in their responses to medications, and there will likely always be a subpopulation of patients who do not respond well to other

medications. The combination of cannabinoid drug effects (anxiety reduction, appetite stimulation, nausea reduction, and pain relief) suggests that cannabinoids would be moderately well suited for particular conditions, such as chemotherapy-induced nausea and vomiting and AIDS wasting.

Defined substances, such as purified cannabinoid compounds, are preferable to plant products, which are of variable and uncertain composition. Use of defined cannabinoids permits a more precise evaluation of their effects, whether in combination or alone. Medications that can maximize the desired effects of cannabinoids and minimize the undesired effects can very likely be identified.

Although most scientists who study cannabinoids agree that the pathways to cannabinoid drug development are clearly marked, there is no guarantee that the fruits of scientific research will be made available to the public for medical use. Cannabinoid-based drugs will only become available if public investment in cannabinoid drug research is sustained and if there is enough incentive for private enterprise to develop and market such drugs.

CONCLUSION: Scientific data indicate the potential therapeutic value of cannabinoid drugs, primarily THC, for pain relief, control of nausea and vomiting, and appetite stimulation; smoked marijuana, however, is a crude THC delivery system that also delivers harmful substances.

RECOMMENDATION 2: Clinical trials of cannabinoid drugs for symptom management should be conducted with the goal of developing rapid-onset, reliable, and safe delivery systems.

Influence of Psychological Effects on Therapeutic Effects

The psychological effects of THC and similar cannabinoids pose three issues for the therapeutic use of cannabinoid drugs. First, for some patients—particularly older patients with no previous marijuana experience—the psychological effects are disturbing. Those patients report experiencing unpleasant feelings and disorientation after being treated with THC, generally more severe for oral THC than for smoked marijuana. Second, for conditions such as movement disorders or nausea, in which anxiety exacerbates the symptoms, the antianxiety effects of cannabinoid drugs can influence symptoms indirectly. This can be beneficial or can create false impressions of the drug effect. Third, for cases in which symptoms are multifaceted, the combination of THC effects might provide a form of adjunctive therapy; for example, AIDS wasting patients would likely benefit from a medication that simultaneously reduces anxiety, pain, and nausea while stimulating appetite.

CONCLUSION: The psychological effects of cannabinoids, such as anxiety reduction, sedation, and euphoria can influence their potential therapeutic value. Those effects are potentially undesirable for certain patients and situations and beneficial for others. In addition, psychological effects can complicate the interpretation of other aspects of the drug's effect.

RECOMMENDATION 3: Psychological effects of cannabinoids such as anxiety reduction and sedation, which can influence medical benefits, should be evaluated in clinical trials.

RISKS ASSOCIATED WITH MEDICAL USE OF MARIJUANA

Physiological Risks

Marijuana is not a completely benign substance. It is a powerful drug with a variety of effects. However, except for the harms associated with smoking, the adverse effects of marijuana use are within the range of effects tolerated for other medications. The harmful effects to individuals from the perspective of possible medical use of marijuana are not necessarily the same as the harmful physical effects of drug abuse. When interpreting studies purporting to show the harmful effects of marijuana, it is important to keep in mind that the majority of those studies are based on *smoked* marijuana, and cannabinoid effects cannot be separated from the effects of inhaling smoke from burning plant material and contaminants.

For most people the primary adverse effect of *acute* marijuana use is diminished psychomotor performance. It is, therefore, inadvisable to operate any vehicle or potentially dangerous equipment while under the influence of marijuana, THC, or any cannabinoid drug with comparable effects. In addition, a minority of marijuana users experience dysphoria, or unpleasant feelings. Finally, the short-term immunosuppressive effects are not well established but, if they exist, are not likely great enough to preclude a legitimate medical use.

The *chronic* effects of marijuana are of greater concern for medical use and fall into two categories: the effects of chronic smoking and the effects of THC. Marijuana smoking is associated with abnormalities of cells lining the human respiratory tract. Marijuana smoke, like tobacco smoke, is associated with increased risk of cancer, lung damage, and poor pregnancy outcomes. Although cellular, genetic, and human studies all suggest that marijuana smoke is an important risk factor for the development of respiratory cancer, proof that habitual marijuana smoking does or does not cause cancer awaits the results of well-designed studies.

CONCLUSION: Numerous studies suggest that marijuana smoke is an important risk factor in the development of respiratory disease.

RECOMMENDATION 4: Studies to define the individual health risks of smoking marijuana should be conducted, particularly among populations in which marijuana use is prevalent.

Marijuana Dependence and Withdrawal

A second concern associated with chronic marijuana use is dependence on the psychoactive effects of THC. Although few marijuana users develop dependence, some do. Risk factors for marijuana dependence are similar to those for other forms of substance abuse. In particular, anti-social personality and conduct disorders are closely associated with substance abuse.

CONCLUSION: A distinctive marijuana withdrawal syndrome has been identified, but it is mild and short lived. The syndrome includes restlessness, irritability, mild agitation, insomnia, sleep disturbance, nausea, and cramping.

Marijuana as a “Gateway” Drug

Patterns in progression of drug use from adolescence to adulthood are strikingly regular. Because it is the most widely used illicit drug, marijuana is predictably the first illicit drug most people encounter. Not surprisingly, most users of other illicit drugs have used marijuana first. In fact, most drug users begin with alcohol and nicotine before marijuana—usually before they are of legal age.

In the sense that marijuana use typically precedes rather than follows initiation of other illicit drug use, it is indeed a “gateway” drug. But because underage smoking and alcohol use typically precede marijuana use, marijuana is not the most common, and is rarely the first, “gateway” to illicit drug use. There is no conclusive evidence that the drug effects of marijuana are causally linked to the subsequent abuse of other illicit drugs. An important caution is that data on drug use progression cannot be assumed to apply to the use of drugs for medical purposes. It does not follow from those data that if marijuana were available by prescription for medical use, the pattern of drug use would remain the same as seen in illicit use.

Finally, there is a broad social concern that sanctioning the medical use of marijuana might increase its use among the general population. At

this point there are no convincing data to support this concern. The existing data are consistent with the idea that this would not be a problem if the medical use of marijuana were as closely regulated as other medications with abuse potential.

CONCLUSION: Present data on drug use progression neither support nor refute the suggestion that medical availability would increase drug abuse. However, this question is beyond the issues normally considered for medical uses of drugs and should not be a factor in evaluating the therapeutic potential of marijuana or cannabinoids.

USE OF SMOKED MARIJUANA

Because of the health risks associated with smoking, smoked marijuana should generally not be recommended for long-term medical use. Nonetheless, for certain patients, such as the terminally ill or those with debilitating symptoms, the long-term risks are not of great concern. Further, despite the legal, social, and health problems associated with smoking marijuana, it is widely used by certain patient groups.

RECOMMENDATION 5: Clinical trials of marijuana use for medical purposes should be conducted under the following limited circumstances: trials should involve only short-term marijuana use (less than six months), should be conducted in patients with conditions for which there is reasonable expectation of efficacy, should be approved by institutional review boards, and should collect data about efficacy.

The goal of clinical trials of smoked marijuana would not be to develop marijuana as a licensed drug but rather to serve as a first step toward the possible development of nonsmoked rapid-onset cannabinoid delivery systems. However, it will likely be many years before a safe and effective cannabinoid delivery system, such as an inhaler, is available for patients. In the meantime there are patients with debilitating symptoms for whom smoked marijuana might provide relief. The use of smoked marijuana for those patients should weigh both the expected efficacy of marijuana and ethical issues in patient care, including providing information about the known and suspected risks of smoked marijuana use.

RECOMMENDATION 6: Short-term use of smoked marijuana (less than six months) for patients with debilitating symptoms (such as intractable pain or vomiting) must meet the following conditions:

- **failure of all approved medications to provide relief has been documented,**
- **the symptoms can reasonably be expected to be relieved by rapid-onset cannabinoid drugs,**
- **such treatment is administered under medical supervision in a manner that allows for assessment of treatment effectiveness, and**
- **involves an oversight strategy comparable to an institutional review board process that could provide guidance within 24 hours of a submission by a physician to provide marijuana to a patient for a specified use.**

Until a nonsmoked rapid-onset cannabinoid drug delivery system becomes available, we acknowledge that there is no clear alternative for people suffering from *chronic* conditions that might be relieved by smoking marijuana, such as pain or AIDS wasting. One possible approach is to treat patients as *n*-of-1 clinical trials (single-patient trials), in which patients are fully informed of their status as experimental subjects using a harmful drug delivery system and in which their condition is closely monitored and documented under medical supervision, thereby increasing the knowledge base of the risks and benefits of marijuana use under such conditions.

STATEMENT OF TASK

The study will assess what is currently known and not known about the medical use of marijuana. It will include a review of the science base regarding the mechanism of action of marijuana, an examination of the peer-reviewed scientific literature on the efficacy of therapeutic uses of marijuana, and the costs of using various forms of marijuana versus approved drugs for specific medical conditions (e.g., glaucoma, multiple sclerosis, wasting diseases, nausea, and pain).

The study will also include an evaluation of the acute and chronic effects of marijuana on health and behavior; a consideration of the adverse effects of marijuana use compared with approved drugs; an evaluation of the efficacy of different delivery systems for marijuana (e.g., inhalation vs. oral); an analysis of the data concerning marijuana as a gateway drug; and an examination of the possible differences in the effects of marijuana due to age and type of medical condition.

Specific Issues

Specific issues to be addressed fall under three broad categories: science base, therapeutic use, and economics.

Science Base

- Review of the neuroscience related to marijuana, particularly the relevance of new studies on addiction and craving
- Review of the behavioral and social science base of marijuana use, particularly an assessment of the relative risk of progression to other drugs following marijuana use
- Review of the literature determining which chemical components of crude marijuana are responsible for possible therapeutic effects and for side effects

Therapeutic Use

- Evaluation of any conclusions on the medical use of marijuana drawn by other groups
- Efficacy and side effects of various delivery systems for marijuana compared to existing medications for glaucoma, wasting syndrome, pain, nausea, or other symptoms
- Differential effects of various forms of marijuana that relate to age or type of disease

Economics

- Costs of various forms of marijuana compared with costs of existing medications for glaucoma, wasting syndrome, pain, nausea, or other symptoms
- Assessment of differences between marijuana and existing medications in terms of access and availability

RECOMMENDATIONS

RECOMMENDATION 1: Research should continue into the physiological effects of synthetic and plant-derived cannabinoids and the natural function of cannabinoids found in the body. Because different cannabinoids appear to have different effects, cannabinoid research should include, but not be restricted to, effects attributable to THC alone.

Scientific data indicate the potential therapeutic value of cannabinoid drugs for pain relief, control of nausea and vomiting, and appetite stimulation. This value would be enhanced by a rapid onset of drug effect.

RECOMMENDATION 2: Clinical trials of cannabinoid drugs for symptom management should be conducted with the goal of developing rapid-onset, reliable, and safe delivery systems.

The psychological effects of cannabinoids are probably important determinants of their potential therapeutic value. They can influence symptoms indirectly which could create false impressions of the drug effect or be beneficial as a form of adjunctive therapy.

RECOMMENDATION 3: Psychological effects of cannabinoids such as anxiety reduction and sedation, which can influence medical benefits, should be evaluated in clinical trials.

Numerous studies suggest that marijuana smoke is an important risk factor in the development of respiratory diseases, but the data that could conclusively establish or refute this suspected link have not been collected.

RECOMMENDATION 4: Studies to define the individual health risks of smoking marijuana should be conducted, particularly among populations in which marijuana use is prevalent.

Because marijuana is a crude THC delivery system that also delivers harmful substances, smoked marijuana should generally not be recom-

mended for medical use. Nonetheless, marijuana is widely used by certain patient groups, which raises both safety and efficacy issues.

RECOMMENDATION 5: Clinical trials of marijuana use for medical purposes should be conducted under the following limited circumstances: trials should involve only short-term marijuana use (less than six months), should be conducted in patients with conditions for which there is reasonable expectation of efficacy, should be approved by institutional review boards, and should collect data about efficacy.

If there is any future for marijuana as a medicine, it lies in its isolated components, the cannabinoids and their synthetic derivatives. Isolated cannabinoids will provide more reliable effects than crude plant mixtures. Therefore, the purpose of clinical trials of smoked marijuana would not be to develop marijuana as a licensed drug but rather to serve as a first step toward the development of nonsmoked rapid-onset cannabinoid delivery systems.

RECOMMENDATION 6: Short-term use of smoked marijuana (less than six months) for patients with debilitating symptoms (such as intractable pain or vomiting) must meet the following conditions:

- **failure of all approved medications to provide relief has been documented,**
- **the symptoms can reasonably be expected to be relieved by rapid-onset cannabinoid drugs,**
- **such treatment is administered under medical supervision in a manner that allows for assessment of treatment effectiveness, and**
- **involves an oversight strategy comparable to an institutional review board process that could provide guidance within 24 hours of a submission by a physician to provide marijuana to a patient for a specified use.**

1

Introduction

This report summarizes and analyzes what is known about the medical use of marijuana; it emphasizes evidence-based medicine (derived from knowledge and experience informed by rigorous scientific analysis), as opposed to belief-based medicine (derived from judgment, intuition, and beliefs untested by rigorous science).

Scientific data on controversial subjects are commonly misinterpreted, overinterpreted, and misrepresented, and the medical marijuana debate is no exception. We have tried to present the scientific studies in such a way as to reveal their strengths and limitations. One of the goals of this report is to help people to understand the scientific data, including the logic behind the scientific conclusions, so it goes into greater detail than previous reports on the subject. In many cases, we have explained why particular studies are inconclusive and what sort of evidence is needed to support particular claims about the harms or benefits attributed to marijuana. Ideally, this report will enable the thoughtful reader to interpret new information about marijuana that will continue to emerge rapidly well after this report is published.

Can marijuana relieve health problems? Is it safe for medical use? Those straightforward questions are embedded in a web of social concerns, which lie outside the scope of this report. Controversies concerning nonmedical use of marijuana spill over onto the medical marijuana debate and tend to obscure the real state of scientific knowledge. In contrast

with the many disagreements bearing on the social issues, the study team found substantial consensus, among experts in the relevant disciplines, on the scientific evidence bearing on potential medical use. This report analyzes science, not the law. As in any policy debate, the value of scientific analysis is that it can provide a foundation for further discussion. Distilling scientific evidence does not in itself solve a policy problem. What it can do is illuminate the common ground, bringing to light fundamental differences out of the shadows of misunderstanding and misinformation that currently prevail. Scientific analysis cannot be the end of the debate, but it should at least provide the basis for an honest and informed discussion.

Our analysis of the evidence and arguments concerning the medical use of marijuana focuses on the strength of the supporting evidence and does not refer to the motivations of people who put forth the evidence and arguments. That is, it is not relevant to scientific validity whether an argument is put forth by someone who believes that all marijuana use should be legal or by someone who believes that any marijuana use is highly damaging to individual users and to society as a whole. Nor does this report comment on the degree to which scientific analysis is compatible with current regulatory policy. Although many have argued that current drug laws pertaining to marijuana are inconsistent with scientific data, it is important to understand that decisions about drug regulation are based on a variety of moral and social considerations, as well as on medical and scientific ones.

Even when a drug is used only for medical purposes, value judgments affect policy decisions concerning its medical use. For example, the magnitude of a drug's expected medical benefit affects regulatory judgments about the acceptability of risks associated with its use. Also, although a drug is normally approved for medical use only on proof of its "safety and efficacy," patients with life-threatening conditions are sometimes (under protocols for "compassionate use") allowed access to unapproved drugs whose benefits and risks are uncertain. Value judgments play an even more substantial role in regulatory decisions concerning drugs, such as marijuana, that are sought and used for nonmedical purposes. Then policymakers must take into account not only the risks and benefits associated with medical use but also possible interactions between the regulatory arrangements governing medical use and the integrity of the legal controls set up to restrict nonmedical use.

It should be clear that many elements of drug control policy lie outside the realm of biology and medicine. Ultimately, the complex moral and social judgments that underlie drug control policy must be made by the American people and their elected officials. A goal of this report is to

evaluate the biological and medical factors that should be taken into account in making those judgments.

HOW THIS STUDY WAS CONDUCTED

Information was gathered through scientific workshops, site visits, analysis of the relevant scientific literature, and extensive consultation with biomedical and social scientists. The three 2-day workshops—in Irvine, California; New Orleans, Louisiana; and Washington, D.C.—were open to the public and included scientific presentations and reports, mostly from patients and their families, about their experiences with and perspectives on the medical use of marijuana. Scientific experts in various fields were selected to talk about the latest research on marijuana, cannabinoids, and related topics (listed in Appendix B). Selection of the experts was based on recommendations by their peers, who ranked them among the most accomplished scientists and the most knowledgeable about marijuana and cannabinoids in their own fields. In addition, advocates for (John Morgan) and against (Eric A. Voth) the medical use of marijuana were invited to present scientific evidence in support of their positions.

Information presented at the scientific workshops was supplemented by analysis of the scientific literature and evaluating the methods used in various studies and the validity of the authors' conclusions. Different kinds of clinical studies are useful in different ways: results of a controlled double-blind study with adequate sample sizes can be expected to apply to the general population from which study subjects were drawn; an isolated case report can suggest further studies but cannot be presumed to be broadly applicable; and survey data can be highly informative but are generally limited by the need to rely on self-reports of drug use and on unconfirmed medical diagnoses. This report relies mainly on the most relevant and methodologically rigorous studies available and treats the results of more limited studies cautiously. In addition, study results are presented in such a way as to allow thoughtful readers to judge the results themselves.

The Institute of Medicine (IOM) appointed a panel of nine experts to advise the study team on technical issues. These included neurology and the treatment of pain (Howard Fields); regulation of prescription drugs (J. Richard Crout); AIDS wasting and clinical trials (Judith Feinberg); treatment and pathology of multiple sclerosis (Timothy Vollmer); drug dependence among adolescents (Thomas Crowley); varieties of drug dependence (Dorothy Hatsukami); internal medicine, health care delivery, and clinical epidemiology (Eric B. Larson); cannabinoids and marijuana pharmacology (Billy R. Martin); and cannabinoid neuroscience (Steven R. Childers).

Public outreach included setting up a Web site that provided information about the study and asked for input from the public. The Web site was open for comment from November 1997 until November 1998. Some 130 organizations were invited to participate in the public workshops. Many people in the organizations—particularly those opposed to the medical use of marijuana—felt that a public forum was not conducive to expressing their views; they were invited to communicate their opinions (and reasons for holding them) by mail or telephone. As a result, roughly equal numbers of persons and organizations opposed to and in favor of the medical use of marijuana were heard from.

The study team visited four cannabis buyers' clubs in California (the Oakland Cannabis Buyers' Cooperative, the San Francisco Cannabis Cultivators Club, the Los Angeles Cannabis Resource Center, and Californians Helping Alleviate Medical Problems, or CHAMPS) and two HIV/AIDS clinics (AIDS Health Care Foundation in Los Angeles and Louisiana State University Medical Center in New Orleans). We listened to many individual stories from the buyers' clubs about using marijuana to treat a variety of symptoms and heard clinical observations on the use of Marinol to treat AIDS patients. Marinol is the brand name for dronabinol, which is Δ^9 -tetrahydrocannabinol (THC) in pill form and is available by prescription for the treatment of nausea associated with chemotherapy and AIDS wasting.

MARIJUANA TODAY

The Changing Legal Landscape

In the 20th century, marijuana has been used more for its euphoric effects than as a medicine. Its psychological and behavioral effects have concerned public officials since the drug first appeared in the southwestern and southern states during the first two decades of the century. By 1931, at least 29 states had prohibited use of the drug for nonmedical purposes.³ Marijuana was first regulated at the federal level by the Marijuana Tax Act of 1937, which required anyone producing, distributing, or using marijuana for medical purposes to register and pay a tax and which effectively prohibited nonmedical use of the drug. Although the act did not make medical use of marijuana illegal, it did make it expensive and inconvenient. In 1942, marijuana was removed from the U.S. Pharmacopoeia because it was believed to be a harmful and addictive drug that caused psychoses, mental deterioration, and violent behavior.

In the late 1960s and early 1970s, there was a sharp increase in marijuana use among adolescents and young adults. The current legal status of marijuana was established in 1970 with the passage of the Controlled

Medical Marijuana Legislation Among the States

The 1996 California referendum known as Proposition 215 allowed seriously ill Californians to obtain and use marijuana for medical purposes without criminal prosecution or sanction. A physician's recommendation is needed. Under the law, physicians cannot be punished or denied any right or privilege for recommending marijuana to patients who suffer from any illness for which marijuana will provide relief.

The 1996 Arizona referendum known as Proposition 200 was largely about prison reform but also gave physicians the option to prescribe controlled substances, including those in Schedule I (e.g., marijuana), to treat the disease or relieve the suffering of seriously or terminally ill patients. Five months after the referendum was passed, it was stalled when Arizona legislators voted that all prescription medications must be approved by the Food and Drug Administration, and marijuana is not so approved. In November 1998, Arizona voters passed a second referendum designed to allow physician's to prescribe marijuana as medicine, but this is still at odds with federal law.⁸

As of summer 1998, eight states—California, Connecticut, Louisiana, New Hampshire, Ohio, Vermont, Virginia, and Wisconsin—had laws that permit physicians to prescribe marijuana for medical purposes or to allow a medical necessity defense.⁸ In November 1998, five states—Arizona, Alaska, Oregon, Nevada, and Washington—passed medical marijuana ballot initiatives. The District of Columbia also voted on a medical marijuana initiative, but was barred from counting the votes because an amendment designed to prohibit them from doing so was added to the federal appropriations bill; however, exit polls suggested that a majority of voters had approved the measure.

Substances Act, which divided drugs into five schedules and placed marijuana in Schedule I, the category for drugs with high potential for abuse and no accepted medical use (see Appendix C, Scheduling Definitions). In 1972, the National Organization for the Reform of Marijuana Legislation (NORML), an organization that supports decriminalization of marijuana, unsuccessfully petitioned the Bureau of Narcotics and Dangerous Drugs to move marijuana from Schedule I to Schedule II. NORML argued that marijuana is therapeutic in numerous serious ailments, less toxic, and in many cases more effective than conventional medicines.¹³ Thus, for 25 years the medical marijuana movement has been closely linked with the marijuana decriminalization movement, which has colored the debate. Many people criticized that association in their letters to IOM and during the public workshops of this study. The argument against the medical use

of marijuana presented most often to the IOM study team was that “the medical marijuana movement is a Trojan horse”; that is, it is a deceptive tactic used by advocates of marijuana decriminalization who would exploit the public’s sympathy for seriously ill patients.

Since NORML’s petition in 1972, there have been a variety of legal decisions concerning marijuana. From 1973 to 1978, 11 states adopted statutes that decriminalized use of marijuana, although some of them recriminalized marijuana use in the 1980s and 1990s. During the 1970s, reports of the medical value of marijuana began to appear, particularly claims that marijuana relieved the nausea associated with chemotherapy. Health departments in six states conducted small studies to investigate the reports. When the AIDS epidemic spread in the 1980s, patients found that marijuana sometimes relieved their symptoms, most dramatically those associated with AIDS wasting. Over this period a number of defendants charged with unlawful possession of marijuana claimed that they were using the drug to treat medical conditions and that violation of the law was therefore justified (the so-called medical necessity defense). Although most courts rejected these claims, some accepted them.⁸

Against that backdrop, voters in California and Arizona in 1996 passed two referenda that attempted to legalize the medical use of marijuana under particular conditions. Public support for patient access to marijuana for medical use appears substantial; public opinion polls taken during 1997 and 1998 generally reported 60–70 percent of respondents in favor of allowing medical uses of marijuana.¹⁵ However, those referenda are at odds with federal laws regulating marijuana, and their implementation raises complex legal questions.

Despite the current level of interest, referenda and public discussions have not been well informed by carefully reasoned scientific debate. Although previous reports have all called for more research, the nature of the research that will be most helpful depends greatly on the specific health conditions to be addressed. And while there have been important recent advances in our understanding of the physiological effects of marijuana, few of the recent investigators have had the time or resources to permit detailed analysis. The results of those advances, only now beginning to be explored, have significant implications for the medical marijuana debate.

Several months after the passage of the California and Arizona medical marijuana referendums, the Office of National Drug Control Policy (ONDCP) asked whether IOM would conduct a scientific review of the medical value of marijuana and its constituent compounds. In August 1997, IOM formally began the study and appointed John A. Benson Jr. and Stanley J. Watson Jr. to serve as principal investigators for the study.

The charge to IOM was to review the medical use of marijuana and the harms and benefits attributed to it (details are given in Appendix D).

MARIJUANA AND MEDICINE

Marijuana plants have been used since antiquity for both herbal medication and intoxication. The current debate over the medical use of marijuana is essentially a debate over the value of its medicinal properties relative to the risk posed by its use.

Marijuana's use as an herbal remedy before the 20th century is well documented.^{1,10,11} However, modern medicine adheres to different standards from those used in the past. The question is not whether marijuana can be used as an herbal remedy but rather how well this remedy meets today's standards of efficacy and safety. We understand much more than previous generations about medical risks. Our society generally expects its licensed medications to be safe, reliable, and of proven efficacy; contaminants and inconsistent ingredients in our health treatments are not tolerated. That refers not only to prescription and over-the-counter drugs but also to vitamin supplements and herbal remedies purchased at the grocery store. For example, the essential amino acid *l*-tryptophan was widely sold in health food stores as a natural remedy for insomnia until early 1990 when it became linked to an epidemic of a new and potentially fatal illness (eosinophilia-myalgia syndrome).^{9,12} When it was removed from the market shortly thereafter, there was little protest, despite the fact that it was safe for the vast majority of the population. The 1,536 cases and 27 deaths were later traced to contaminants in a batch produced by a single Japanese manufacturer.

Although few herbal medicines meet today's standards, they have provided the foundation for modern Western pharmaceuticals. Most current prescriptions have their roots either directly or indirectly in plant remedies.⁷ At the same time, most current prescriptions are synthetic compounds that are only distantly related to the natural compounds that led to their development. Digitalis was discovered in foxglove, morphine in poppies, and taxol in the yew tree. Even aspirin (acetylsalicylic acid) has its counterpart in herbal medicine: for many generations, American Indians relieved headaches by chewing the bark of the willow tree, which is rich in a related form of salicylic acid.

Although plants continue to be valuable resources for medical advances, drug development is likely to be less and less reliant on plants and more reliant on the tools of modern science. Molecular biology, bioinformatics software, and DNA array-based analyses of genes and chemistry are all beginning to yield great advances in drug discovery and development. Until recently, drugs could only be *discovered*; now they can

be *designed*. Even the discovery process has been accelerated through the use of modern drug-screening techniques. It is increasingly possible to identify or isolate the chemical compounds in a plant, determine which compounds are responsible for the plant's effects, and select the most effective and safe compounds—either for use as purified substances or as tools to develop even more effective, safer, or less expensive compounds.

Yet even as the modern pharmacological toolbox becomes more sophisticated and biotechnology yields an ever greater abundance of therapeutic drugs, people increasingly seek alternative, low-technology therapies.^{4,5} In 1997, 46 percent of Americans sought nontraditional medicines and spent over 27 billion unreimbursed dollars; the total number of visits to alternative medicine practitioners appears to have exceeded the number of visits to primary care physicians.^{5,6} Recent interest in the medical use of marijuana coincides with this trend toward self-help and a search for “natural” therapies. Indeed, several people who spoke at the IOM public hearings in support of the medical use of marijuana said that they generally preferred herbal medicines to standard pharmaceuticals. However, few alternative therapies have been carefully and systematically tested for safety and efficacy, as is required for medications approved by the FDA (Food and Drug Administration).²

WHO USES MEDICAL MARIJUANA?

There have been no comprehensive surveys of the demographics and medical conditions of medical marijuana users, but a few reports provide some indication. In each case, survey results should be understood to reflect the situation in which they were conducted and are not necessarily characteristic of medical marijuana users as a whole. Respondents to surveys reported to the IOM study team were all members of “buyers’ clubs,” organizations that provide their members with marijuana, although not necessarily through direct cash transactions. The atmosphere of the marijuana buyers’ clubs ranges from that of the comparatively formal and closely regulated Oakland Cannabis Buyers’ Cooperative to that of a “country club for the indigent,” as Denis Peron described the San Francisco Cannabis Cultivators Club (SFCCC), which he directed.

John Mendelson, an internist and pharmacologist at the University of California, San Francisco (UCSF) Pain Management Center, surveyed 100 members of the SFCCC who were using marijuana at least weekly. Most of the respondents were unemployed men in their forties. Subjects were paid \$50 to participate in the survey; this might have encouraged a greater representation of unemployed subjects. All subjects were tested for drug use. About half tested positive for marijuana only; the other half tested positive for drugs in addition to marijuana (23% for cocaine and 13% for

TABLE 1.1 Self-Reported Disorders Treated with Marijuana by Members of San Francisco Cannabis Cultivators Club

Disorder	No. of Subjects
HIV	60
Musculoskeletal disorders and arthritis	39
Psychiatric disorders (primarily depression)	27
Neurological disorders and nonmusculoskeletal pain syndromes	9
Gastrointestinal disorders (most often nausea)	7
Other disorders	
Glaucoma, allergies, nephrolithiasis, and the skin manifestations of Reiter syndrome	7
Total disorders	149
Total number of respondents	100

amphetamines). The predominant disorder was AIDS, followed by roughly equal numbers of members who reported chronic pain, mood disorders, and musculoskeletal disorders (Table 1.1).

The membership profile of the San Francisco club was similar to that of the Los Angeles Cannabis Resource Center (LACRC), where 83% of the 739 patients were men, 45% were 36–45 years old, and 71% were HIV positive. Table 1.2 shows a distribution of conditions somewhat different from that in SFCCC respondents, probably because of a different membership profile. For example, cancer is generally a disease that occurs late in life; 34 (4.7%) of LACRC members were over 55 years old; only 2% of survey respondents in the SFCCC study were over 55 years old.

Jeffrey Jones, executive director of the Oakland Cannabis Buyers' Cooperative, reported that its largest group of patients is HIV-positive men in their forties. The second-largest group is patients with chronic pain.

Among the 42 people who spoke at the public workshops or wrote to the study team, only six identified themselves as members of marijuana buyers' clubs. Nonetheless, they presented a similar profile: HIV/AIDS was the predominant disorder, followed by chronic pain (Tables 1.3 and 1.4). All HIV/AIDS patients reported that marijuana relieved nausea and vomiting and improved their appetite. About half the patients who reported using marijuana for chronic pain also reported that it reduced nausea and vomiting.

Note that the medical conditions referred to are only those reported to the study team or to interviewers; they cannot be assumed to represent complete or accurate diagnoses. Michael Rowbotham, a neurologist at the UCSF Pain Management Center, noted that many pain patients referred

TABLE 1.2 Self-Reported Disorders Treated with Marijuana by Members of Los Angeles Cannabis Resource Center (LACRC), According to Center Staff^a

Treated Disorder	No. of Subjects	% of Subjects
HIV ^b	528	71
Cancer	40	5.4
Terminal cancer	10	1.4
Mood disorders (depression)	4	0.5
Musculoskeletal (multiple sclerosis, arthritis)	30	4.1
Chronic pain and back pain	33	4.5
Gastrointestinal	7	2.3
Neurological disorders (epilepsy, Tourette syndrome, brain trauma)	7	0.9
Seizures or migraines ^c	13	1.8
Glaucoma	15	2.0
Miscellaneous	42	5.7
Total number	739	100

^aResults are based on a review of 739 individual records by LACRC staff members. In contrast with Mendelson's survey of San Francisco Cannabis Cultivators Club (Table 1.1), only the primary disorder is indicated here. Membership in LACRC is contingent on a doctor's letter of acknowledgment, but diagnoses are not independently confirmed.

^bHIV patients use marijuana to control nausea, increase appetite (to combat wasting), and relieve gastrointestinal distress caused by AIDS medications. These uses are not indicated separately.

^cAs described by LACRC staff, some of these cases might also be neurological disorders.

to that center arrive with incorrect diagnoses or with pain of unknown origin. At that center the patients who report medical benefit from marijuana say that it does not reduce their pain but enables them to cope with it.

Most—not all—people who use marijuana to relieve medical conditions have previously used it recreationally. An estimated 95% of the LACRC members had used marijuana before joining the club. It is important to emphasize the absence of comprehensive information on marijuana use before its use for medical conditions. Frequency of prior use almost certainly depends on many factors, including membership in a buyers' club, membership in a population sector that uses marijuana more often than others (for example, men 20–30 years old), and the medical condition being treated with marijuana (for example, there are probably relatively fewer recreational marijuana users among cancer patients than among AIDS patients).

TABLE 1.3 Summary of Reports to IOM Study Team by 43 Individuals

Symptoms	Dominant Disease	Symptoms	Dominant Disease
Anorexia, nausea, vomiting	AIDS	Pain	Migraine
	AIDS		Injury
	AIDS		Injury
	AIDS		Epilepsy and postpolio syndrome
	AIDS		Trauma and epilepsy
	AIDS		Degenerative disk disease
	AIDS		Rheumatoid arthritis
	AIDS and cancer		Nail-patella syndrome
	Cancer		Reflex sympathetic dystrophy
	Testicular cancer		Gulf War chemical exposure
	Cancer and multiple sclerosis		Multiple congenital cartilaginous exostosis
	Thyroid condition ^a		Histiocytosis X
	Migraine		
Wilson’s disease			
Mood disorders	Depression	Muscle spasticity	Spasticity ^a
	Depression		Multiple sclerosis
	Depression and anxiety		Multiple sclerosis
	Depression and anxiety		Multiple sclerosis
	Manic depression		Paralysis
		Spinal-cord injury	
		Spasmodic torticollis	
		Intraocular pressure	Glaucoma
		Diarrhea	Crohn’s disease

^aNot specified.

NOTE: This table lists the people who reported to the IOM study team during the public workshops, or through letters, that they use marijuana as medicine; it should not be interpreted as a representative sample of the full spectrum of people who use marijuana as medicine. Each dominant disease represents an individual report.

Patients who reported their experience with marijuana at the public workshops said that marijuana provided them with great relief from symptoms associated with disparate diseases and ailments, including AIDS wasting, spasticity from multiple sclerosis, depression, chronic pain, and nausea associated with chemotherapy. Their circumstances and symptoms were varied, and the IOM study team was not in a position to make medical evaluations or confirm diagnoses. Three representative cases presented to the IOM study team are presented in Box 1.1; the stories have been edited for brevity, but each case is presented in the patient’s words and with the patient’s permission.

TABLE 1.4 Primary Symptoms of 43 Individuals Who Reported to IOM Study Team

Primary Symptom	Symptom Frequency		Multiple Symptoms	
	No. of Reports ^a	% of Total Symptoms Reported	No. Who Reported (primary) Additional Symptoms	% of Those Who Reported Primary Symptoms
Anorexia, nausea, vomiting	21	31	13	62
Diarrhea	4	6	3	75
Intraocular pressure	2	3	1	50
Mood disorders	12	18	7	58
Muscle spasticity	12	18	7	58
Pain	16	24	13	81
Total	67		44	66

^aForty-three persons reporting; 20 reported relief from more than one symptom.

The variety of stories presented left the study team with a clear view of people's beliefs about how marijuana had helped them. But this collection of anecdotal data, although useful, is limited. We heard many positive stories but no stories from people who had tried marijuana but found it ineffective. This is a fraction with an unknown denominator. For the numerator we have a sample of positive responses; for the denominator we have no idea of the total number of people who have tried marijuana for medical purposes. Hence, it is impossible to estimate the clinical value of marijuana or cannabinoids in the general population based on anecdotal reports. Marijuana clearly seems to relieve some symptoms for some people—even if only as a placebo effect. But what is the balance of harmful and beneficial effects? That is the essential medical question that can be answered only by careful analysis of data collected under controlled conditions.

CANNABIS AND THE CANNABINOIDS

Marijuana is the common name for *Cannabis sativa*, a hemp plant that grows throughout temperate and tropical climates. The most recent review of the constituents of marijuana lists 66 cannabinoids (Table 1.5).¹⁶ But that does not mean there are 66 different cannabinoid effects or interactions. Most of the cannabinoids are closely related; they fall into only 10

TABLE 1.5 Cannabinoids Identified in Marijuana

Cannabinoid Group	Common Abbreviation	No. of Known Variants in Each Group
Δ^9 -Tetrahydrocannabinol	Δ^9 -THC	9
Δ^8 -Tetrahydrocannabinol	Δ^8 -THC	2
Cannabichromene	CBC	5
Cannabicyclol	CBL	3
Cannabidiol	CBD	7
Cannabielsoin	CBE	5
Cannabigerol	CBG	6
Cannabinidiol	CBND	2
Cannabinol	CBN	7
Cannabitriol	CBT	9
Miscellaneous types		11
Total		66

groups of closely related cannabinoids, many of which differ by only a single chemical moiety and might be midpoints along biochemical pathways—that is, degradation products, precursors, or byproducts.^{16,18} Δ^9 -tetrahydrocannabinol (Δ^9 -THC) is the primary psychoactive ingredient; depending on the particular plant, either THC or cannabidiol is the most abundant cannabinoid in marijuana (Figure 1.1). Throughout this report, THC is used to indicate Δ^9 -THC. In the few cases where variants of THC are discussed, the full names are used. All the cannabinoids are lipophilic—they are highly soluble in fatty fluids and tissues but not in water. Indeed, THC is so lipophilic that it is aptly described as “greasy.”

Throughout this report, *marijuana* refers to unpurified plant extracts, including leaves and flower tops, regardless of how they are consumed—whether by ingestion or by smoking. References to the effects of marijuana should be understood to include the composite effects of its various components; that is, the effects of THC are included among the effects of marijuana, but not all the effects of marijuana are necessarily due to THC. Discussions concerning *cannabinoids* refer only to those particular compounds and not to the plant extract. This distinction is important; it is often blurred or exaggerated.

Cannabinoids are produced in epidermal glands on the leaves (especially the upper ones), stems, and the bracts that support the flowers of the marijuana plant. Although the flower itself has no epidermal glands, it has the highest cannabinoid content anywhere on the plant, probably because of the accumulation of resin secreted by the supporting bracteole

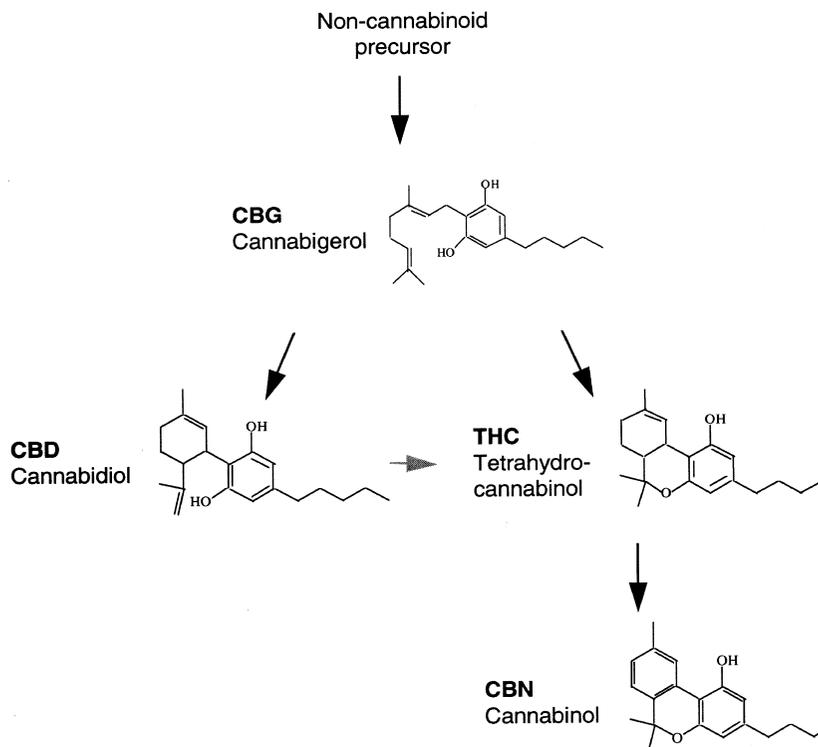

FIGURE 1.1 Cannabinoid biosynthesis. Arrows indicate cannabinoid biosynthesis pathway; dark arrows indicate established pathways; the light gray arrow indicates a probable but not well-established pathway (R. Mechoulam, Hebrew University, personal communication, 1999).¹¹ The great majority of studies reporting on the effects of cannabinoids refer to THC; most of the rest are about CBD and CBN. Other cannabinoids found in marijuana do not appear to play an important role in the drug's effects.

(the small leaf-like part below the flower). The amounts of cannabinoids and their relative abundance in a marijuana plant vary with growing conditions, including humidity, temperature, and soil nutrients (reviewed in Pate, 1994¹⁴). The chemical stability of cannabinoids in harvested plant material is also affected by moisture, temperature, sunlight, and storage. They degrade under any storage condition.

BOX 1.1 Selected Cases from the Public Sessions

G.S. spoke at the IOM workshop in Louisiana about his use of marijuana first to combat AIDS wasting syndrome and later for relief from the side effects of AIDS medications.

Skin rashes, dry mouth, foul metallic aftertaste, numbness of the face, swelling of the limbs, fever spikes, headaches, dizziness, anemia, clinical depression, neuropathy so crippling that I could not type, so painful that the bed sheets felt like sandpaper, nausea so severe that I sometimes had to leave the dinner table to vomit, and diarrhea so unpredictable that I dared not leave the house without diapers.

These are some of the horrors that I have endured in the past 10 years during my fight for life against the human immunodeficiency virus. But these ravages were not caused by HIV itself, or by any of the opportunistic infections that mark the steady progression of AIDS. Each of these nightmares was a side effect of one of the hundreds of medications I have taken to fight one infection after another on my way to a seemingly certain early grave.

Had you known me three years ago, you would not recognize me now. After years of final-stage AIDS, I had wasted to 130 lb. The purple Kaposi's sarcoma lesions were spreading. The dark circles under my eyes told of sleepless nights and half-waking days. I encountered passages of time marked by medication schedules, nausea, and diarrhea. I knew that I was dying. Every reflection shimmered with death, my ghost-like pallor in the mirror, the contained terror on the face of a bus passenger beside me, and most of all the resigned sadness in my mother's eyes.

But still I was fortunate because along the way I rediscovered the ancient understanding of marijuana's medicinal benefit. So I smoked pot. Every day. The pot calmed my stomach against handfuls of pills. The pot made me hungry so that I could eat without a tube. The pot eased the pain of crippling neural side effects so that I could dial the phone by myself. The pot calmed my soul and allowed me to accept that I would probably die soon. Because I smoked pot I lived long enough to see the development of the first truly effective HIV therapies. I lived to gain 50 lb., regain my vigor, and celebrate my 35th birthday. I lived to sit on the bus without frightening the passenger beside me.

Even at this stage of my recovery I take a handful of pills almost every day and will probably continue to do so for the rest of my life. While I am grateful for the life-saving protease inhibitor therapies, they bring with them a host of adverse reactions and undesirable side effects. Different patients experience different reactions, of course, but almost all patients experience some. Smoking marijuana relieves many of these side effects.

I am not one of the exceptional eight patients in the United States with

Continued

legal permission to smoke marijuana. Every day I risk arrest, property forfeiture, fines, and imprisonment. But I have no choice, you see, just as I have no choice but to endure the side effects of these toxic medications. So, many patients like me are breaking the law to enjoy relief that no other therapy provides.

I sit here, I believe, as living proof that marijuana can have a beneficial effect in staving off wasting. Every pound was a day. I figured that for every pound of body weight I could maintain, that was another day that I could live in hopes that some effective therapy would emerge.

* * *

B.D. spoke at the IOM workshop in Louisiana. She is one of eight patients who are legally allowed to smoke marijuana under a Compassionate Use Protocol. She uses marijuana to relieve nausea, muscle spasticity, and pain associated with multiple sclerosis.

I was diagnosed with multiple sclerosis in 1988. Prior to that, I was an active person with ballet and swimming. I now have a swimming pool, so I swim each and every day, and I smoke marijuana. The government has given me the marijuana to smoke. Each month I pick up a can filled with the marijuana cigarettes rolled by the government.

At one time I weighed 85 lb. and I now weigh 105. Twenty pounds is quite a bit to put on. I could not walk. I did not have the appetite. I use a scooter now for distance. I can get around the house. I have a standard poodle who is kind of like an assistant dog. She is good at it. She helps me.

When I found out that there was a program to get marijuana from the government, I decided that was the answer. I was not a marijuana smoker before that. In fact, I used to consider the people I knew who smoked the marijuana as undesirables. Now, I myself am an undesirable.

But it works. It takes away the backache. With multiple sclerosis, you can get spasms, and your leg will just go straight out and you cannot stop that leg. You may have danced all of your life and put the leg where you wanted it to be, but the MS takes that from you. So I use the swimming pool, and that helps a lot. The kicks are much less when I have smoked a marijuana cigarette. Since 1991, I've smoked 10 cigarettes a day. I do not take any other drugs. Marijuana seems to have been my helper. At one time, I did not think much of the people who smoke it. But when it comes to your health, it makes a big difference.

* * *

J.H. spoke at the IOM workshop in Washington, D.C. He was seriously injured in an accident, suffers from a form of arthritis associated with abnormal activity of the sympathetic nervous system known as reflex sympathetic dystrophy, and has hepatitis C. He uses marijuana to relieve nausea from liver disease, pain, and muscle spasms.

I am 48 years old, married with two children. I am a veteran who served during the Vietnam war. I was exposed to hepatitis C in 1972 by a blood

transfusion, which I needed because of a motor vehicle accident that broke my back; ruined my right shoulder, my left thumb, and hand; and almost amputated my right leg at the knee. My hepatitis C was not diagnosed until 1997—after the disease had destroyed my pancreas* and I had four heart attacks, one angioplasty, and a minor stroke. In 1989, while at work, I was involved in an accident with a large soil survey auger. My pelvis was crushed, and serious nerve damage was the result. I also have reflex sympathetic dystrophy, which is a neurological disease that has a tremendous amount of pain and muscle spasms.

I have reached what the doctors call end-stage liver disease from the hepatitis C. I have lost 85 lbs. due to the severe bouts of nausea and vomiting. Every time I come home from a hospital stay, my 7 year old asks if I got the liver transplant. I am on a transplant list, but I am not a candidate until I am seven days from death.

In October 1997, after trying four different anti-nausea medications, four of the doctors that I see told me to go to Europe and see a doctor and try medicinal cannabis. My primary care doctor wrote me a letter to carry with my medical records asking that the doctor help me in any way that he could to alleviate the symptoms of the hepatitis C and the reflex sympathetic dystrophy. Those symptoms are severe nausea and pain from the hepatitis C and pain and muscle spasms from the neurological disease.

I went to Europe in November 1997, where I saw a doctor of internal medicine. He prescribed me cannabis, 1–2 g a day. I got the medicine and a pipe and tried it. Within two minutes of taking two puffs from the pipe, the nausea was gone. I don't think that I felt the high, although I was quite elated. In about 45 min. I was starving. Normally, I have a fear of eating because I vomit almost always after I eat or take a pill. I forgot about that, and I think I ate more that night than I had eaten in months. I did feel a little nauseated after about four hours, but I smoked two more puffs, and in about two hours I went to bed. The next morning I felt hungry. During my nine-day stay in Europe, I was able to stay free of vomiting and the waves of nausea became less frequent.

I had experienced four years of pain control using Tegretol, a drug used by epileptics to control seizures. Now I can't use that medication because of the damage that it causes my cirrhotic liver. When I smoked about 2 g of marijuana a day, the nausea was gone and I was no longer losing weight. The pain was at an acceptable level. Sometimes I still find it necessary to use an opiate painkiller, but only when the pain is at its worst. Surprisingly, I lost an associated high within a few days. I also think the cannabis has an antidepressant effect on me, as I no longer have what I call the "poor me" feelings that I experienced after learning about the hepatitis C.

*This is an unlikely consequence of hepatitis C; it is more likely that the patient's liver was damaged.

ORGANIZATION OF THE REPORT

Throughout the report, steps that might be taken to fill the gaps in understanding both the potential harms and benefits of marijuana and cannabinoid use are identified. Those steps include identifying knowledge gaps, promising research directions, and potential therapies based on scientific advances in cannabinoid biology.

Chapter 2 reviews basic cannabinoid biology and provides a foundation to understand the medical value of marijuana or its constituent cannabinoids. In consideration of the physician's first rule, "first, do no harm," the potential harms attributed to the medical use of marijuana are reviewed before the potential medical benefits. Chapter 3 reviews the risks posed by marijuana use, with emphasis on medical use.

Chapter 4 analyzes the most credible clinical data relevant to the medical use of marijuana. It reviews what is known about the physiological mechanisms underlying particular conditions (for example, chronic pain, vomiting, anorexia, and muscle spasticity), what is known about the cellular actions of cannabinoids, and the levels of proof needed to show that marijuana is an effective treatment for specific symptoms. It does not analyze the historical literature; history is informative in enumerating uses of marijuana, but it does not provide the sort of information needed for a scientifically sound evaluation of the efficacy and safety of marijuana for clinical use. Because marijuana is advocated primarily as affording relief from the symptoms of disease rather than as a cure, this chapter is organized largely by symptoms as opposed to disease categories. Finally, chapter 4 compares the conclusions of this report with those of other recent reports on the medical use of marijuana.

Chapter 5 describes the process of and analyzes the prospects for cannabinoid drug development.

Cannabinoids and Animal Physiology

INTRODUCTION

Much has been learned since the publication of the 1982 Institute of Medicine (IOM) report *Marijuana and Health*.^{*} Although it was clear then that most of the effects of marijuana were due to its actions on the brain, there was little information about how THC acted on brain cells (neurons), which cells were affected by THC, or even what general areas of the brain were most affected by THC. Too little was known about cannabinoid physiology to offer any scientific insights into the harmful or therapeutic effects of marijuana. That is no longer true. During the past 16 years, there have been major advances in what basic science discloses about the potential medical benefits of cannabinoids, the group of compounds related to THC. Many variants are found in the marijuana plant, and other cannabinoids not found in the plant have been chemically synthesized. Sixteen years ago it was still a matter of debate as to whether THC acted nonspecifically by affecting the fluidity of cell membranes or whether a specific pathway of action was mediated by a receptor that responded selectively to THC (Table 2.1).

^{*}The field of neuroscience has grown substantially since the publication of the 1982 IOM report. The number of members in the Society for Neuroscience provides a rough measure of the growth in research and knowledge about the brain: as of the middle of 1998, there were over 27,000 members, more than triple the number in 1982.

TABLE 2.1 Landmark Discoveries Since the 1982 IOM Report

Year	Discovery	Primary Investigators
1986	Potent cannabinoid agonists are developed; they are the key to discovering the receptor.	M. R. Johnson and L. S. Melvin ⁷⁵
1988	First conclusive evidence of specific cannabinoid receptors.	A. Howlett and W. Devane ³⁶
1990	The cannabinoid brain receptor (CB ₁) is cloned, its DNA sequence is identified, and its location in the brain is determined.	L. Matsuda ¹⁰⁷ and M. Herkenham et al. ⁶⁰
1992	Anandamide is discovered—a naturally occurring substance in the brain that acts on cannabinoid receptors.	R. Mechoulam and W. Devane ³⁷
1993	A cannabinoid receptor is discovered outside the brain; this receptor (CB ₂) is related to the brain receptor but is distinct.	S. Munro ¹¹²
1994	The first specific cannabinoid antagonist, SR 141716A, is developed.	M. Rinaldi-Carmona ¹³²
1998	The first cannabinoid antagonist, SR144528, that can distinguish between CB ₁ and CB ₂ receptors discovered.	M. Rinaldi-Carmona ¹³³

Basic science is the wellspring for developing new medications and is particularly important for understanding a drug that has as many effects as marijuana. Even committed advocates of the medical use of marijuana do not claim that all the effects of marijuana are desirable for every medical use. But they do claim that the combination of specific effects of marijuana enhances its medical value. An understanding of those specific effects is what basic science can provide. The multiple effects of marijuana can be singled out and studied with the goals of evaluating the medical value of marijuana and cannabinoids in specific medical conditions, as well as minimizing unwanted side effects. An understanding of the basic mechanisms through which cannabinoids affect physiology permits more strategic development of new drugs and designs for clinical trials that are most likely to yield conclusive results.

Research on cannabinoid biology offers new insights into clinical use, especially given the scarcity of clinical studies that adequately evaluate the medical value of marijuana. For example, despite the scarcity of sub-

stantive clinical data, basic science has made it clear that cannabinoids can affect pain transmission and, specifically, that cannabinoids interact with the brain's endogenous opioid system, an important system for the medical treatment of pain (see chapter 4).

The cellular machinery that underlies the response of the body and brain to cannabinoids involves an intricate interplay of different systems. This chapter reviews the components of that machinery with enough detail to permit the reader to compare what is known about basic biology with the medical uses proposed for marijuana. For some readers that will be too much detail. Those readers who do not wish to read the entire chapter should, nonetheless, be mindful of the following key points in this chapter:

- The most far reaching of the recent advances in cannabinoid biology are the identification of two types of cannabinoid receptors (CB_1 and CB_2) and of anandamide, a substance naturally produced by the body that acts at the cannabinoid receptor and has effects similar to those of THC. The CB_1 receptor is found primarily in the brain and mediates the psychological effects of THC. The CB_2 receptor is associated with the immune system; its role remains unclear.
- The physiological roles of the brain cannabinoid system in humans are the subject of much active research and are not fully known; however, cannabinoids likely have a natural role in pain modulation, control of movement, and memory.
- Animal research has shown that the potential for cannabinoid dependence exists, and cannabinoid withdrawal symptoms can be observed. However, both appear to be mild compared to dependence and withdrawal seen with other drugs.
- Basic research in cannabinoid biology has revealed a variety of cellular pathways through which potentially therapeutic drugs could act on the cannabinoid system. In addition to the known cannabinoids, such drugs might include chemical derivatives of plant-derived cannabinoids or of endogenous cannabinoids such as anandamide but would also include noncannabinoid drugs that act on the cannabinoid system.

This chapter summarizes the basics of cannabinoid biology—as known today. It thus provides a scientific basis for interpreting claims founded on anecdotes and for evaluating the clinical studies of marijuana presented in chapter 4.

The Value of Animal Studies

Much of the research into the effects of cannabinoids on the brain is based on animal studies. Many speakers at the public workshops associated with this study argued that animal studies of marijuana are not relevant to humans. Animal studies are not a substitute for clinical trials, but they are a necessary complement. Ultimately, every biologically active substance exerts its effects at the cellular and molecular levels, and the evidence has shown that this is remarkably consistent among mammals, even those as different in body and mind as rats and humans. Animal studies typically provide information about how drugs work that would not be obtainable in clinical studies. At the same time, animal studies can never inform us completely about the full range of psychological and physiological effects of marijuana or cannabinoids on humans.

The Active Constituents of Marijuana

Δ^9 -THC and Δ^8 -THC are the only compounds in the marijuana plant that produce all the psychoactive effects of marijuana. Because Δ^9 -THC is much more abundant than Δ^8 -THC, the psychoactivity of marijuana has been attributed largely to the effects of Δ^9 -THC. 11-OH- Δ^9 -THC is the primary product of Δ^9 -THC metabolism by the liver and is about three times as potent as Δ^9 -THC.¹²⁸

There have been considerably fewer experiments with cannabinoids other than Δ^9 -THC, although a few studies have been done to examine whether other cannabinoids modulate the effects of THC or mediate the nonpsychological effects of marijuana. Cannabidiol (CBD) does not have the same psychoactivity as THC, but it was initially reported to attenuate the psychological response to THC in humans;^{81,177} however, later studies reported that CBD did not attenuate the psychological effects of THC.^{11,69} One double-blind study of eight volunteers reported that CBD can block the anxiety induced by high doses of THC (0.5 mg/kg).¹⁷⁷ There are numerous anecdotal reports claiming that marijuana with relatively higher ratios of THC:CBD is less likely to induce anxiety in the user than marijuana with low THC:CBD ratios; but, taken together, the results published thus far are inconclusive.

The most important effect of CBD seems to be its interference with drug metabolism, including Δ^9 -THC metabolism in the liver.^{14,114} It exerts that effect by inactivating cytochrome P450s, which are the most important class of enzymes that metabolize drugs. Like many P450 inactivators, CBD can also induce P450s after repeated doses.¹³ Experiments in which mice were treated with CBD followed by THC showed that CBD treatment was associated with a substantial increase in brain concentrations of

THC and its major metabolites, most likely because it decreased the rate of clearance of THC from the body.¹⁵

In mice, THC inhibits the release of luteinizing hormone, the pituitary hormone that triggers the release of testosterone from the testes; this effect is increased when THC is given with cannabiniol or CBD.¹¹³

Cannabiniol also lowers body temperature and increases sleep duration in mice.¹⁷⁵ It is considerably less active than THC in the brain, but studies of immune cells have shown that it can modulate immune function (see “Cannabinoids and the Immune System” later in this chapter).

The Pharmacological Toolbox

A researcher needs certain key tools in order to understand how a drug acts on the brain. To appreciate the importance of these tools, one must first understand some basic principles of drug action. All recent studies have indicated that the behavioral effects of THC are receptor mediated.²⁷ Neurons in the brain are activated when a compound binds to its receptor, which is a protein typically located on the cell surface. Thus, THC will exert its effects only after binding to its receptor. In general, a given receptor will accept only particular classes of compounds and will be unaffected by other compounds.

Compounds that activate receptors are called *agonists*. Binding to a receptor triggers an event or a series of events in the cell that results in a change in the cell’s activity, its gene regulation, or the signals that it sends to neighboring cells (Figure 2.1). This agonist-induced process is called signal transduction.

Another set of tools for drug research, which became available only recently for cannabinoid research, are the *receptor antagonists*, so-called because they selectively bind to a receptor that would have otherwise been available for binding to some other compound or drug. Antagonists block the effects of agonists and are tools to identify the functions of a receptor by showing what happens when its normal functions are blocked. Agonists and antagonists are both *ligands*; that is, they bind to receptors. Hormones, neurotransmitters, and drugs can all act as ligands. Morphine and naloxone provide a good example of how agonists and antagonists interact. A large dose of morphine acts as an agonist at opioid receptors in the brain and interferes with, or even arrests, breathing. Naloxone, a powerful opioid antagonist, blocks morphine’s effects on opiate receptors, thereby allowing an overdose victim to resume breathing normally. Naloxone itself has no effect on breathing.

Another key tool involves identifying the receptor protein and determining how it works. That makes it possible to locate where a drug activates its receptor in the brain—both the general region of the brain and

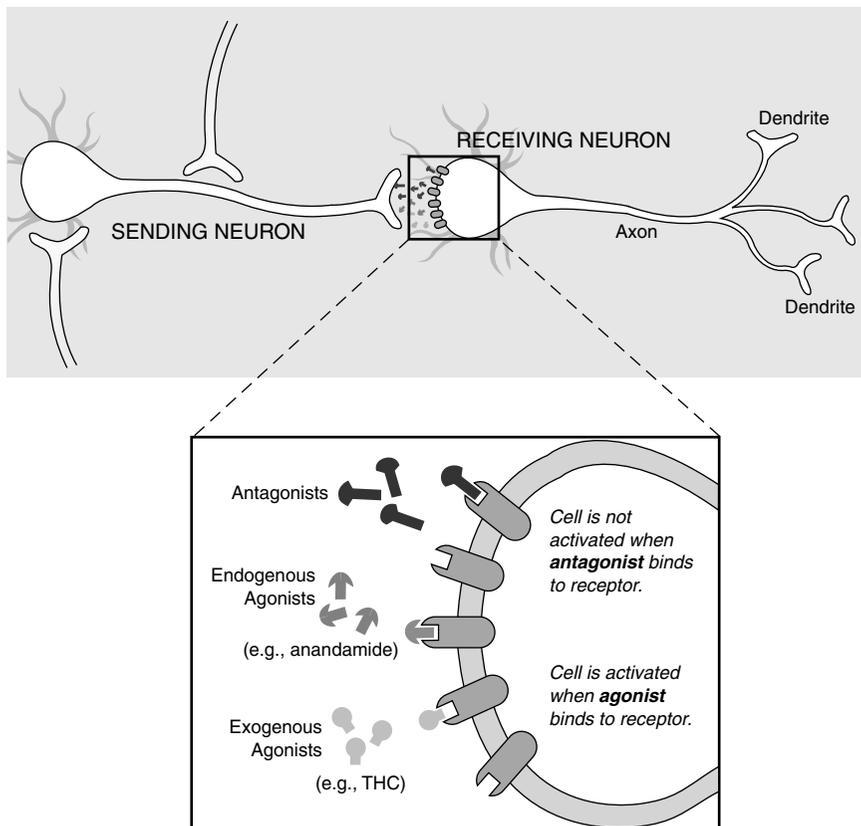

FIGURE 2.1 Diagram of neuron with synapse. Individual nerve cells, or neurons, both send and receive cellular signals to and from neighboring neurons, but for the purposes of this diagram only one activity is indicated for each cell. Neurotransmitter molecules are released from the neuron terminal and move across the gap between the “sending” and “receiving” neurons. A signal is transmitted to the receiving neuron when the neurotransmitters have bound to the receptor on its surface. The effects of a transmitted signal include:

- Changing the cell’s permeability to ions, such as calcium and potassium.
- Turning a particular gene on or off.
- Sending a signal to another neuron.
- Increasing or decreasing the responsiveness of the cell to other cellular signals.

Those effects can lead to cognitive, behavioral, or physiological changes, depending on which neuronal system is activated.

Continued on bottom of p. 39

the cell type where the receptor is located. The way to find a receptor for a drug in the brain is to make the receptor “visible” by attaching a radioactive or fluorescent marker to the drug. Such markers show where in the brain a drug binds to the receptor, although this is not necessarily the part of the brain where the drug ultimately has its greatest effects.

Because drugs injected into animals must be dissolved in a water-based solution, it is easier to deliver water-soluble molecules than to deliver fat-soluble (lipophilic) molecules such as THC. THC is so lipophilic that it can stick to glass and plastic syringes used for injection. Because it is lipophilic, it readily enters cell membranes and thus can cross the blood brain barrier easily. (This barrier insulates the brain from many blood-borne substances.) Early cannabinoid research was hindered by the lack of potent cannabinoid ligands (THC binds to its cannabinoid receptors rather weakly) and because they were not readily water soluble. The synthetic agonist CP 55,940, which is more water soluble than THC, was the first useful research tool for studying cannabinoid receptors because of its high potency and ability to be labeled with a radioactive molecule, which enabled researchers to trace its activity.

CANNABINOID RECEPTORS

The cannabinoid receptor is a typical member of the largest known family of receptors: the G protein-coupled receptors with their distinctive pattern in which the receptor molecule spans the cell membrane seven times (Figure 2.2). For excellent recent reviews of cannabinoid receptor biology, see Childers and Breivogel,²⁷ Abood and Martin,¹ Felder and Glass,⁴³ and Pertwee.¹²⁴ Cannabinoid receptor ligands bind *reversibly* (they bind to the receptor briefly and then dissociate) and *stereoselectively* (when there are molecules that are mirror images of each other, only one

The expanded view of the synapse illustrates a variety of *ligands*, that is, molecules that bind to receptors. Anandamide is a substance produced by the body that binds to and activates cannabinoid receptors; it is an *endogenous agonist*. THC can also bind to and activate cannabinoid receptors but is not naturally found in the body; it is an *exogenous agonist*. SR 141716A binds to but does not activate cannabinoid receptors. In this way it prevents agonists, such as anandamide and THC, from activating cannabinoid receptors by binding to the receptors without activating them; SR 141716A is an *antagonist*, but it is not normally produced in the body. Endogenous antagonists, that is, those normally produced in the body, might also exist, but none has been identified.

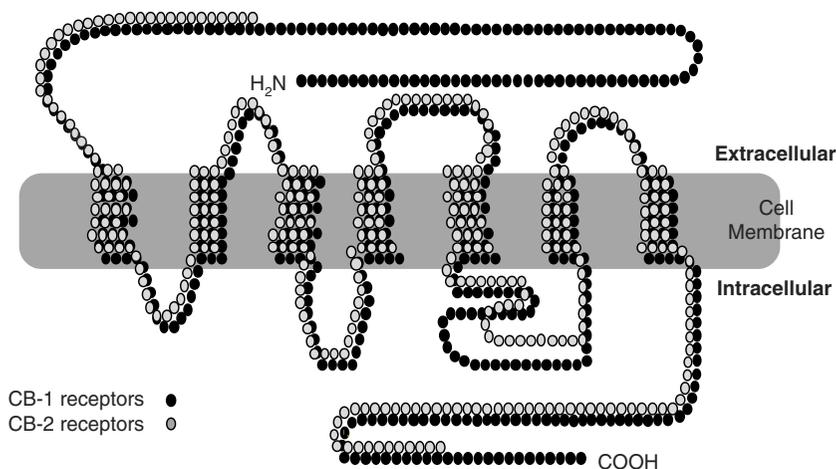

FIGURE 2.2 Cannabinoid receptors. Receptors are proteins, and proteins are made up of strings of amino acids. Each circle in the diagram represents one amino acid. The shaded bar represents the cell membrane, which like all cell membranes in animals is composed largely of phospholipids. Like many receptors, the cannabinoid receptors span the cell membrane; some sections of the receptor protein are outside the cell membrane (extracellular); some are inside (intracellular). THC, anandamide, and other known cannabinoid receptor agonists bind to the extracellular portion of the receptor, thereby activating the signal pathway inside the cell. The CB₁ molecule is larger than CB₂. The receptor molecules are most similar in four of the seven regions where they are embedded in the cell membrane (known as the transmembrane regions). The intracellular loops of the two receptor subtypes are quite different, which might affect the cellular response to the ligand because these loops are known to mediate G protein signaling, the next step in the cell signaling pathway after the receptor. Receptor homology between the two receptor subtypes is 44% for the full-length protein and 68% within the seven transmembrane regions. The ligand binding sites are typically defined by the extracellular loops and the transmembrane regions.

version activates the receptor). Thus far, two cannabinoid receptor subtypes (CB₁ and CB₂) have been identified, of which only CB₁ is found in the brain.

The cell responds in a variety of ways when a ligand binds to the cannabinoid receptor (Figure 2.3). The first step is activation of G proteins, the first components of the signal transduction pathway. That leads to changes in several intracellular components—such as cyclic AMP and calcium and potassium ions—which ultimately produce the changes in cell functions. The final result of cannabinoid receptor stimulation de-

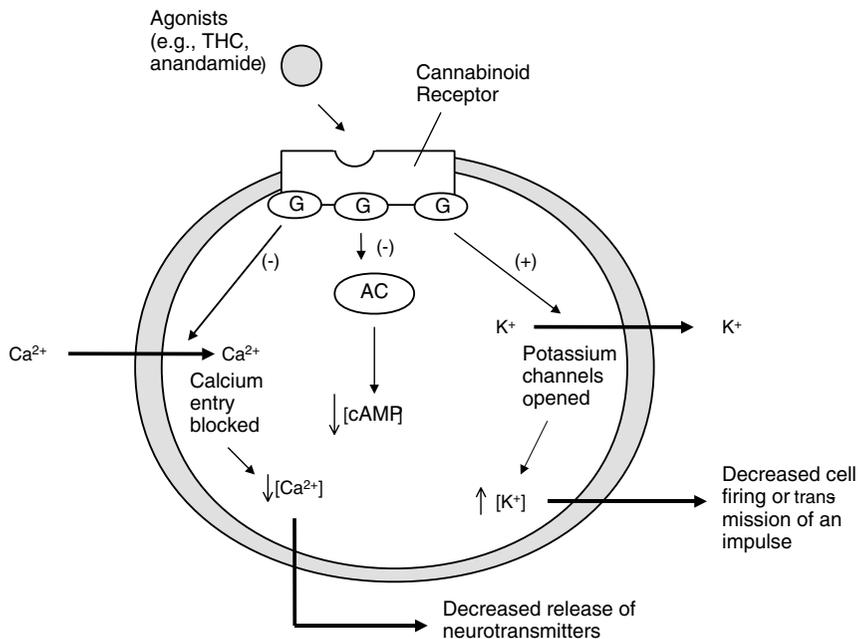

FIGURE 2.3 Cannabinoid agonists trigger a series of reactions within cells. Cannabinoid receptors are embedded in the cell membrane, where they are coupled to G proteins (G) and the enzyme adenylyl cyclase (AC). Receptors are activated when they bind to ligands, such as anandamide or THC in this case. This triggers a variety of reactions, including inhibition (-) of AC, which decreases the production of cAMP and cellular activities dependent on cAMP; opening of potassium (K^+) channels, which decreases cell firing; and closing of calcium (Ca^{2+}) channels, which decreases the release of neurotransmitters. Each of those changes can influence cellular communication.

depends on the particular type of cell, the particular ligand, and the other molecules that might be competing for receptor binding sites. Different agonists vary in binding *potency*, which determines the effective dose of the drug, and *efficacy*, which determines the maximal strength of the signal that they transmit to the cell. The potency and efficacy of THC are both relatively lower than those of some synthetic cannabinoids; in fact, synthetic compounds are generally more potent and efficacious than endogenous agonists.

CB_1 receptors are extraordinarily abundant in the brain. They are more abundant than most other G protein-coupled receptors and 10 times more abundant than *mu* opioid receptors, the receptors responsible for the effects of morphine.¹⁴⁸

The cannabinoid receptor in the brain is a protein referred to as CB₁. The peripheral receptor (outside the nervous system), CB₂, is most abundant on cells of the immune system and is not generally found in the brain.^{43,124} Although no other receptor subtypes have been identified, there is a genetic variant known as CB₁A (such variants are somewhat different proteins that have been produced by the same genes via alternative processing). In some cases, proteins produced via alternative splicing have different effects on cells. It is not yet known whether there are any functional differences between the two, but the structural differences raise the possibility.

CB₁ and CB₂ are similar, but not as similar as members of many other receptor families are to each other. On the basis of a comparison of the sequence of amino acids that make up the receptor protein, the similarity of the CB₁ and CB₂ receptors is 44% (Figure 2.2). The differences between the two receptors indicate that it should be possible to design therapeutic drugs that would act only on one or the other receptor and thus would activate or attenuate (block) the appropriate cannabinoid receptors. This offers a powerful method for producing biologically selective effects. In spite of the difference between the receptor subtypes, most cannabinoid compounds bind with similar affinity* to both CB₁ and CB₂ receptors. One exception is the plant-derived compound CBD, which appears to have greater binding affinity for CB₂ than for CB₁,¹¹² although another research group has failed to substantiate that observation.¹²⁹ Other exceptions include the synthetic compound WIN 55,212-2, which shows greater affinity for CB₂ than CB₁, and the endogenous ligands, anandamide and 2-AG, which show greater affinity for CB₁ than CB₂.⁴³ The search for compounds that bind to only one or the other of the cannabinoid receptor types has been under way for several years and has yielded a number of compounds that are useful research tools and have potential for medical use.

Cannabinoid receptors have been studied most in vertebrates, such as rats and mice. However, they are also found in invertebrates, such as leeches and mollusks.¹⁵⁶ The evolutionary history of vertebrates and invertebrates diverged more than 500 million years ago, so cannabinoid receptors appear to have been conserved throughout evolution at least this long. This suggests that they serve an important and basic function in animal physiology. In general, cannabinoid receptor molecules are similar among different species.¹²⁴ Thus, cannabinoid receptors likely fill many similar functions in a broad range of animals, including humans.

**Affinity* is a measure of how avidly a compound binds to a receptor. The higher the affinity of a compound, the higher its potency; that is, lower doses are needed to produce its effects.

THE ENDOGENOUS CANNABINOID SYSTEM

For any drug for which there is a receptor, the logical question is, "Why does this receptor exist?" The short answer is that there is probably an endogenous agonist (that is, a compound that is naturally produced in the brain) that acts on that receptor. The long answer begins with a search for such compounds in the area of the body that produces the receptors and ends with a determination of the natural function of those compounds. So far, the search has yielded several endogenous compounds that bind selectively to cannabinoid receptors. The best studied of them are anandamide³⁷ and arachidonyl glycerol (2-AG).¹⁰⁸ However, their physiological roles are not yet known.

Initially, the search for an endogenous cannabinoid was based on the premise that its chemical structure would be similar to that of THC; that was reasonable, in that it was really a search for another "key" that would fit into the cannabinoid receptor "keyhole," thereby activating the cellular message system. One of the intriguing discoveries in cannabinoid biology was how chemically different THC and anandamide are. A similar search for endogenous opioids (endorphins) also revealed that their chemical structure is very different from the plant-derived opioids, opium and morphine.

Further research has uncovered a variety of compounds with quite different chemical structures that can activate cannabinoid receptors (Table 2.2 and Figure 2.4). It is not yet known exactly how anandamide and THC bind to cannabinoid receptors. Knowing this should permit more precise design of drugs that selectively activate the endogenous cannabinoid systems.

Anandamide

The first endogenous cannabinoid to be discovered was arachidonyl-ethanolamine, named anandamide from the Sanskrit word *ananda*, meaning "bliss."³⁷ Compared with THC, anandamide has only moderate affinity for CB₁ receptor and is rapidly metabolized by amidases (enzymes that remove amide groups). Despite its short duration of action, anandamide shares most of the pharmacological effects of THC.^{37,152} Rapid degradation of active molecules is a feature of neurotransmitter systems that allows them control of signal timing by regulating the abundance of signaling molecules. It creates problems for interpreting the results of many experiments and might explain why *in vivo* studies with anandamide injected into the brain have yielded conflicting results.

Anandamide appears to have both central (in the brain) and peripheral (in the rest of the body) effects. The precise neuroanatomical localiza-

TABLE 2.2 Compounds That Bind to Cannabinoid Receptors

Compound	Properties
Agonists (receptor activators)	
<i>Plant-derived compounds</i>	
Δ^9 -THC	Main psychoactive cannabinoid in marijuana plant; largely responsible for psychological and physiological effects (except in discussions of the different forms of THC, THC is used as a synonym for Δ^9 -THC).
Δ^8 -THC	Slightly less potent than Δ^9 -THC and much less abundant in marijuana plant but otherwise similar.
11-OH- Δ^9 -THC	Bioactive compound formed when body breaks down Δ^9 -THC; presumed to be responsible for some effects of marijuana.
<i>Cannabinoid agonists found in animals</i>	
Anandamide (arachidonyl-ethanolamide)	Found in animals ranging from mollusks to mammals; appears to be primary endogenous cannabinoid agonist in mammals; chemical structure very different from plant cannabinoids and related to prostaglandins.
2-AG (arachidonyl glycerol)	Endogenous agonist; structurally similar to anandamide; more abundant but less potent than anandamide.
<i>THC analogues</i>	
Dronabinol	Synthetic THC; marketed in the United States as Marinol for nausea associated with chemotherapy and for AIDS-related wasting.
Nabilone	THC analogue; marketed in the United Kingdom as Cesamet for same indications as dronabinol.
CP 55,940	Synthetic cannabinoid; THC analogue; that is, it is structurally similar to THC.
Levonantradol	THC analogue.
HU-210	THC analogue, 100- to 800-fold greater potency than THC ⁹⁷ .
<i>Chemical structure unlike THC or anandamide</i>	
WIN-55,212-2	Chemical structure different from known cannabinoids, but binds to both cannabinoid receptors; chemically related to cyclo-oxygenase inhibitors, which include antiinflammatory drugs.
Antagonists (receptor blockers)	
SR 141716A	Synthetic CB ₁ antagonist; developed in 1994 ¹³² .
SR 144528	Synthetic CB ₂ antagonist; developed in 1997 ¹³³ .

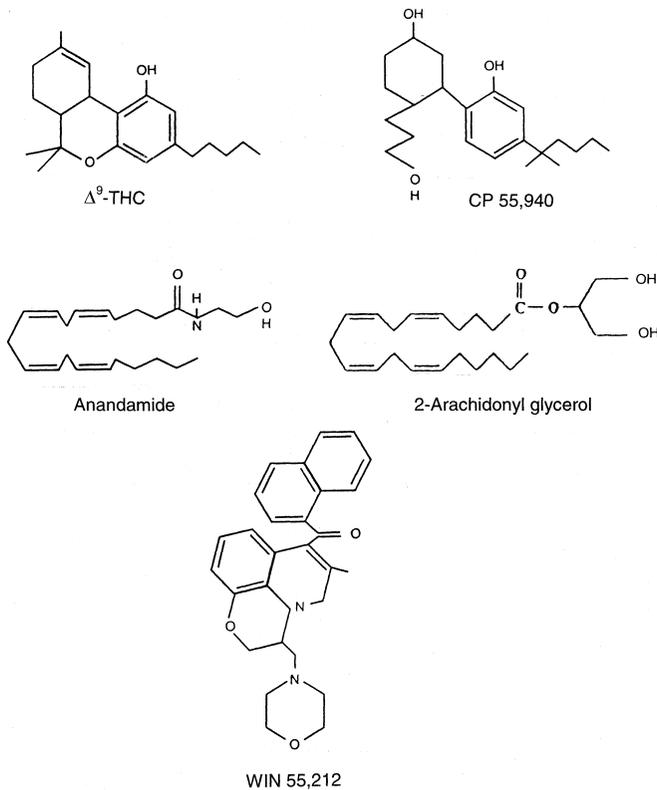

FIGURE 2.4 Chemical structures of selected cannabinoid agonists or molecules that bind to and activate cannabinoid receptors. **THC** is the primary psychoactive molecule found in marijuana. **CP 55,940** is a THC analogue; that is, its chemical structure is related to THC. **Anandamide** and **2-arachidonyl glycerol (2-AG)** are endogenous molecules, meaning they are naturally produced in the body. Although the chemical structure of **WIN 55,212** is very different from either THC or anandamide, it is also a cannabinoid agonist.

tion of anandamide and the enzymes that synthesize it are not yet known. This information will provide essential clues to the natural role of anandamide and an understanding of the brain circuits in which it is a neurotransmitter. The importance of knowing specific brain circuits that involve anandamide (and other endogenous cannabinoid ligands) is that such circuits are the pivotal elements for regulating specific brain functions, such as mood, memory, and cognition. Anandamide has been found in numerous regions of the human brain: hippocampus (and

TABLE 2.3 Comparison of Cannabinoid Receptor Agonists

Potency can be measured in a variety of ways, from behavioral to physiological to cellular. This table shows potency in terms of receptor binding, which is the most broadly applicable to the many possible actions of cannabinoids. For example, anandamide binds to the cannabinoid receptor only about half as avidly as does THC. Measures of potency might include effects on activity (behavior) or hypothermia (physiologic).

The apparently low potency of 2-AG may, however, be misleading. A study published late in 1998 reports that 2-AG is found with two other closely related compounds that by themselves are biologically inactive; but in the presence of those two compounds, 2-AG is only three times less active than THC.⁹ Further, 2-AG is much more abundant than anandamide, although the biological significance of this remains to be determined.

Receptor Binding in Brain Tissue¹²⁴

Compound	Potency Relative to Δ^9 -THC
CP 55,940	59
Δ^9 -THC	1
Anandamide	0.47
2-AG	0.08

parahippocampic cortex), striatum, and cerebellum; but it has not been precisely identified with specific neuronal circuits. CB₁ receptors are abundant in these regions, and this further implies a physiological role for endogenous cannabinoids in the brain functions controlled by these areas. But substantial concentrations of anandamide are also found in the thalamus, an area of the brain that has relatively few CB₁ receptors.¹²⁴

Anandamide has also been found outside the brain. It has been found in spleen tissue, which also has high concentrations of CB₂ receptors, and small amounts have been detected in heart tissue.⁴⁴

In general, the affinity of anandamide for cannabinoid receptors is only one-fourth to one-half that of THC (see Table 2.3). The differences depend on the cells or tissue that are tested and on the experimental conditions, such as the binding assay used (reviewed by Pertwee¹²⁴).

The molecular structure of anandamide is relatively simple, and it can be formed from arachidonic acid and ethanolamine. Arachidonic acid is a common precursor of a group of biologically active molecules known as eicosanoids, including prostaglandins.* Although anandamide can be synthesized in a variety of ways, the physiologically relevant pathway

*Eicosanoids all contain a chain of 20 carbon atoms and are named after *eikosi*, the Greek word for 20.

seems to be through enzymatic cleavage of *N*-arachidonyl-phosphatidylethanolamine (NAPE), which yields anandamide and phosphatidic acid (reviewed by Childers and Breivogel²⁷).

Anandamide can be inactivated in the brain via two mechanisms. In one it is enzymatically cleaved to yield arachidonic acid and ethanolamine—the reverse of what was initially proposed as its primary mode of synthesis. In the other it is inactivated through neuronal uptake—that is, by being transported into the neuron, which prevents its continuing activation of neighboring neurons.

Other Endogenous Agonists

Several other endogenous compounds that are chemically related to anandamide and that bind to cannabinoid receptors have been discovered, one of which is 2-AG.¹⁰⁸ 2-AG is closely related to anandamide and is even more abundant in the brain. At the time of this writing, all known endogenous cannabinoid receptor agonists (including anandamide) were eicosanoids, which are arachidonic acid metabolites. Arachidonic acid (a free fatty acid) is released via hydrolysis of membrane phospholipids.

Other, noneicosanoid, compounds that bind cannabinoid receptors have recently been isolated from brain tissue, but they have not been identified, and their biological effects are under investigation. This is a fast-moving field of research, and no review over six months old will be fully up to date.

The endogenous compounds that bind to cannabinoid receptors probably perform a broad range of natural functions in the brain. This neural signaling system is rich and complex and has many subtle variations, many of which await discovery. In the next few years much more will probably be known about these naturally occurring cannabinoids.

Some effects of cannabinoid agonists are receptor independent. For example, both THC and CBD can be neuroprotective through their antioxidative activity; that is, they can reduce the toxic forms of oxygen that are released when cells are under stress.⁵⁴ Other likely examples of receptor-independent cannabinoid activity are modulation of activation of membrane-bound enzymes (such as ATPase), arachidonic acid release, and perturbation of membrane lipids. An important caution in interpreting those reports is that concentrations of THC or CBD used in cellular studies, such as these, are generally much higher than the concentrations of THC or CBD in the body that would likely be achieved by smoking marijuana.

TABLE 2.4 Cellular Processes That Can Be Targeted for Drug Development

Drug Action		Biological Result
Block synthesis	Synthesis of bioactive compounds is a continuous process and is one means by which concentrations of that compound are regulated.	<i>Weaker signal</i> , due to decreased agonist concentration.
Inhibit degradation	Chemical breakdown is one method the body uses to inactivate endogenous substances.	<i>Stronger signal</i> , due to increased agonist concentration.
Facilitate neuronal uptake	Neuronal uptake is one of the natural ways in which a receptor agonist is inactivated.	<i>Stronger signal</i> , due to increased amount of time during which agonist is present in the synapse where it can stimulate the receptor.

NOTE: Endogenous cannabinoids are part of a cellular signaling system. This table lists categories of natural processes that regulate such systems and shows the results of altering those processes.

Novel Targets for Therapeutic Drugs

Drugs that alter the natural biology of anandamide or other endogenous cannabinoids might have therapeutic uses (Table 2.4). For example, drugs that selectively inhibit neuronal uptake of anandamide would increase the brain's own natural cannabinoids, thereby mimicking some of the effects of THC. A number of important psychotherapeutic drugs act by inhibiting neurotransmitter uptake. For example, antidepressants like fluoxetine (Prozac) inhibit serotonin uptake and are known as selective serotonin reuptake inhibitors, or SSRIs. Another way to alter levels of endogenous cannabinoids would be to develop drugs that act on the enzymes involved in anandamide synthesis. Some antihypertensive drugs work by inhibiting enzymes involved in the synthesis of endogenous hypertensive agents. For example, anti-converting enzyme (ACE) inhibitors are used in hypertensive patients to interfere with the conversion of angiotensin I, which is inactive, to the active hormone, angiotensin II.

SITES OF ACTION

Cannabinoid receptors are particularly abundant in some areas of the brain. The normal biology and behavior associated with these brain areas

TABLE 2.5 Brain Regions in Which Cannabinoid Receptors Are Abundant

Brain Region	Functions Associated with Region
Brain regions in which cannabinoid receptors are abundant	
Basal ganglia	Movement control
Substantia nigra pars reticulata	
Entopeduncular nucleus	
Globus pallidus	
Putamen	
Cerebellum	Body movement coordination
Hippocampus	Learning and memory, stress
Cerebral cortex, especially cingulate, frontal, and parietal regions	Higher cognitive functions
Nucleus accumbens	Reward center
Brain regions in which cannabinoid brain receptors are moderately concentrated	
Hypothalamus	Body housekeeping functions (body temperature regulation, salt and water balance, reproductive function)
Amygdala	Emotional response, fear
Spinal cord	Peripheral sensation, including pain
Brain stem	Sleep and arousal, temperature regulation, motor control
Central gray	Analgesia
Nucleus of the solitary tract	Visceral sensation, nausea and vomiting

SOURCES: Based on reviews by Pertwee (1997b)¹²⁴ and Herkenham (1995).⁵⁷

are consistent with the behavioral effects produced by cannabinoids (Table 2.5 and Figure 2.5). The highest receptor density is found in cells of the basal ganglia that project locally and to other brain regions. These cells include the substantia nigra pars reticulata, entopeduncular nucleus, and globus pallidus, regions that are generally involved in coordinating body movements. Patients with Parkinson's or Huntington's disease tend to have impaired functions in these regions.

CB₁ receptors are also abundant in the putamen, part of the relay system within the basal ganglia that regulates body movements; the cerebellum, which coordinates body movements; the hippocampus, which is involved in learning, memory, and response to stress; and the cerebral cortex, which is concerned with the integration of higher cognitive functions.

CB₁ receptors are found on various parts of neurons, including the

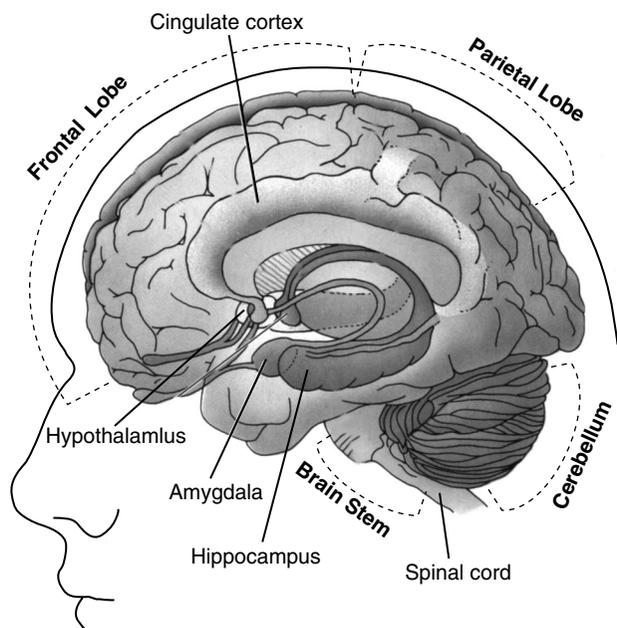

FIGURE 2.5 Locations of brain regions in which cannabinoid receptors are abundant. See Table 2.5 for a summary of functions associated with those regions.

axon, cell bodies, terminals, and dendrites.^{57,165} Dendrites are generally the “receiving” part of a neuron, and receptors on axons or cell bodies generally modulate other signals. Axon terminals are the “sending” part of the neuron.

Cannabinoids tend to inhibit neurotransmission, although the results are somewhat variable. In some cases, cannabinoids diminish the effects of the inhibitory neurotransmitter, *g*-aminobutyric acid (GABA);¹⁴⁴ in other cases, cannabinoids can augment the effects of GABA.¹²⁰ The effect of activating a receptor depends on where it is found on the neuron: if cannabinoid receptors are presynaptic (on the “sending” side of the synapse) and inhibit the release of GABA, cannabinoids would diminish GABA effects; the net effect would be stimulation. However, if cannabinoid receptors are postsynaptic (on the “receiving” side of the synapse) and on the same cell as GABA receptors, they will probably mimic the effects of GABA; in that case, the net effect would be inhibition.^{120,144,160}

CB₁ is the predominant brain cannabinoid receptor. CB₂ receptors have not generally been found in the brain, but there is one isolated report suggesting some in mouse cerebellum.¹⁵⁰ CB₂ is found primarily on cells

TABLE 2.6 Cannabinoid Receptors

	CB ₁	CB ₂
Effects of various cannabinoids		
Δ ⁹ -THC	Agonist	Weak antagonist
Anandamide	Agonist	Agonist
Cannabinol	Weak agonist	Agonist; greater affinity for CB ₂ than for CB ₁
Cannabidiol	Does not bind to receptor	Does not bind to receptor
Receptor distribution		
Areas of greatest abundance	Brain	Immune system, especially B cells and natural killer cells

of the immune system. CB₁ receptors are also found in immune cells, but CB₂ is considerably more abundant there (Table 2.6) (reviewed by Kaminski⁸⁰ in 1998).

As can be appreciated in the next section, the presence of cannabinoid systems in key brain regions is strongly tied to the functions and pathology associated with those regions. The clinical value of cannabinoid systems is best understood in the context of the biology of these brain regions.

CANNABINOID RECEPTORS AND BRAIN FUNCTIONS

Motor Effects

Marijuana affects psychomotor performance in humans. The effects depend both on the nature of the task and the experience with marijuana. In general, effects are clearest in steadiness (body sway and hand steadiness) and in motor tasks that require attention. The results of testing cannabinoids in rodents are much clearer.

Cannabinoids clearly affect movement in rodents, but the effects depend on the dose: low doses stimulate and higher doses inhibit locomotion.^{111,159} Cannabinoids mainly inhibit the transmission of neural signals, and they inhibit movement through their actions on the basal ganglia and cerebellum, where cannabinoid receptors are particularly abundant (Figure 2.6). Cannabinoid receptors are also found in the neurons that project from the striatum and subthalamic nucleus, which inhibit and stimulate movement, respectively.^{58,101}

Cannabinoids decrease both the inhibitory and stimulatory inputs to the substantia nigra and therefore might provide dual regulation of move-

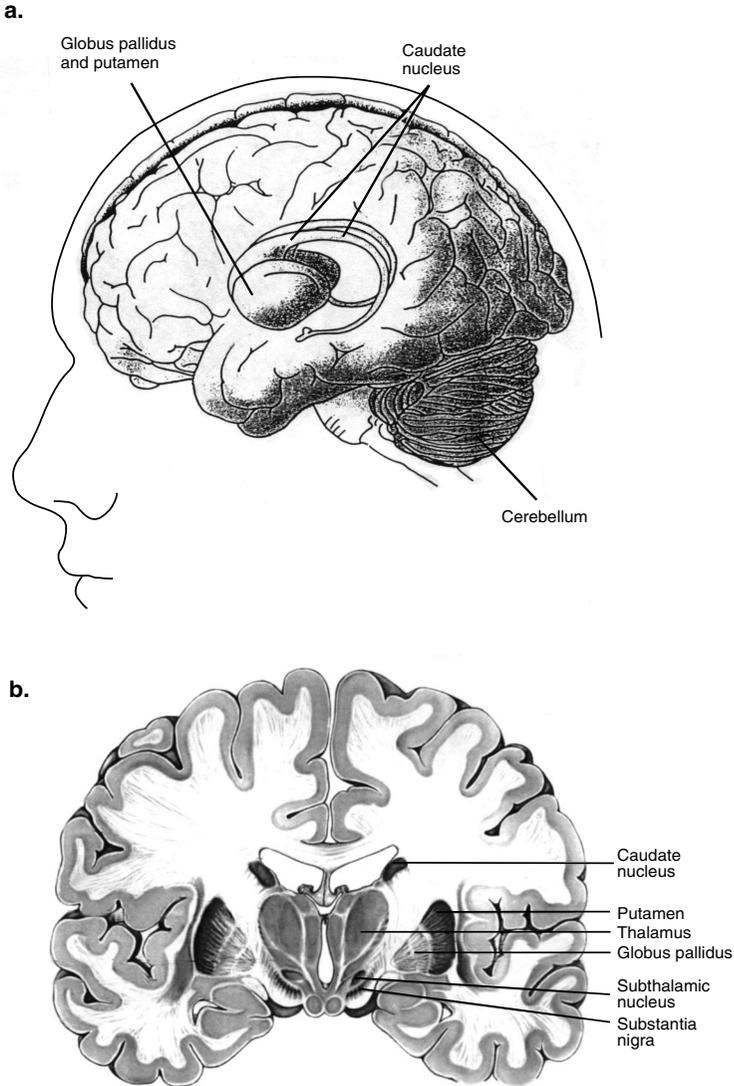

FIGURE 2.6 Diagrams showing motor regions of the brain. Basal ganglia are a group of three brain regions, or nuclei—**caudate**, **putamen**, and **globus pallidus**. Figure 2.6a is a three-dimensional view showing the location of those nuclei in the brain. Figure 2.6b shows those structures in a vertical cross-sectional view. The major output pathways of the basal ganglia arise from the globus pallidus and pars reticulata of the **substantia nigra**. Their main target is the **thalamus**. SOURCE: Figure 2.6a is reprinted from *Principles of Neural Science*, 2nd ed., 1985 (E.R. Kandel and J.H. Schwartz, eds.), with permission from the copyright holder, Appleton and Lange.

ment at this nucleus. In the substantia nigra, cannabinoids decrease transmission from both the striatum and the subthalamic nucleus.¹⁴¹ The globus pallidus has been implicated in mediating the cataleptic effects of large doses of cannabinoids in rats.¹²⁶ (Catalepsy is a condition of diminished responsiveness usually characterized by trancelike states and waxy rigidity of the muscles.) Several other brain regions—the cortex, the cerebellum, and the neural pathway from cortex to striatum—are also involved in the control of movement and contain abundant cannabinoid receptors.^{52,59,101} They are therefore possible additional sites that might underlie the effects of cannabinoids on movement.

Memory Effects

One of the primary effects of marijuana in humans is disruption of short-term memory.⁶⁸ That is consistent with the abundance of CB₁ receptors in the hippocampus, the brain region most closely associated with memory. The effects of THC resemble a temporary hippocampal lesion.⁶³ Deadwyler and colleagues have demonstrated that cannabinoids decrease neuronal activity in the hippocampus and its inputs.^{23,24, 83} *In vitro*, several cannabinoid ligands and endogenous cannabinoids can block the cellular processes associated with memory formation.^{29,30,116,157,163} Furthermore, cannabinoid agonists inhibit release of several neurotransmitters: acetylcholine from the hippocampus,⁴⁹⁻⁵¹ norepinephrine from human and guinea pig (but not rat or mouse) hippocampal slices,¹⁴³ and glutamate in cultured hippocampal cells.¹⁴⁴ Cholinergic and noradrenergic neurons project into the hippocampus, but circuits within the hippocampus are glutamatergic.* Thus, cannabinoids could block transmission both into and within the hippocampus by blocking presynaptic neurotransmitter release.

Pain

After nausea and vomiting, chronic pain was the condition cited most often to the IOM study team as a medical use for marijuana. Recent research presented below has shown intriguing parallels with anecdotal reports of the modulating effects of cannabinoids on pain—both the effects of cannabinoids acting alone and the effects of their interaction with opioids.

*Neurons are often defined by the primary neurotransmitter released at their terminals. Thus, *cholinergic* neurons release acetylcholine, *noradrenergic* neurons release noradrenalin (also known as norepinephrine), and *glutamergic* neurons release glutamate.

Behavioral Studies

Cannabinoids reduce reactivity to acute painful stimuli in laboratory animals. In rodents, cannabinoids reduced the responsiveness to pain induced through various stimuli, including thermal, mechanical, and chemical stimuli.^{12,19,46,72,96,154,174} Cannabinoids were comparable with opiates in potency and efficacy in these experiments.^{12,72}

Cannabinoids are also effective in rodent models of chronic pain. Herzberg and co-workers found that cannabinoids can block allodynia and hyperalgesia associated with neuropathic pain in rats.⁶² This is an important advance because chronic pain frequently results in a series of neural changes that increase suffering due to allodynia (pain elicited by stimuli that are normally innocuous), hyperalgesia (abnormally increased reactivity to pain), and spontaneous pain; furthermore, some chronic pain syndromes are not amenable to therapy, even with the most powerful narcotic analgesics.¹⁰

Pain perception is controlled mainly by neurotransmitter systems within the central nervous system, and cannabinoids clearly play a role in the control of pain in those systems.⁴⁵ However, pain-relieving and pain-preventing mechanisms also occur in peripheral tissues, and endogenous cannabinoids appear to play a role in peripheral tissues. Thus, the different cannabinoid receptor subtypes might act synergistically. Experiments in which pain is induced by injecting dilute formalin into a mouse's paw have shown that anandamide and palmitylethanolamide (PEA) can block peripheral pain.^{22,73} Anandamide acts primarily at the CB₁ receptor, whereas PEA has been proposed as a possible CB₂ agonist; in short, there might be a biochemical basis for their independent effects. When injected together, the analgesic effect is stronger than that of either alone. That suggests an important strategy for the development of a new class of analgesic drug: a mixture of CB₁ and CB₂ agonists. Because there are few, if any, CB₂ receptors in the brain, it might be possible to develop drugs that enhance the peripheral analgesic effect while minimizing the psychological effects.

Neural Sites of Altered Responsiveness to Painful Stimuli

The brain and spinal cord mediate cannabinoid analgesia. A number of brain areas participate in cannabinoid analgesia and support the role of descending pathways (neural pathways that project from the brain to the spinal cord).^{103,105} Although more work is needed to produce a comprehensive map of the sites of cannabinoid analgesia, it is clear that the effects are limited to particular areas, most of which have an established role in pain.

Specific sites where cannabinoids act to affect pain processing include the periaqueductal gray,¹⁰⁴ rostral ventral medulla,^{105,110} thalamic nucleus submedius,¹⁰² thalamic ventroposterolateral nucleus,¹⁰² dorsal horn of the spinal cord,^{64,65} and peripheral sensory nerves.^{64-66,131} Those nuclei also participate in opiate analgesia. Although similar to opiate analgesia, cannabinoid analgesia is not mediated by opioid receptors; morphine and cannabinoids sometimes act synergistically, and opioid antagonists generally have no effect on cannabinoid-induced analgesia.¹⁷¹ However, a *kappa*-receptor antagonist has been shown to attenuate spinal, but not supraspinal, cannabinoid analgesia.^{153,170,171} (*Kappa* opioid receptors constitute one of the three major types of opioid receptors; the other two types are *mu* and *delta* receptors.)

Neurophysiology and Neurochemistry of Cannabinoid Analgesia

Because of the marked effects of cannabinoids on motor function, behavioral studies in animals alone cannot provide sufficient grounds for the conclusion that cannabinoids depress pain perception. Motor behavior is typically used to measure responses to pain, but this behavior is itself affected by cannabinoids. Thus, experimental results include an unmeasured combination of cannabinoid effects on motor and pain systems. The effects on specific neural systems, however, can be measured at the neurophysiological and neurochemical levels. Cannabinoids decrease the response of immediate-early genes (genes that are activated in the early or immediate stage of response to a broad range of cellular stimuli) to noxious stimuli in the spinal cord, decrease response of pain neurons in the spinal cord, and decrease the responsiveness of pain neurons in the ventral posterolateral nucleus of the thalamus.^{67,102} Those changes are mediated by cannabinoid receptors, are selective for pain neurons, and are unrelated to changes in skin temperature or depth of anesthesia, and they follow the time course of the changes in behavioral responses to painful stimuli but not the time course of motor changes.⁶⁷ On-cells and off-cells in the rostral ventral medulla control pain transmission at the level of the spinal cord, and cannabinoids also modulate their responses in a manner that is very similar to that of morphine.¹¹⁰

Endogenous Cannabinoids Modulate Pain

Endogenous cannabinoids can modulate pain sensitivity through both central and peripheral mechanisms. For example, animal studies have shown that pain sensitivity can be increased when endogenous cannabinoids are blocked from acting at CB₁ receptors.^{22,62,110,130,158} Administration of cannabinoid antagonists in either the spinal cord¹³⁰ or paw²² in-

crease the sensitivity of animals to pain. In addition, there is evidence that cannabinoids act at the site of injury to reduce peripheral inflammation.¹³¹

Current data suggest that the endogenous cannabinoid analgesic system might offer protection against the long-lasting central hyperalgesia and allodynia that sometimes follow skin or nerve injuries.^{130,158} These results raise the possibility that therapeutic interventions that alter the levels of endogenous cannabinoids might be useful for managing pain in humans.

CHRONIC EFFECTS OF THC

Most substances of abuse produce tolerance, physical dependence, and withdrawal symptoms. *Tolerance* is the most common response to repetitive use of a drug and is the condition in which, after repeated exposure to a drug, increasing doses are needed to achieve the same effect. *Physical dependence* develops as a result of a resetting of homeostatic mechanisms in response to repeated drug use. Tolerance, dependence, and withdrawal are not peculiar to drugs of abuse. Many medicines that are not addicting can produce these types of effects; examples of such medications include clonidine, propranolol, and tricyclic antidepressants. The following sections discuss what is known about the biological mechanisms that underlie tolerance, reward, and dependence; clinical studies about those topics are discussed in chapter 3.

Tolerance

Chronic administration of cannabinoids to animals results in tolerance to many of the acute effects of THC, including memory disruption,³⁴ decreased locomotion,^{2,119} hypothermia,^{42,125} neuroendocrine effects,¹³⁴ and analgesia.⁴ Tolerance also develops to the cardiovascular and psychological effects of THC and marijuana in humans (see also discussion in chapter 3).^{55,56,76}

Tolerance to cannabinoids appears to result from both *pharmacokinetic* changes (how the drug is absorbed, distributed, metabolized, and excreted) and *pharmacodynamic* changes (how the drug interacts with target cells). Chronic treatment with the cannabinoid agonist, CP 55,940, increases the activity of the microsomal cytochrome P450 oxidative system,³¹ the system through which drugs are metabolized in the liver; this suggests pharmacokinetic tolerance. Chronic cannabinoid treatment also produces changes in brain cannabinoid receptors and cannabinoid receptor mRNA concentrations—an indication that pharmacodynamic effects are important as well.

Most studies have found that brain cannabinoid receptor concentra-

tions usually decrease after prolonged exposure to agonists,^{42,119,136,138} although some studies have reported increases¹³⁷ or no changes² in receptor binding in brain. Differences among studies could be due to the particular agonist tested, the assay used, the brain region examined, or the treatment time. For example, the THC analogue, levonantradol, produces a greater desensitization of adenylyl cyclase inhibition than does THC in cultured neuroblastoma cells.⁴⁰ This might be explained by differences in efficacy between these two agonists.^{18,147} A time course study revealed differences among brain regions in the rates and magnitudes of receptor down regulation.¹⁶ Those findings suggest that tolerance to different effects of cannabinoids develops at different rates.

Chronic treatment with THC also produces variable effects on cannabinoid-mediated signal transduction systems. It produces substantial desensitization of cannabinoid-activated G proteins in a number of rat brain regions.¹⁴⁷ The time course of this desensitization varies across brain regions.¹⁶

It is difficult to extend the findings of short-term animal studies to human marijuana use. To simulate long-term use, higher doses are used in animal studies than are normally achieved by smoking marijuana. For example, the average human will feel "high" after injection of THC at a level of 0.06 mg/kg,¹¹⁸ compared with the 10–20 mg/kg per day used in many chronic rat studies. At the same time, doses of marijuana needed to observe behavioral changes in rats (usually changes in locomotor behavior) are substantially higher than doses at which people feel "high." The pharmacokinetics of THC distribution in the body are also dramatically different between rats and humans and depend heavily on whether it is inhaled, injected, or swallowed. It is likely that some of the same biochemical adaptations to chronic cannabinoid administration occur in laboratory animals and humans, but the magnitude of the effects in humans might be less than that in animals in proportion to the doses used.

Reward and Dependence

Experimental animals that are given the opportunity to self-administer cannabinoids generally do not choose to do so, which has led to the conclusion that they are not reinforcing and rewarding.³⁸ However, behavioral⁹⁵ and brain stimulation⁹⁴ studies have shown that THC can be rewarding to animals. The behavioral study used a "place preference" test, in which an animal is given repeated doses of a drug in one place, and is then given a choice between a place where it received the drug and a place where it did not. The animals chose the place where they received the THC. These rewarding effects are highly dose dependent. In all models studied, cannabinoids are only rewarding at midrange; doses that are

too low are not rewarding; doses that are too high can be aversive. Mice will self-administer the cannabinoid agonist WIN 55,212-2 but only at low doses.¹⁰⁶ This effect is specifically mediated by CB₁ receptors and indicates that stimulation of those receptors is rewarding to the mice. Antagonism of cannabinoid receptors is also rewarding in rats; in conditioned place preference tests, animals show a preference for the place they receive the cannabinoid antagonist SR 141716A at both low and high doses.¹⁴⁰ Cannabinoids increase dopamine concentrations in the mesolimbic dopamine system of rats, a pathway associated with reinforcement.^{25,39,161} However, the mechanism by which THC increases dopamine concentrations appears to be different from that of other abused drugs⁵¹ (see chapter 3 for further discussion of reinforcement). THC-induced increases in dopamine are due to increases in the firing rate of dopamine cells in the ventral tegmental area by Δ^9 -THC.⁴⁷ However, these increases in firing rate in the ventral tegmental area could not be explained by increases in the firing of the A10 dopamine cell group, where other abused drugs have been shown to act.⁵¹

Physical dependence on cannabinoids has been observed only under experimental conditions of "precipitated withdrawal" in which animals are first treated chronically with cannabinoids and then given the CB₁ antagonist SR 141716A.^{3,166} The addition of the antagonist accentuates any withdrawal effect by competing with the agonist at receptor sites; that is, the antagonist helps to clear agonists off and keep them off receptor sites. This suggests that, under normal cannabis use, the long half-life and slow elimination from the body of THC and the residual bioactivity of its metabolite, 11-OH-THC, can prevent substantial abstinence symptoms. The precipitated withdrawal produced by SR 141716A has some of the characteristics of opiate withdrawal, but it is not affected by opioid antagonists, and it affects motor systems differently. An earlier study with monkeys also suggested that abrupt cessation of chronic THC is associated with withdrawal symptoms.⁸ Monkeys in that study were trained to work for food after which they were given THC on a daily basis; when the investigators stopped administering THC, the animals stopped working for food.

A study in rats indicated that the behavioral cannabinoid withdrawal syndrome is consistent with the consequences of withdrawal from other drugs of abuse in that it correlates with the effects of stimulation of central amygdaloid corticotropin-releasing hormone release.¹³⁵ However, the withdrawal syndrome for cannabinoids and the corresponding increase in corticotropin-releasing hormone are observed only after administration of the CB₁ antagonist SR 141716A to cannabinoid-tolerant animals.^{3,166} The implications of data based on precipitated withdrawal in animals for human cannabinoid abuse have not been established.¹⁶⁶ Furthermore, acute administration of THC also produces increases in corticotropin-

releasing hormone and adrenocorticotropin release; both are stress-related hormones.⁷¹ This set of withdrawal studies may explain the generally aversive effects of cannabinoids in animals and could indicate that the increase in corticotropin-releasing hormone is merely a rebound effect. Thus, cannabinoids appear to be conforming to some of the neurobiological effects of other drugs abused by humans, but the underlying mechanisms of these actions and their value for determining the reinforcement and dependence liability of cannabinoids in humans remain undetermined.

CANNABINOIDS AND THE IMMUNE SYSTEM

The human body protects itself from invaders, such as bacteria and viruses through the elaborate and dynamic network of organs and cells referred to as the immune system. Cannabinoids, especially THC, can modulate the function of immune cells in various ways—in some cases enhancing and in others diminishing the immune response⁸⁵ (summarized in Table 2.7). However, the natural function of cannabinoids in the immune system is not known. Immune cells respond to cannabinoids in a variety of ways, depending on such factors as drug concentration, timing of drug delivery to leukocytes in relation to antigen stimulation, and type of cell function. Although the chronic effects of cannabinoids on the immune system have not been studied, based on acute exposure studies in experimental animals it appears that THC concentrations that modulate immunological responses are higher than those required for psychoactivity.

The CB₂ receptor gene, which is not expressed in the brain, is particularly abundant in immune tissues, with an expression level 10–100 times higher than that of CB₁. In spleen and tonsils the CB₂ mRNA* content is equivalent to that of CB₁ mRNA in the brain.⁴⁸ The rank order, from high to low, of CB₂ mRNA levels in immune cells is B-cells > natural killer cells >> monocytes > polymorphonuclear neutrophil cells > T8 cells > T4 cells. In tonsils the CB₂ receptors appear to be restricted to B-lymphocyte-enriched areas. In contrast, CB₁ receptors are mainly expressed in the central nervous system and, to a lesser extent, in several peripheral tissues such as adrenal gland, heart, lung, prostate, uterus, ovary, testis, bone marrow, thymus, and tonsils.

*After a gene is transcribed, it is often spliced and modified into mRNA, or message RNA. The CB-2 mRNA is the gene "message" that moves from the cell nucleus into the cytoplasm where it will be translated into the receptor protein.

TABLE 2.7 Effects of Cannabinoids on the Immune System

Drug Tested	Cell Types Tested or Type of Animal Experiment	Drug Concentration*
THC, 2-AG, 11-OH-THC, CBN	Lymphocytes and splenocytes <i>in vitro</i>	0.1–30 μ M
THC, 2-AG	Lymphocytes and splenocytes	0.1–25 μ M
Anandamide	Splenocytes <i>in vitro</i>	1–25 μ M
THC, 11-OH-THC, 2-AG	Splenocytes <i>in vitro</i>	3–30 μ M
THC, CP 55,940, WIN 55,212-2	Lymphocytes <i>in vitro</i>	0.1–100 nM (0.0001–0.1 μ M)
THC	Drug injected into mice	>5 mg/kg
HU-210	Drug injected into mice	>0.05 mg/kg
THC, 11-OH-THC, CBD, CP 55,940, CBN	Splenocytes <i>in vitro</i>	1–30 μ M
THC	Drug injected into rodents	3 mg/kg per day for 25 days, 40 mg/kg per day for 2 days
THC, 11-OH-THC	Natural killer cells <i>in vitro</i>	0.1–32 μ M
THC	Peritoneal macrophages and monocytes	3–30 μ M
THC, CBD	Drug injected into mice; in one case, <i>in vitro</i> tests done on spleens	>5 mg/kg per day for 4 days or 50 mg/kg every 5 days for up to 8 weeks
THC, CBD	Peripheral blood mononuclear cells <i>in vitro</i>	<0.1 μ M 30 μ M
THC, CBD	Splenocytes and T cells <i>in vitro</i>	10 μ M
THC	Phorbol myristate acetate-differentiated macrophage <i>in vitro</i>	10–20 μ M
THC	Endotoxin-activated macrophages <i>in vitro</i>	10–30 μ M
THC	Peritoneal macrophages <i>in vitro</i>	10–30 μ M

Result	Reference
Higher doses suppressed T cell proliferation	Luo, 1992; Pross, 1992; ^b Klein, 1985; ^c Specter, 1990; ^d Lee, 1995; ^a Herring, 1998
Lower doses increased T cell proliferation <i>in vitro</i>	Luo, 1992; Lee, 1995; ^a Pross, 1992 ^b
Little or no effect on T cell proliferation	Lee, 1995; ^a Devane, 1992
Decreased B cell proliferation	Klein, 1985; ^c Lee, 1995 ^a
Increased B cell proliferation	Derocq, 1995
Antibody production suppressed	Baczynsky, 1983; Schatz, 1993
Antibody production suppressed	Titishov, 1989
Antibody production suppressed	Klein, 1990; Baczynsky, 1983; Kaminski, 1992, 1994; Herring, 1998
Repeated low doses or a high dose of THC suppressed the activity of natural killer cells	Patel, 1985; Klein, 1987
Doses of $\geq 10 \mu\text{M}$ suppressed natural killer cell cytolytic activity; doses $< 10 \mu\text{M}$ produced no effect	Klein, 1987; Luo, 1989
Variable doses of THC suppressed macrophage functions <i>in vitro</i>	Lopez-Cepero, 1986; Specter, 1991; Tang, 1992
THC suppressed normal immune response; interferons failed to increase when exposed to cytokine inducer; CBD had no suppressive effect	Cabral, 1986; Blanchard, 1986
Increased interferon production	Watzl, 1991
Decreased interferon production	
Both THC and CBD suppressed interleukin-2 secretion and number of interleukin-2 transcripts	Condie, 1996
Increased tumor necrosis factor production and interleukin-1 supernatant bioactivity	Shivers, 1994
Increased processing and release of interleukin-1 rather than cellular production of interleukin-1	Zhu, 1994
Increased interleukin-1 bioactivity	Klein, 1990

*Drug concentrations are given in the standard format of molarity (M). A 1-M solution is the molecular weight of the compound (in grams) in 1 liter (L) of solution. The molecular

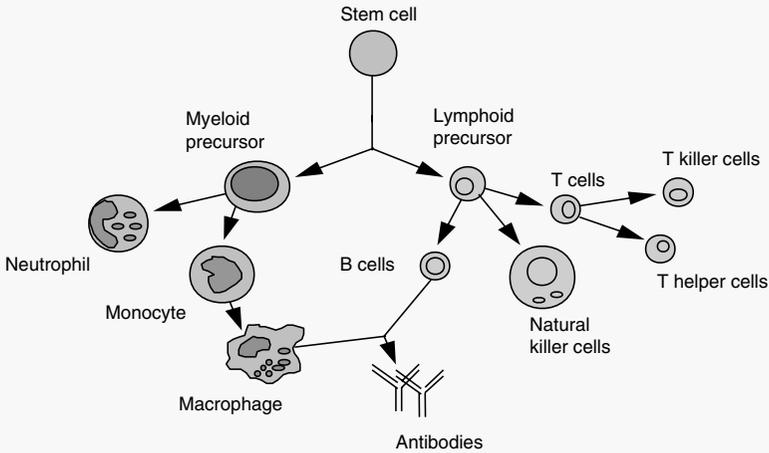

Box 2.1 Cells of the Immune System

The various organs of the immune system are positioned throughout the body and include bone marrow, thymus, lymph nodes, and spleen. The cells of the immune system consist of white blood cells, or leukocytes, which are formed in the bone marrow from stem cells—so-called because a great variety of cells descend from them (see below). There are two kinds of leukocytes: lymphocytes and phagocytes. *Lymphocytes* consist of B cells, T cells (B and T refer to where the cells mature, either in the bone marrow [B] or thymus [T]), and natural killer (NK) cells; the major phagocytes are monocytes, macrophages, and neutrophils. *Phagocytes* have many important roles in the immune response; most important is that they initiate the response by engulfing and digesting foreign substances, or antigens (such as bacteria, viruses, and foreign proteins), that enter the body. Once digested, the antigens are exposed to specialized lymphocytes, some of which produce antibodies and effector T cells, which help destroy any antigens remaining in the body. *Antibodies* are proteins produced by B cells that bind to antigens and promote antigen destruction. Effector T cells include killer T cells, which attack and kill antigen laden cells, and helper T cells, which secrete special proteins called cytokines that promote antigen elimination. NK cells are specialized lymphocytes that are also activated by antigen to either kill infected targets or secrete immunoregulatory cytokines.

Result	Reference
Cytokine-mediated septic shock and death occurred with exposure to sublethal dose of bacteria	Klein, 1993, 1994; Newton, 1994
Survival occurred, but with greater susceptibility to infection when challenged with bacteria and death when challenged with a lethal dose of bacteria	
Two high doses of THC potentiated the effects of herpes simplex and enhanced the progression of death	Specter, 1991
Single dose did not promote death	

weight of THC is 314, so a 1-M solution would be 314 g of THC in 1 L of solution, and a 10- μ M solution would be 3.14 mg THC/L.

A 1- to 10- μ M concentration will generally elicit a physiologically relevant response in immune cell cultures. Higher doses are often suspected of not being biologically meaningful because they are much larger than would ever be achieved in the body. The doses listed in this table are, for the most part, very high. See text for further discussion.

Cannabinoid Receptors and Intracellular Action in Immune Cells

CB₂ appears to be the predominant gene expressed in resting leukocytes.^{78,112} The level of CB₁ gene activity is normally low in resting cells but increases with cell activation.³² Thus the CB₁ receptor might be important only when immune responses are stimulated, but the physiological relevance of this observation remains to be determined. Some of the cannabinoid effects observed in immune systems, especially at high drug concentrations, are likely mediated through nonreceptor mechanisms, but these have not yet been identified.⁴

Ligand binding to either CB₁ or CB₂ inhibits adenylate cyclase, an enzyme that is responsible for cAMP production and is, thus, an integral aspect of intracellular signal transduction (see Figure 2.3).^{53,79,91,122,139,151,167} Increases in intracellular cAMP concentrations lead to immune enhancement, and decreases lead to an inhibition of the immune response.⁷⁷ Cannabinoids inhibit the rise in intracellular cAMP that normally results from leukocyte activation, and this might be the pathway through which cannabinoids suppress immune cell functions.^{28,74,167} In addition, cannabinoids activate other molecular pathways such as the nuclear factor-kB pathway, and therefore these signals might be modified in drug-treated immune cells.^{33,74}

T and B Cells

When stimulated by antigen, lymphocytes (see Box 2.1) first proliferate and then mature or differentiate to become potent effector cells, such as B cells that release antibodies or T cells that release cytokines. The normal T-cell proliferation that is seen when human lymphocytes and mouse splenocytes (spleen cells) are exposed to antigens and mitogens* can be inhibited by THC, 11-OH-THC, cannabinol, and 2-AG, as well as synthetic cannabinoid agonists such as CP 55,940; WIN 55,212-2; and HU-210.^{61,89,93,99,127,155} In contrast, one study testing anandamide revealed little or no effect on T cell proliferation.⁹³

However, these drug effects are variable and depend on experimental conditions, such as the experimental drug dose used, the mitogen used, the percentage of serum in the culture, and the timing of cannabinoid drug exposure. In general, lower doses of cannabinoids increase proliferation and higher doses suppress proliferation. Doses that are effective in suppressing immune function are typically greater than 10 μ M in cell culture studies and greater than 5 mg/kg in whole-animal studies.⁸⁵ By

*Mitogens are substances that stimulate cell division (mitosis) and cell transformation.

comparison, at 0.05 mg/kg, people will experience the full psychoactive effects of THC; however, because of their high metabolic rates, small rodents frequently require drug doses that are 100-fold higher than doses needed for humans to achieve comparable drug effects. Thus, the immune effects of doses of cannabinoids higher than those ever experienced by humans should be interpreted with caution.⁹³

As with T cells, B cell proliferation can be suppressed by various cannabinoids, such as THC, 11-OH-THC, and 2-AG, but B cell proliferation is more inhibited at lower drug concentrations than T cell proliferation.^{89,93} Conversely, low doses of THC, CP 55,940 and WIN 55,212-2 *increase* B cell proliferation in cultured human cells exposed to mitogen.³⁵ This effect possibly involves the CB₂ receptor, because the effect appears to be the same when the CB₁ receptor was blocked by the antagonist SR 141716A (which does not block the CB₂ receptor). The reason for the differences in B cell responsiveness to cannabinoids is probably due to differences in cell type and source; for example, B cells collected from mouse spleen might respond to cannabinoids somewhat differently than B cells from human tonsils.

Natural Killer Cells

Repeated injections of relatively low doses of THC (3 mg/kg/day^{121*}) or two injections of a high dose (40 mg/kg⁸⁶) suppress the ability of NK cells to destroy foreign cells in rats and mice. THC can also suppress cytolytic activity of the NK cells in cell cultures; 11-OH-THC is even more potent.⁸⁶ In contrast, THC concentrations below 10 μ M had no effect on NK cell activity in mouse cell cultures.⁹⁸

Macrophages

Macrophages perform various functions, including phagocytosis (ingestion and destruction of foreign substances), cytolysis, antigen presentation to lymphocytes, and production of active proteins involved in destroying microorganisms, tissue repair, and modulation of immune cells. Those functions can be suppressed by THC doses similar to those capable of modulating lymphocyte functions (see above).^{88,109}

*While 3 mg/kg would be a high dose for humans (see Table 3.1), in rodents, it is a low dose for immunological effects and a moderate dose for behavioral effects.

Cytokines

Cytokines are proteins produced by immune cells. When released from the producing cell, they can alter the function of other cells they come in contact with. In a sense they are like hormones. Thus, cannabinoids can either increase or decrease cytokine production depending upon experimental conditions.

Some cytokines, such as interferon- γ and interleukin-2 (IL-2), are produced by T helper-1 (Th1) cells. These cytokines help to activate cell-mediated immunity and the killer cells that eliminate microorganisms from the body (see Box 2.1). When injected into mice, THC suppresses the production of those cytokines that modulate the host response to infection (see below).¹¹⁵ Cannabinoids also modulate interferons induced by viral infection,²¹ as well as other interferon inducers.⁸⁵ Furthermore, in human cell cultures, interferon production can be increased by low concentrations but decreased by high concentrations of either THC or CBD.¹⁶⁸ In addition to Th1 cytokines, cannabinoids modulate the production of cytokines such as interleukin-1 (IL-1), tumor necrosis factor (TNF), and interleukin-6 (IL-6).^{145,176} At 8 mg/kg, THC can increase the *in vivo* mobilization of serum acute-phase cytokines, including IL-1, TNF, and IL-6.⁹⁰ Finally, although these studies suggest that cannabinoids can induce an increase in cytokines, other studies suggest that they can also suppress cytokine production.⁸⁵ The different results might be due to different cell culture conditions or because different cell lines were studied.

Antibody Production

Antibody production is an important measure of humoral immune function as contrasted with cellular (cell-mediated) immunity. Antibody production can be suppressed in mice injected with relatively low doses of THC (>5 mg/kg) or HU-210 (>0.05 mg/kg) and in mouse spleen cell cultures exposed to a variety of cannabinoids, including THC, 11-OH-THC, cannabinal, cannabidiol, CP 55,940, or HU-210.^{5,6,61,78,79,84,85,142,164} However, the inhibition of antibody response by cannabinoids was only observed when antibody-forming cells were exposed to T-cell-dependent antigens (the responses require functional T cells and macrophages as accessory cells). Conversely, antibody responses to several T-cell-independent antigens were not inhibited by THC; this suggests that B cells are relatively insensitive to inhibition by cannabinoids.¹⁴²

Resistance to Infection in Animals Exposed to Cannabinoids

Evaluation of bacterial infections in mice that received injections of

THC can suppress resistance to infection, although the effect depends on the dose and timing of drug administration. Mice pretreated with THC (8 mg/kg) one day before infection with a sublethal dose of the pneumonia-causing bacteria *Legionella pneumophila* and then treated again one day after the infection with THC developed symptoms of cytokine-mediated septic shock and died; control mice that were not pretreated with THC became immune to repeated infection and survived the bacterial challenge.⁹⁰ If only one injection of THC was given or doses less than 5 mg/kg were used, all the mice survived the initial infection but failed to survive later challenge with a lethal dose of the bacteria; hence, these mice failed to develop immune memory in response to the initial sublethal infection.⁸⁷ Note that these are very high doses and are considerably higher than doses experienced by marijuana users (see Figure 3.1).¹¹⁵ In rats, doses of 4.0 mg/kg THC are aversive.⁹⁵

Few studies have been done to evaluate the effect of THC on viral infections, and this subject needs further study.²⁰ Compared to healthy animals, THC might have greater immunosuppressive effects in animals whose immune systems are severely weakened. For example, a very high dose of THC (100 mg/kg) given two days before and after herpes simplex virus infection was shown to be a cofactor with the virus in advancing the progression to death in an immunodeficient mouse model infected with a leukemia virus.⁸⁵ However, THC given as a single dose (100 mg/kg) two days before herpes simplex virus infection did not promote the progression to death. Hence, whether THC is immunosuppressive probably depends on the timing of THC exposure relative to an infection.

Antiinflammatory Effects

As discussed above, cannabinoid drugs can modulate the production of cytokines, which are central to inflammatory processes in the body. In addition, several studies have shown directly that cannabinoids can be antiinflammatory. For example, in rats with autoimmune encephalomyelitis (an experimental model used to study multiple sclerosis), cannabinoids were shown to attenuate the signs and the symptoms of central nervous system damage.^{100,172} (Some believe that nerve damage associated with multiple sclerosis is caused by an inflammatory reaction.) Likewise, the cannabinoid, HU-211, was shown to suppress brain inflammation that resulted from closed-head injury¹⁴⁶ or infectious meningitis⁷ in studies on rats. HU-211 is a synthetic cannabinoid that does not bind to cannabinoid receptors and is not psychoactive;⁷ thus, without direct evidence, the effects of marijuana cannot be assumed to include those of HU-211. CT-3, another atypical cannabinoid, suppresses acute and chronic joint inflammation in animals.¹⁷⁸ It is a nonpsychoactive synthetic deriva-

tive of 11-THC-oic acid (a breakdown product of THC) and does not appear to bind to cannabinoid receptors.¹²⁹ Cannabichromene, a cannabinoid found in marijuana, has also been reported to have antiinflammatory properties.¹⁷³ No mechanism of action for possible antiinflammatory effects of cannabinoids has been identified, and the effects of these atypical cannabinoids and effects of marijuana are not yet established.

It is interesting to note that two reports of cannabinoid-induced analgesia are based on the ability of the endogenous cannabinoids, anandamide and PEA, to reduce pain associated with local inflammation that was experimentally induced by subcutaneous injections of dilute formalin.^{22,73} Both THC and anandamide can increase serum levels of ACTH and corticosterone in animals.¹⁶⁹ Those hormones are involved in regulating many responses in the body, including those to inflammation. The possible link between experimental cannabinoid-induced analgesia and reported antiinflammatory effects of cannabinoids is important for potential therapeutic uses of cannabinoid drugs but has not yet been established.

Conclusions Regarding Effects on the Immune System

Cell culture and animal studies have established cannabinoids as immunomodulators—that is, they increase some immune responses and decrease others. The variable responses depend on such experimental factors as drug dose, timing of delivery, and type of immune cell examined. Cannabinoids affect multiple cellular targets in the immune system and a variety of effector functions. Many of the effects noted above appear to occur at concentrations over 5 μM *in vitro* and over 5 $\mu\text{g}/\text{kg}$ *in vivo*.^{*} By comparison, a 5-mg injection of THC into a person (about 0.06 mg/kg) is enough to produce strong psychoactive effects. It should be emphasized, however, that little is known about the immune effects of chronic low-dose exposure to cannabinoids.

Another issue in need of further clarification involves the potential usefulness of cannabinoids as therapeutic agents in inflammatory diseases. Glucocorticoids have historically been used for these diseases, but nonpsychotropic cannabinoids potentially have fewer side effects and might thus offer an improvement over glucocorticoids in treating inflammatory diseases.

^{*}*In vitro* studies are those in which animal cells or tissue are removed and studied outside the animal; *in vivo* studies are those in which experiments are conducted in the whole animal.

TABLE 2.8 Historical Comparisons Between Cannabinoids and Opiates

Pharmacological Discoveries	Cannabinoids	Opiates
Discovery of receptor existence	1988 (Devane et al. and Dill and Howlett) ^{36,40}	1973 (Pert and Snyder, Simon, and Terenius) ^{123,149,162}
Identification of receptor antagonist	1994 SR 141716A (Rinaldi-Carmona et al.) ¹³²	Before 1973: naloxone

First receptor cloned	1990 (Matsuda et al.) ¹⁰⁷	1992 (Evans et al. and Kieffer et al.) ^{41,82}
Natural functions	Unknown	Pain, reproduction, mood, movement, and others

CONCLUSIONS AND RECOMMENDATIONS

Given the progress of the past 15 years in understanding the effects of cannabinoids, research in the next decade is likely to reveal even more. It is interesting to compare how little we know about cannabinoids with how much we know about opiates. Table 2.8 suggests good reason for optimism about the future of cannabinoid drug development. Now that many of the basic tools of cannabinoid pharmacology and biology have been developed, one can expect to see rapid advances that can begin to match what is known of opiate systems in the brain.

Despite the tremendous progress in understanding the pharmacology and neurobiology of brain cannabinoid systems, this field is still in its early developmental stages. A key focus for future study is the neurobiology of endogenous cannabinoids; establishing the precise brain localization (in which cells and where) of cannabinoids, cellular storage and release mechanisms, and uptake mechanisms will be crucial in determining the biological role of this system. Technology needed to establish the biological significance of these systems will be broad based and include such research tools as the transgenic or gene knockout mice, as has already been accomplished for various opioid-receptor types.²⁶ In 1997, both CB₁ and CB₂ knockout mice were generated by a team of scientists at the National Institutes of Health, and a group in France has developed another strain of CB₁ knockout mice.⁹²

Several research tools will greatly aid such investigations, in particular a greater selection of agonists and antagonists that permit discrimination in activation between CB₁ and CB₂ and hydrophilic agonists that can be delivered to animals or cells more effectively than hydrophobic compounds. In the area of drug development, future progress should continue to provide more specific agonists and antagonists for CB₁ and CB₂ receptors, with varying potential for therapeutic uses.

There are certain areas that will provide keys to a better understanding of the potential therapeutic value of cannabinoids. For example, basic biology indicates a role for cannabinoids in pain and control of movement, which is consistent with a possible therapeutic role in these areas. The evidence is relatively strong for the treatment of pain and, intriguing although less well established, for movement disorders. The neuroprotective properties of cannabinoids might prove therapeutically useful, although it should be noted that this is a new area and other, better studied, neuroprotective drugs have not yet been shown to be therapeutically useful. Cannabinoid research is clearly relevant not only to drug abuse but also to understanding basic human biology. Further, it offers the potential for the discovery and development of new therapeutically useful drugs.

CONCLUSION: At this point, our knowledge about the biology of marijuana and cannabinoids allows us to make some general conclusions:

- Cannabinoids likely have a natural role in pain modulation, control of movement, and memory.
- The natural role of cannabinoids in immune systems is likely multi-faceted and remains unclear.
- The brain develops tolerance to cannabinoids.
- Animal research has demonstrated the potential for dependence, but this potential is observed under a narrower range of conditions than with benzodiazepines, opiates, cocaine, or nicotine.
- Withdrawal symptoms can be observed in animals but appear mild compared with those of withdrawal from opiates or benzodiazepines, such as diazepam (Valium).

CONCLUSION: The different cannabinoid receptor types found in the body appear to play different roles in normal physiology. In addition, some effects of cannabinoids appear to be independent of those receptors. The variety of mechanisms through which cannabinoids can influence human physiology underlies the variety

of potential therapeutic uses for drugs that might act selectively on different cannabinoid systems.

RECOMMENDATION: Research should continue into the physiological effects of synthetic and plant-derived cannabinoids and the natural function of cannabinoids found in the body. Because different cannabinoids appear to have different effects, cannabinoid research should include, but not be restricted to, effects attributable to THC alone.

This chapter has summarized recent progress in understanding the basic biology of cannabinoids and provides a foundation for the next two chapters which review studies on the potential health risks (chapter 3) and benefits of marijuana use (chapter 4).

3

First, Do No Harm: Consequences of Marijuana Use and Abuse

Primum non nocere. This is the physician's first rule: whatever treatment a physician prescribes to a patient—first, that treatment must not harm the patient.

The most contentious aspect of the medical marijuana debate is not whether marijuana can alleviate particular symptoms but rather the degree of harm associated with its use. This chapter explores the negative health consequences of marijuana use, first with respect to drug abuse, then from a psychological perspective, and finally from a physiological perspective.

THE MARIJUANA "HIGH"

The most commonly reported effects of smoked marijuana are a sense of well-being or euphoria and increased talkativeness and laughter alternating with periods of introspective dreaminess followed by lethargy and sleepiness (see reviews by Adams and Martin, 1996,¹ Hall and Solowij,⁵⁹ and Hall et al.⁶⁰). A characteristic feature of a marijuana "high" is a distortion in the sense of time associated with deficits in short-term memory and learning. A marijuana smoker typically has a sense of enhanced physical and emotional sensitivity, including a feeling of greater interpersonal closeness. The most obvious behavioral abnormality displayed by someone under the influence of marijuana is difficulty in carrying on an intelli-

gible conversation, perhaps because of an inability to remember what was just said even a few words earlier.

The high associated with marijuana is not generally claimed to be integral to its therapeutic value. But mood enhancement, anxiety reduction, and mild sedation can be desirable qualities in medications—particularly for patients suffering pain and anxiety. Thus, although the psychological effects of marijuana are merely side effects in the treatment of some symptoms, they might contribute directly to relief of other symptoms. They also must be monitored in controlled clinical trials to discern which effect of cannabinoids is beneficial. These possibilities are discussed later under the discussions of specific symptoms in chapter 4.

The effects of various doses and routes of delivery of THC are shown in Table 3.1.

Adverse Mood Reactions

Although euphoria is the more common reaction to smoking marijuana, adverse mood reactions can occur. Such reactions occur most frequently in inexperienced users after large doses of smoked or oral marijuana. They usually disappear within hours and respond well to reassurance and a supportive environment. Anxiety and paranoia are the most common acute adverse reactions;⁵⁹ others include panic, depression, dysphoria, depersonalization, delusions, illusions, and hallucinations.^{1,40,66,69} Of regular marijuana smokers, 17% report that they have experienced at least one of the symptoms, usually early in their use of marijuana.¹⁴⁵ Those observations are particularly relevant for the use of medical marijuana in people who have not previously used marijuana.

DRUG DYNAMICS

There are many misunderstandings about drug abuse and dependence (see reviews by O'Brien¹¹⁴ and Goldstein⁵⁴). The terms and concepts used in this report are as defined in the most recent *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*,³ the most influential system in the United States for diagnoses of mental disorders, including substance abuse (see Box 3.1). Tolerance, dependence, and withdrawal are often presumed to imply abuse or addiction, but this is not the case. Tolerance and dependence are *normal* physiological adaptations to repeated use of any drug. The correct use of prescribed medications for pain, anxiety, and even hypertension commonly produces tolerance and some measure of physiological dependence.

Even a patient who takes a medicine for appropriate medical indications and at the correct dosage can develop tolerance, physical depen-

TABLE 3.1 Psychoactive Doses of THC in Humans

Investigators	THC Delivery System	THC Dose Administered	Resulting Plasma Concentrations of THC	Subjects' Reactions
Heishman and co-workers (1990) ^{62a}	One 2.75% THC cigarette smoked	0.32 mg/kg ^a	50–100 ng/ml	At higher level, subjects felt 100% "high" and psychomotor performance was decreased; at 50 ng/ml, subjects felt about 50% "high"
Kelly and co-workers (1993) ⁸⁵	1-g marijuana cigarette smoked (2% or 3.5% THC)	0.25–0.50 mg/kg ^a	Not measured	Enough to feel psychological effects of THC
Ohlsson and co-workers (1980) ¹¹⁸	19-mg THC cigarette smoked (about 1.9% THC)	About 0.22 mg/kg ^b	100 ng/ml	Subjects felt "high"
	5 mg of THC injected intravenously	About 0.06 mg/kg ^b	100 ng/ml	Subjects felt "high"
	Chocolate chip cookie containing 20 mg of THC	About 0.24 mg/kg	8 ng/ml	Subjects rated "high" as only about 40%
Lindgren and co-workers (1981) ⁹⁵	19-mg THC cigarette smoked to "desired high"	12 mg smoked (7 mg remained in cigarette butt)	85 ng/ml after 3 min., 35 ng/ml after 15 min.	Subjects felt "high" after 3 min., and maximally high after 10–20 min. (average self-ratings of 5.5 on 10-point scale)
	5 mg of THC injected intravenously	0.06 mg/kg ^c	300 ng/ml after 3 min., 65 ng/ml after 15 min.	Subjects felt maximally "high" after 10 min. (average self ratings of 7.5 on a 10-point scale)

^aSubjects' weights and cigarette weights were not given. Calculation based on 85-kg body weight and 1-g cigarette weight. Note that some THC would have remained in the cigarette butt and some would have been lost in sidestream smoke, so these represent maximal possible doses. Actual doses would have been slightly less.

^bBased on estimated average 85-kg weight of 11 men 18–35 years old.

^cBased on approximate 80-kg weight of subjects (including men and women).

Box 3.1 Definitions

Addiction. Substance dependence.

Craving refers to the intense desire for a drug and is the most difficult aspect of addiction to overcome.

Physiological dependence is diagnosed when there is evidence of either tolerance or withdrawal; it is sometimes, but not always, manifested in substance dependence.

Reinforcement. A drug—or any other stimulus—is referred to as a reinforcer if exposure to it is followed by an increase in frequency of drug-seeking behavior. The taste of chocolate is a reinforcer for biting into a chocolate bar. Likewise, for many people the sensation experienced after drinking alcohol or smoking marijuana is a reinforcer.

Substance dependence is a cluster of cognitive, behavioral, and physiological symptoms indicating that a person continues use of the substance despite significant substance-related problems.

Tolerance is the most common response to repetitive use of a drug and can be defined as the reduction in responses to the drug after repeated administrations.

Withdrawal. The collective symptoms that occur when a drug is abruptly withdrawn are known as withdrawal syndrome and are often the only evidence of physical dependence.

dence, and withdrawal symptoms if the drug is stopped abruptly rather than gradually. For example, a hypertensive patient receiving a beta-adrenergic receptor blocker, such as propranolol, might have a good therapeutic response; but if the drug is stopped abruptly, there can be a withdrawal syndrome that consists of tachycardia and a rebound increase in blood pressure to a point that is temporarily higher than before administration of the medication began.

Because it is an illegal substance, some people consider any use of marijuana as substance abuse. However, this report uses the medical definition; that is, substance abuse is a maladaptive pattern of repeated substance use manifested by recurrent and significant adverse consequences.³ Substance abuse and dependence are both diagnoses of pathological substance use. Dependence is the more serious diagnosis and implies compulsive drug use that is difficult to stop despite significant substance-related problems (see Box 3.2).

Box 3.2

DSM-IV Criteria for Substance Dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

- (1) Tolerance, as defined by either of the following:
 - (a) A need for markedly increased amount of the substance to achieve intoxication or desired effect.
 - (b) Markedly diminished effect with continued use of the same amount of the substance.
- (2) Withdrawal, as defined by either of the following:
 - (a) The characteristic withdrawal syndrome for the substance.
 - (b) The same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms.
- (3) The substance is often taken in larger amounts or over a longer period than was intended.
- (4) There is a persistent desire or unsuccessful efforts to cut down or control substance use.
- (5) A great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), to use the substance (e.g., chain-smoking), or to recover from its effects.
- (6) Important social, occupational, or recreational activities are given up or reduced because of substance use.
- (7) The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression or continued drinking despite recognition that an ulcer was made worse by alcohol consumption).

Substance abuse with physiological dependence is diagnosed if there is evidence of tolerance or withdrawal.

Substance abuse without physiological dependence is diagnosed if there is no evidence of tolerance or withdrawal.

Reinforcement

Drugs vary in their ability to produce good feelings in users, and the more strongly reinforcing a drug is, the more likely it will be abused (G. Koob, Institute of Medicine (IOM) workshop). Marijuana is indisputably reinforcing for many people. The reinforcing properties of even so mild a

stimulant as caffeine are typical of reinforcement by addicting drugs (reviewed by Goldstein⁵⁴ in 1994). Caffeine is reinforcing for many people at low doses (100–200 mg, the average amount of caffeine in one to two cups of coffee) and is aversive at high doses (600 mg, the average amount of caffeine in six cups of coffee). The reinforcing effects of many drugs are different for different people. For example, caffeine was most reinforcing for test subjects who scored lowest on tests of anxiety but tended not to be reinforcing for the most anxious subjects.

As an argument to dispute the abuse potential of marijuana, some have cited the observation that animals do not willingly self-administer THC, as they will cocaine. Even if that were true, it would not be relevant to human use of marijuana. The value in animal models of drug self-administration is not that they are necessary to show that a drug is reinforcing but rather that they provide a model in which the effects of a drug can be studied. Furthermore, THC is indeed rewarding to animals at some doses but, like many reinforcing drugs, is aversive at high doses (4.0 mg/kg).⁹³ Similar effects have been found in experiments conducted in animals outfitted with intravenous catheters that allow them to self-administer WIN 55,212, a drug that mimics the effects of THC.¹⁰⁰

A specific set of neural pathways has been proposed to be a “reward system” that underlies the reinforcement of drugs of abuse and other pleasurable stimuli.⁵¹ Reinforcing properties of drugs are associated with their ability to increase concentrations of particular neurotransmitters in areas that are part of the proposed brain reward system. The median forebrain bundle and the nucleus accumbens are associated with brain reward pathways.⁸⁸ Cocaine, amphetamine, alcohol, opioids, nicotine, and THC¹⁴⁴ all increase extracellular fluid dopamine in the nucleus accumbens region (reviewed by Koob and Le Moal⁸⁸ and Nestler and Aghajanian¹¹⁰ in 1997). However, it is important to note that brain reward systems are not strictly “drug reinforcement centers.” Rather, their biological role is to respond to a range of positive stimuli, including sweet foods and sexual attraction.

Tolerance

The rate at which tolerance to the various effects of any drug develops is an important consideration for its safety and efficacy. For medical use, tolerance to some effects of cannabinoids might be desirable. Differences in the rates at which tolerance to the multiple effects of a drug develops can be dangerous. For example, tolerance to the euphoric effects of heroin develops faster than tolerance to its respiratory depressant effects, so heroin users tend to increase their daily doses to reach their desired level of euphoria, thereby putting themselves at risk for respiratory arrest. Because tolerance to the various effects of cannabinoids might

develop at different rates, it is important to evaluate independently their effects on mood, motor performance, memory, and attention, as well as any therapeutic use under investigation.

Tolerance to most of the effects of marijuana can develop rapidly after only a few doses, and it also disappears rapidly. Tolerance to large doses has been found to persist in experimental animals for long periods after cessation of drug use. Performance impairment is less among people who use marijuana heavily than it is among those who use marijuana only occasionally,^{29,104,124} possibly because of tolerance. Heavy users tend to reach higher plasma concentrations of THC than light users after similar doses of THC, arguing against the possibility that heavy users show less performance impairment because they somehow absorb less THC (perhaps due to differences in smoking behavior).⁹⁵

There appear to be variations in the development of tolerance to the different effects of marijuana and oral THC. For example, daily marijuana smokers participated in a residential laboratory study to compare the development of tolerance to THC pills and to smoked marijuana.^{61,62} One group was given marijuana cigarettes to smoke four times per day for four consecutive days; another group was given THC pills on the same schedule. During the four-day period, both groups became tolerant to feeling "high" and what they reported as a "good drug effect." In contrast, neither group became tolerant to the stimulatory effects of marijuana or THC on appetite. "Tolerance" does not mean that the drug no longer produced the effects but simply that the effects were less at the end than at the beginning of the four-day period. The marijuana smoking group reported feeling "mellow" after smoking and did not show tolerance to this effect; the group that took THC pills did not report feeling "mellow." The difference was also reported by many people who described their experiences to the IOM study team.

The oral and smoked doses were designed to deliver roughly equivalent amounts of THC to a subject. Each smoked marijuana dose consisted of five 10-second puffs of a marijuana cigarette containing 3.1% THC; the pills contained 30 mg of THC. Both groups also received placebo drugs during other four-day periods. Although the dosing of the two groups was comparable, different routes of administration resulted in different patterns of drug effect. The peak effect of smoked marijuana is usually felt within minutes and declines sharply after 30 minutes^{68,95}; the peak effect of oral THC is usually not felt until about an hour and lasts for several hours.¹¹⁸

Withdrawal

A distinctive marijuana and THC withdrawal syndrome has been

identified, but it is mild and subtle compared with the profound physical syndrome of alcohol or heroin withdrawal.^{31,74} The symptoms of marijuana withdrawal include restlessness, irritability, mild agitation, insomnia, sleep EEG disturbance, nausea, and cramping (Table 3.2). In addition to those symptoms, two recent studies noted several more. A group of adolescents under treatment for conduct disorders also reported fatigue and illusions or hallucinations after marijuana abstinence (this study is discussed further in the section on “Prevalence and Predictors of Dependence on Marijuana and Other Drugs”).³¹ In a residential study of daily

TABLE 3.2 Drug Withdrawal Symptoms

Nicotine	Alcohol	Marijuana	Cocaine	Opioids (e.g., heroin or morphine)
Restlessness Irritability Impatience, hostility Dysphoria Depression Anxiety Difficulty concentrating	Irritability Sleep disturbance Nausea	Restlessness Irritability Mild agitation Insomnia Sleep EEG disturbance Nausea Cramping	 Dysphoria Depression Sleepiness, fatigue Bradycardia	Restlessness Irritability Dysphoria Anxiety Insomnia Nausea Cramping
Decreased heart rate	Tachycardia, hypertension Sweating Seizures			Muscle aches Increased sensitivity to pain
Increased appetite or weight gain	Alcohol craving Delirium tremens ^a Tremor Perceptual distortion		Cocaine craving	Opioid craving

^aSevere agitation, confusion, visual hallucinations, fever, profuse sweating, nausea, diarrhea, dilated pupils.
SOURCE: O’Brien (1996).¹¹³

marijuana users, withdrawal symptoms included sweating and runny nose, in addition to those listed above.⁶² A marijuana withdrawal syndrome, however, has been reported only in a group of adolescents in treatment for substance abuse problems³¹ and in a research setting where subjects were given marijuana or THC daily.^{62,74}

Withdrawal symptoms have been observed in carefully controlled laboratory studies of people after use of both oral THC and smoked marijuana.^{61,62} In one study, subjects were given very high doses of oral THC: 180–210 mg per day for 10–20 days, roughly equivalent to smoking 9–10 2% THC cigarettes per day.⁷⁴ During the abstinence period at the end of the study, the study subjects were irritable and showed insomnia, runny nose, sweating, and decreased appetite. The withdrawal symptoms, however, were short lived. In four days they had abated. The time course contrasts with that in another study in which lower doses of oral THC were used (80–120 mg/day for four days) and withdrawal symptoms were still near maximal after four days.^{61,62}

In animals, simply discontinuing chronic heavy dosing of THC does not reveal withdrawal symptoms, but the “removal” of THC from the brain can be made abrupt by another drug that blocks THC at its receptor if administered when the chronic THC is withdrawn. The withdrawal syndrome is pronounced, and the behavior of the animals becomes hyperactive and disorganized.¹⁵³ The half-life of THC in brain is about an hour.^{16,24} Although traces of THC can remain in the brain for much longer periods, the amounts are not physiologically significant. Thus, the lack of a withdrawal syndrome when THC is abruptly withdrawn without administration of a receptor-blocking drug is probably not due to a prolonged decline in brain concentrations.

Craving

Craving, the intense desire for a drug, is the most difficult aspect of addiction to overcome. Research on craving has focused on nicotine, alcohol, cocaine, and opiates but has not specifically addressed marijuana.¹¹⁵ Thus, while this section briefly reviews what is known about drug craving, its relevance to marijuana use has not been established.

Most people who suffer from addiction relapse within a year of abstinence, and they often attribute their relapse to craving.⁵⁸ As addiction develops, craving increases even as maladaptive consequences accumulate. Animal studies indicate that the tendency to relapse is based on changes in brain function that continue for months or years after the last use of the drug.¹¹⁵ Whether neurobiological conditions change during the manifestation of an abstinence syndrome remains an unanswered question in drug abuse research.⁸⁸ The “liking” of sweet foods, for example, is

mediated by opioid forebrain systems and by brain stem systems, whereas “wanting” seems to be mediated by ascending dopamine neurons that project to the nucleus accumbens.¹⁰⁹

Anticraving medications have been developed for nicotine and alcohol. The antidepressant, bupropion, blocks nicotine craving, while naltrexone blocks alcohol craving.¹¹⁵ Another category of addiction medication includes drugs that block other drugs’ effects. Some of those drugs also block craving. For example, methadone blocks the euphoric effects of heroin and also reduces craving.

MARIJUANA USE AND DEPENDENCE

Prevalence of Use

Millions of Americans have tried marijuana, but most are not regular users. In 1996, 68.6 million people—32% of the U.S. population over 12 years old—had tried marijuana or hashish at least once in their lifetime, but only 5% were current users.¹³² Marijuana use is most prevalent among 18- to 25-year-olds and declines sharply after the age of 34 (Figure 3.1).^{77,132} Whites are more likely than blacks to use marijuana in adolescence, although the difference decreases by adulthood.¹³²

Most people who have used marijuana did so first during adolescence. Social influences, such as peer pressure and prevalence of use by peers, are highly predictive of initiation into marijuana use.⁹ Initiation is not, of course, synonymous with continued or regular use. A cohort of 456 students who experimented with marijuana during their high school years were surveyed about their reasons for initiating, continuing, and stopping their marijuana use.⁹ Students who began as heavy users were excluded from the analysis. Those who did not become regular marijuana users cited two types of reasons for discontinuing. The first was related to health and well-being; that is, they felt that marijuana was bad for their health or for their family and work relationships. The second type was based on age-related changes in circumstances, including increased responsibility and decreased regular contact with other marijuana users. Among high school students who quit, parental disapproval was a stronger influence than peer disapproval in discontinuing marijuana use. In the initiation of marijuana use, the reverse was true. The reasons cited by those who continued to use marijuana were to “get in a better mood or feel better.” Social factors were not a significant predictor of continued use. Data on young adults show similar trends. Those who use drugs in response to social influences are more likely to stop using them than those who also use them for psychological reasons.⁸⁰

The age distribution of marijuana users among the general popula-

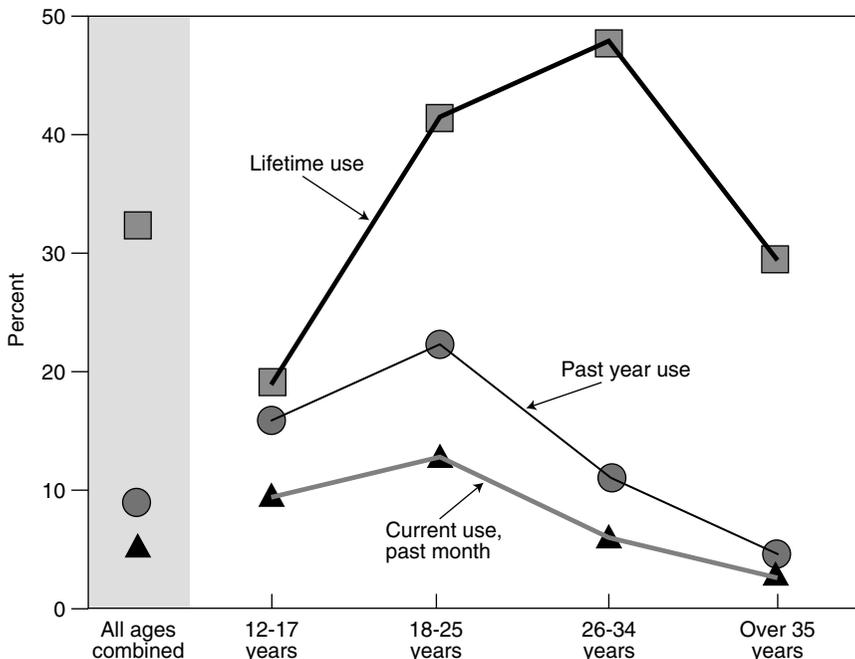

FIGURE 3.1 Age distribution of marijuana users among the general population.

tion contrasts with that of medical marijuana users. Marijuana use generally declines sharply after the age of 34 years, whereas medical marijuana users tend to be over 35. That raises the question of what, if any, relationship exists between abuse and medical use of marijuana; however, no studies reported in the scientific literature have addressed this question.

Prevalence and Predictors of Dependence on Marijuana and Other Drugs

Many factors influence the likelihood that a particular person will become a drug abuser or an addict; the user, the environment, and the drug are all important factors (Table 3.3).¹¹⁴ The first two categories apply to potential abuse of any substance; that is, people who are vulnerable to drug abuse for individual reasons and who find themselves in an environment that encourages drug abuse are initially likely to abuse the most readily available drug—regardless of its unique set of effects on the brain. The third category includes drug-specific effects that influence the abuse

TABLE 3.3 Factors That Are Correlated with Drug Dependence

Individual Factors

- Pharmacological effects of the drug
- Gender
- Age
- Genetic factors
- Individual risk-taking propensities
- Prior drug use

Environmental Factors

- Availability of the drug
- Acceptance of use of that drug in society
- Balance of social reinforcements and of punishments for use
- Balance of social reinforcements and of punishments for abstinence

SOURCE: Crowley and Rhine (1985).³²

liability of a particular drug. As discussed earlier in this chapter, the more strongly reinforcing a drug is, the more likely that it will be abused. The abuse liability of a drug is enhanced by how quickly its effects are felt, and this is determined by how the drug is delivered. In general, the effects of drugs that are inhaled or injected are felt within minutes, and the effects of drugs that are ingested take a half hour or more.

The proportion of people who become addicted varies among drugs. Table 3.4 shows estimates for the proportion of people among the general population who used or became dependent on different types of drugs. The proportion of users that ever became dependent includes anyone who was *ever* dependent—whether it was for a period of weeks or years—and thus includes more than those who are currently dependent. Compared to most other drugs listed in this table, dependence among marijuana users is relatively rare. This might be due to differences in specific drug effects, the availability of or penalties associated with the use of the different drugs, or some combination.

Daily use of most illicit drugs is extremely rare in the general population. In 1989, daily use of marijuana among high school seniors was less than that of alcohol (2.9% and 4.2%, respectively).⁷⁶

Drug dependence is more prevalent in some sectors of the population than in others. Age, gender, and race or ethnic group are all important.⁸ Excluding tobacco and alcohol, the following trends of drug dependence are statistically significant:⁸ Men are 1.6 times as likely than women to become drug dependent, non-Hispanic whites are about twice as likely as blacks to become drug dependent (the difference between non-Hispanic

TABLE 3.4 Prevalence of Drug Use and Dependence^a in the General Population

^aDiagnosis of drug dependence used in this study based on DSM-III-R criteria.²

^bThe percentage of people who ever used marijuana is higher than that reported by the National Household Survey on Drug Abuse (32%), probably due to different survey methods (for discussion, see Kandel, 1992⁷⁶).

SOURCE: Adapted from Table 2 in Anthony and co-workers (1994).⁸

and Hispanic whites was not significant), and people 25–44 years old are more than three times as likely as those over 45 years old to become drug dependent.

More often than not, drug dependence co-occurs with other psychiatric disorders. Most people with a diagnosis of drug dependence disorder also have a diagnosis of a another psychiatric disorder (76% of men and 65% of women).⁷⁶ The most frequent co-occurring disorder is alcohol abuse; 60% of men and 30% of women with a diagnosis of drug dependence also abuse alcohol. In women who are drug dependent, phobic disorders and major depression are almost equally common (29% and 28%, respectively). Note that this study distinguished only between alcohol, nicotine and “other drugs”; marijuana was grouped among “other drugs.” The frequency with which drug dependence and other psychiatric disorders co-occur might not be the same for marijuana and other drugs that were included in that category.

A strong association between drug dependence and antisocial personality or its precursor, conduct disorder, is also widely reported in children and adults (reviewed in 1998 by Robins¹²⁶). Although the causes of the association are uncertain, Robins recently concluded that it is more likely that conduct disorders generally lead to substance abuse than the reverse.¹²⁶ Such a trend might, however, depend on the age at which the conduct disorder is manifested.

A longitudinal study by Brooks and co-workers noted a significant relationship between adolescent drug use and disruptive disorders in young adulthood; except for earlier psychopathology, such as childhood conduct disorder, the drug use preceded the psychiatric disorders.¹⁸ In contrast with use of other illicit drugs and tobacco, moderate (less than once a week and more than once a month) to heavy marijuana use did not predict anxiety or depressive disorders; but it was similar to those other drugs in predicting antisocial personality disorder. The rates of disruptive disorders increased with increased drug use. Thus, heavy drug use among adolescents can be a warning sign for later psychiatric disorders; whether it is an early manifestation of or a cause of those disorders remains to be determined.

Psychiatric disorders are more prevalent among adolescents who use drugs—including alcohol and nicotine—than among those who do not.⁷⁹ Table 3.5 indicates that adolescent boys who smoke cigarettes daily are about 10 times as likely to have a psychiatric disorder diagnosis as those who do not smoke. However, the table does not compare intensity of use among the different drug classes. Thus, although *daily* cigarette smoking among adolescent boys is more strongly associated with psychiatric disorders than is any use of illicit substances, it does not follow that this comparison is true for every amount of cigarette smoking.⁷⁹

Few marijuana users become dependent on it (Table 3.4), but those who do encounter problems similar to those associated with dependence on other drugs.^{19,143} Dependence appears to be less severe among people

TABLE 3.5 Relative Prevalence of Diagnoses of Psychiatric Disorders Associated with Drug Use Among Children^a

Drug Use	Relative Prevalence Estimates ^b	
	Boys	Girls
Weekly alcohol use	6.1	1.6 (n.s.)
Daily cigarette smoking	9.8	2.1 (n.s.)
Any illicit substance use	3.2	5.3

^aSubjects were from 9 to 18 years old (average, 13 years old).

^bAn estimate of 1 means that the relative prevalence of the disorder is equal in those who do and those who do not use the particular type of drug; that is, there is no measurable association. An estimate greater than 1 indicates that the factor is associated. Substance abuse was excluded because the subjects were already grouped by high drug use. Except where noted (n.s.), all values are statistically significant.

SOURCE: Data from Table 4 in Kandel and co-workers (1997).⁷⁹

who use only marijuana than among those who abuse cocaine or those who abuse marijuana with other drugs (including alcohol).^{19,143}

Data gathered in 1990–1992 from the National Comorbidity Study of over 8,000 persons 15–54 years old indicate that 4.2% of the general population were dependent on marijuana at some time.⁸ Similar results for the frequency of substance abuse among the general population were obtained from the Epidemiological Catchment Area Program, a survey of over 19,000 people. According to data collected in the early 1980s for that study, 4.4% of adults have, at one time, met the criteria for marijuana dependence. In comparison, 13.8% of adults met the criteria for alcohol dependence and 36.0% for tobacco dependence. After alcohol and nicotine, marijuana was the substance most frequently associated with a diagnosis of substance dependence.

In a 15-year study begun in 1979, 7.3% of 1,201 adolescents and young adults in suburban New Jersey at some time met the criteria for marijuana dependence; this indicates that the rate of marijuana dependence might be even higher in some groups of adolescents and young adults than in the general population.⁷¹ Adolescents meet the criteria for drug dependence at lower rates of marijuana use than do adults, and this suggests that they are more vulnerable to dependence than adults²⁵ (see Box 3.2).

Youths who are already dependent on other substances are particularly vulnerable to marijuana dependence. For example, Crowley and co-workers³¹ interviewed a group of 229 adolescent patients in a residential treatment program for delinquent, substance-involved youth and found that those patients were dependent on an average of 3.2 substances. The adolescents had previously been diagnosed as dependent on at least one substance (including nicotine and alcohol) and had three or more conduct disorder symptoms during their life. About 83% of those who had used marijuana at least six times went on to develop marijuana dependence. About equal numbers of youths in the study had a diagnosis of marijuana dependence and a diagnosis of alcohol dependence; fewer were nicotine dependent. Comparisons of dependence potential between different drugs should be made cautiously. The probability that a particular drug will be abused is influenced by many factors, including the specific drug effects and availability of the drug.

Although parents often state that marijuana caused their children to be rebellious, the troubled adolescents in the study by Crowley and co-workers developed conduct disorders *before* marijuana abuse. That is consistent with reports that the more symptoms of conduct disorders children have, the younger they begin drug abuse,¹²⁷ and that the earlier they begin drug use, the more likely it is to be followed by abuse or dependence.¹²⁵

Genetic factors are known to play a role in the likelihood of abuse for

drugs other than marijuana,^{7,129} and it is not unexpected that genetic factors play a role in the marijuana experience, including the likelihood of abuse. A study of over 8,000 male twins listed in the Vietnam Era Twin Registry indicated that genes have a statistically significant influence on whether a person finds the effects of marijuana pleasant.⁹⁷ Not surprisingly, people who found marijuana to be pleasurable used it more often than those who found it unpleasant. The study suggested that, although social influences play an important role in the initiation of use, individual differences—perhaps associated with the brain’s reward system—influence whether a person will continue using marijuana. Similar results were found in a study of female twins.⁸⁶ Family and social environment strongly influenced the likelihood of ever using marijuana but had little effect on the likelihood of heavy use or abuse. The latter were more influenced by genetic factors. Those results are consistent with the finding that the degree to which rats find THC rewarding is genetically based.⁹²

In summary, although few marijuana users develop dependence, some do. But they appear to be less likely to do so than users of other drugs (including alcohol and nicotine), and marijuana dependence appears to be less severe than dependence on other drugs. Drug dependence is more prevalent in some sectors of the population than others, but no group has been identified as particularly vulnerable to the drug-specific effects of marijuana. Adolescents, especially troubled ones, and people with psychiatric disorders (including substance abuse) appear to be more likely than the general population to become dependent on marijuana.

If marijuana or cannabinoid drugs were approved for therapeutic uses, it would be important to consider the possibility of dependence, particularly for patients at high risk for substance dependence. Some controlled substances that are approved medications produce dependence after long-term use; this, however, is a normal part of patient management and does not generally present undue risk to the patient.

Progression from Marijuana to Other Drugs

The fear that marijuana use might cause, as opposed to merely precede, the use of drugs that are more harmful is of great concern. To judge from comments submitted to the IOM study team, it appears to be of greater concern than the harms directly related to marijuana itself. The discussion that marijuana is a “gateway” drug implicitly recognizes that other illicit drugs might inflict greater damage to health or social relations than marijuana. Although the scientific literature generally discusses drug use progression between a variety of drug classes, including alcohol and tobacco, the public discussion has focused on marijuana as a “gateway”

drug that leads to abuse of more harmful illicit drugs, such as cocaine and heroin.

There are strikingly regular patterns in the progression of drug use from adolescence to adulthood. Because it is the most widely used illicit drug, marijuana is predictably the first illicit drug that most people encounter. Not surprisingly, most users of other illicit drugs used marijuana first.^{81,82} In fact, most drug users do not begin their drug use with marijuana—they begin with alcohol and nicotine, usually when they are too young to do so legally.^{82,90}

The gateway analogy evokes two ideas that are often confused. The first, more often referred to as the “stepping stone” hypothesis, is the idea that progression from marijuana to other drugs arises from pharmacological properties of marijuana itself.⁸² The second is that marijuana serves as a gateway to the world of illegal drugs in which youths have greater opportunity and are under greater social pressure to try other illegal drugs. The latter interpretation is most often used in the scientific literature, and it is supported, although not proven, by the available data.

The stepping stone hypothesis applies to marijuana only in the broadest sense. People who enjoy the effects of marijuana are, logically, more likely to be willing to try other mood-altering drugs than are people who are not willing to try marijuana or who dislike its effects. In other words, many of the factors associated with a willingness to use marijuana are, presumably, the same as those associated with a willingness to use other illicit drugs. Those factors include physiological reactions to the drug effect, which are consistent with the stepping stone hypothesis, but also psychosocial factors, which are independent of drug-specific effects. There is no evidence that marijuana serves as a stepping stone on the basis of its particular physiological effect. One might argue that marijuana is generally used before other illicit mood-altering drugs, in part, because its effects are milder; in that case, marijuana is a stepping stone only in the same sense as taking a small dose of a particular drug and then increasing that dose over time is a stepping stone to increased drug use.

Whereas the stepping stone hypothesis presumes a predominantly physiological component of drug progression, the gateway theory is a social theory. The latter does not suggest that the pharmacological qualities of marijuana make it a risk factor for progression to other drug use. Instead, the legal status of marijuana makes it a gateway drug.⁸²

Psychiatric disorders are associated with substance dependence and are probably risk factors for progression in drug use. For example, the troubled adolescents studied by Crowley and co-workers³¹ were dependent on an average of 3.2 substances, and this suggests that their conduct disorders were associated with increased risk of progressing from one drug to another. Abuse of a single substance is probably also a risk factor

for later multiple drug use. For example, in a longitudinal study that examined drug use and dependence, about 26% of problem drinkers reported that they first used marijuana after the onset of alcohol-related problems (R. Pandina, IOM workshop). The study also found that 11% of marijuana users developed chronic marijuana problems; most also had alcohol problems.

Intensity of drug use is an important risk factor in progression. Daily marijuana users are more likely than their peers to be extensive users of other substances (for review, see Kandel and Davies⁷⁸). Of 34- to 35-year-old men who had used marijuana 10–99 times by the age 24–25, 75% never used any other illicit drug; 53% of those who had used it more than 100 times did progress to using other illicit drugs 10 or more times.⁷⁸ Comparable proportions for women are 64% and 50%.

The factors that best predict use of illicit drugs other than marijuana are probably the following: age of first alcohol or nicotine use, heavy marijuana use, and psychiatric disorders. However, progression to illicit drug use is not synonymous with heavy or persistent drug use. Indeed, although the age of onset of use of licit drugs (alcohol and nicotine) predicts later illicit drug use, it does *not* appear to predict persistent or heavy use of illicit drugs.⁹⁰

Data on the gateway phenomenon are often overinterpreted. For example, one study reports that “marijuana’s role as a gateway drug appears to have increased.”⁵⁵ It was a retrospective study based on interviews of drug abusers who reported smoking crack or injecting heroin daily. The data from the study provide no indication of what proportion of marijuana users become serious drug abusers; rather, they indicate that serious drug abusers usually use marijuana before they smoke crack or inject heroin. Only a small percentage of the adult population uses crack or heroin daily; during the five-year period from 1993 to 1997, an average of three people per 1,000 used crack and about two per 1,000 used heroin in the preceding month.¹³²

Many of the data on which the gateway theory is based do not measure dependence; instead, they measure use—even once-only use. Thus, they show only that marijuana users are more likely to use other illicit drugs (even if only once) than are people who never use marijuana, not that they become dependent or even frequent users. The authors of these studies are careful to point out that their data should not be used as evidence of an inexorable *causal* progression; rather they note that identifying stage-based user groups makes it possible to identify the specific risk factors that predict movement from one stage of drug use to the next—the real issue in the gateway discussion.²⁵

In the sense that marijuana use typically precedes rather than follows initiation into the use of other illicit drugs, it is indeed a gateway drug.

However, it does not appear to be a gateway drug to the extent that it is the *cause* or even that it is the most significant predictor of serious drug abuse; that is, care must be taken not to attribute cause to association. The most consistent predictors of serious drug use appear to be the intensity of marijuana use and co-occurring psychiatric disorders or a family history of psychopathology (including alcoholism).^{78,83}

An important caution is that data on drug use progression pertain to *nonmedical* drug use. It does not follow from those data that if marijuana were available by prescription for *medical* use, the pattern of drug use would be the same. Kandel and co-workers also included nonmedical use of prescription psychoactive drugs in their study of drug use progression.⁸² In contrast with the use of alcohol, nicotine, and illicit drugs, there was not a clear and consistent sequence of drug use involving the abuse of prescription psychoactive drugs. The current data on drug use progression neither support nor refute the suggestion that medical availability would increase drug abuse among medical marijuana users. Whether the medical use of marijuana might encourage drug abuse among the general community—not among medical marijuana users themselves but among others simply because of the fact that marijuana would be used for medical purposes—is another question.

LINK BETWEEN MEDICAL USE AND DRUG ABUSE

Almost everyone who spoke or wrote to the IOM study team about the potential harms posed by the medical use of marijuana felt that it would send the wrong message to children and teenagers. They stated that information about the harms caused by marijuana is undermined by claims that marijuana might have medical value. Yet many of our powerful medicines are also dangerous medicines. These two facets of medicine—effectiveness and risk—are inextricably linked.

The question here is not whether marijuana can be both harmful and helpful but whether the perception of its benefits will increase its abuse. For now any answer to the question remains conjecture. Because marijuana is not an approved medicine, there is little information about the consequences of its medical use in modern society. Reasonable inferences might be drawn from some examples. Opiates, such as morphine and codeine, are an example of a class of drugs that is both abused to great harm and used to great medical benefit, and it would be useful to examine the relationship between their medical use and their abuse. In a “natural experiment” during 1973–1978 some states decriminalized marijuana, and others did not. Finally, one can examine the short-term consequences of the publicity surrounding the 1996 medical marijuana campaign in California and ask whether it had any measurable impact on marijuana con-

sumption among youth in California; the consequences of “message” that marijuana might have medical use are examined below.

Medical Use and Abuse of Opiates

Two highly influential papers published in the 1920s and 1950s led to widespread concern among physicians and medical licensing boards that liberal use of opiates would result in many addicts (reviewed by Moulin and co-workers¹⁰⁶ in 1996). Such fears have proven unfounded; it is now recognized that fear of producing addicts through medical treatment resulted in needless suffering among patients with pain as physicians needlessly limited appropriate doses of medications.^{27,44} Few people begin their drug addiction problems with misuse of drugs that have been prescribed for medical use.¹¹⁴ Opiates are carefully regulated in the medical setting, and diversion of medically prescribed opiates to the black market is not generally considered to be a major problem.

No evidence suggests that the use of opiates or cocaine for medical purposes has increased the perception that their illicit use is safe or acceptable. Clearly, there are risks that patients will abuse marijuana for its psychoactive effects and some likelihood of diversion of marijuana from legitimate medical channels into the illicit market. But those risks do not differentiate marijuana from many accepted medications that are abused by some patients or diverted from medical channels for non-medical use. Medications with abuse potential are placed in Schedule II of the Controlled Substances Act, which brings them under stricter control, including quotas on the amount that can be legally manufactured (see chapter 5 for discussion of the Controlled Substances Act). That scheduling also signals to physicians that a drug has abuse potential and that they should monitor its use by patients who could be at risk for drug abuse.

Marijuana Decriminalization

Monitoring the Future, the annual survey of values and lifestyles of high school seniors, revealed that high school seniors in decriminalized states reported using no more marijuana than did their counterparts in states where marijuana was not decriminalized.⁷² Another study reported somewhat conflicting evidence indicating that decriminalization had increased marijuana use.¹⁰⁵ That study used data from the Drug Awareness Warning Network (DAWN), which has collected data on drug-related emergency room (ER) cases since 1975. There was a greater increase from 1975 to 1978 in the proportion of ER patients who had used marijuana in states that had decriminalized marijuana in 1975–1976 than in states that had not decriminalized it (Table 3.6). Despite the greater

TABLE 3.6 Effect of Decriminalization on Marijuana Use in Emergency Room (ER) Cases

		Total Reports of Drug Use per ER ^a	
		States That Decriminalized Marijuana	States That Did Not Decriminalize Marijuana
	Period ^b		
Marijuana use	1975	0.8	1.5
	1978	2.7	2.5
Other drug use	1975	47	55
	1978	55	70

^aData are based on patient self-reports.

^bStates that decriminalized marijuana did so after 1975 and before 1978. The 1975 values reflect ER marijuana reports before or in the first months of decriminalization, whereas 1978 values reflect ER reports when decriminalization laws had been in effect at least a year. The 1978 levels are median values for quarters in 1978 and are derived from Figures 1 and 2 in Model (1993).¹⁰⁵

SOURCE: Adapted from Figures 1 and 2 in Model (1993).¹⁰⁵

increase among decriminalized states, the proportion of marijuana users among ER patients by 1978 was about equal in states that had and states that had not decriminalized marijuana. That is because the non-decriminalized states had higher rates of marijuana use *before* decriminalization. In contrast with marijuana use, rates of other illicit drug use among ER patients were substantially higher in states that did not decriminalize marijuana use. Thus, there are different possible reasons for the greater increase in marijuana use in the decriminalized states. On the one hand, decriminalization might have led to an increased use of marijuana (at least among people who sought health care in hospital ERs). On the other hand, the lack of decriminalization might have encouraged greater use of drugs that are even more dangerous than marijuana.

The differences between the results for high school seniors from the Monitoring the Future study and the DAWN data are unclear, although the author of the latter study suggests that the reasons might lie in limitations inherent in how the DAWN data are collected.¹⁰⁵

In 1976, the Netherlands adopted a policy of toleration for possession of up to 30 g of marijuana. There was little change in marijuana use during the seven years after the policy change, which suggests that the change itself had little effect; however, in 1984, when Dutch “coffee shops” that sold marijuana commercially spread throughout Amsterdam, marijuana

use began to increase.⁹⁸ During the 1990s, marijuana use has continued to increase in the Netherlands at the same rate as in the United States and Norway—two countries that strictly forbid marijuana sale and possession. Furthermore, during this period, approximately equal percentages of American and Dutch 18 year olds used marijuana; Norwegian 18 year olds were about half as likely to have used marijuana. The authors of this study conclude that there is little evidence that the Dutch marijuana depenalization policy led to increased marijuana use, although they note that commercialization of marijuana might have contributed to its increased use. Thus, there is little evidence that decriminalization of marijuana use necessarily leads to a substantial increase in marijuana use.

The Medical Marijuana Debate

The most recent National Household Survey on Drug Abuse showed that among people 12–17 years old the perceived risk associated with smoking marijuana once or twice a week had decreased significantly between 1996 and 1997.¹³² (Perceived risk is measured as the percentage of survey respondents who report that they “perceive great risk of harm” in using a drug at a specified frequency.) At first glance, that might seem to validate the fear that the medical marijuana debate of 1996—before passage of the California medical marijuana referendum in November 1997—had sent a message that marijuana use is safe. But a closer analysis of the data shows that Californian youth were an exception to the national trend. In contrast to the national trend, the perceived risk of marijuana use did not change among California youth between 1996 and 1997.^{132*} In summary, there is no evidence that the medical marijuana debate has altered adolescents’ perceptions of the risks associated with marijuana use.¹³²

PSYCHOLOGICAL HARMS

In assessing the relative risks and benefits related to the medical use of marijuana, the psychological effects of marijuana can be viewed both as unwanted side effects and as potentially desirable end points in medical treatment. However, the vast majority of research on the psychological effects of marijuana has been in the context of assessing the drug’s intoxicating effects when it is used for nonmedical purposes. Thus, the litera-

*Although Arizona also passed a medical marijuana referendum, it was embedded in a broader referendum concerning prison sentencing. Hence, the debate in Arizona did not focus on medical marijuana the way it did in California, and changes in Arizona youths’ attitudes likely reflect factors peripheral to medical marijuana.

ture does not directly address the effects of marijuana taken for medical purposes.

There are some important caveats to consider in attempting to extrapolate from the research mentioned above to the medical use of marijuana. The circumstances under which psychoactive drugs are taken are an important influence on their psychological effects. Furthermore, research protocols to study marijuana's psychological effects in most instances were required to use participants who already had experience with marijuana. People who might have had adverse reactions to marijuana either would choose not to participate in this type of study or would be screened out by the investigator. Therefore, the incidence of adverse reactions to marijuana that might occur in people with no marijuana experience cannot be estimated from such studies. A further complicating factor concerns the dose regimen used for laboratory studies. In most instances, laboratory research studies have looked at the effects of single doses of marijuana, which might be different from those observed when the drug is taken repeatedly for a chronic medical condition.

Nonetheless, laboratory studies are useful in suggesting what psychological functions might be studied when marijuana is evaluated for medical purposes. Results of laboratory studies indicate that acute and chronic marijuana use has pronounced effects on mood, psychomotor, and cognitive functions. These psychological domains should therefore be considered in assessing the relative risks and therapeutic benefits related to marijuana or cannabinoids for any medical condition.

Psychiatric Disorders

A major question remains as to whether marijuana can produce lasting mood disorders or psychotic disorders, such as schizophrenia. Georgotas and Zeidenberg⁵² reported that smoking 10–22 marijuana cigarettes per day was associated with a gradual waning of the positive mood and social facilitating effects of marijuana and an increase in irritability, social isolation, and paranoid thinking. Inasmuch as smoking *one* cigarette is enough to make a person feel “high” for about 1–3 hours,^{68,95,118} the subjects in that study were taking very high doses of marijuana. Reports have described the development of apathy, lowered motivation, and impaired educational performance in heavy marijuana users who do not appear to be behaviorally impaired in other ways.^{121,122} There are clinical reports of marijuana-induced psychosis-like states (schizophrenia-like, depression, and/or mania) lasting for a week or more.¹¹² Hollister suggests that, because of the varied nature of the psychotic states induced by marijuana, there is no specific “marijuana psychosis.” Rather, the marijuana experience might trigger latent psychopathology of many types.⁶⁶

More recently, Hall and colleagues⁶⁰ concluded that “there is reasonable evidence that heavy cannabis use, and perhaps acute use in sensitive individuals, can produce an acute psychosis in which confusion, amnesia, delusions, hallucinations, anxiety, agitation and hypomanic symptoms predominate.” Regardless of which of those interpretations is correct, the two reports agree that there is little evidence that marijuana alone produces a psychosis that persists after the period of intoxication.

Schizophrenia

The association between marijuana and schizophrenia is not well understood. The scientific literature indicates general agreement that heavy marijuana use can precipitate schizophrenic episodes but not that marijuana use can cause the underlying psychotic disorder.^{59,96,151} As noted earlier, drug abuse is common among people with psychiatric disorders. Estimates of the prevalence of marijuana use among schizophrenics vary considerably but are in general agreement that it is at least as great as that among the general population.¹³⁴ Schizophrenics prefer the effects of marijuana to those of alcohol and cocaine,³⁵ which they seem to use less often than does the general population.¹³⁴ The reasons for this are unknown, but it raises the possibility that schizophrenics might obtain some symptomatic relief from moderate marijuana use. But overall, compared with the general population, people with schizophrenia or with a family history of schizophrenia are likely to be at greater risk for adverse psychiatric effects from the use of cannabinoids.

Cognition

As discussed earlier, acutely administered marijuana impairs cognition.^{60,66,112} Positron emission tomography (PET) imaging allows investigators to measure the acute effects of marijuana smoking on active brain function. Human volunteers who perform auditory attention tasks before and after smoking a marijuana cigarette show impaired performance while under the influence of marijuana; this is associated with substantial reduction in blood flow to the temporal lobe of the brain, an area that is sensitive to such tasks.^{116,117} Marijuana smoking increases blood flow in other brain regions, such as the frontal lobes and lateral cerebellum.^{101,155} Earlier studies purporting to show structural changes in the brains of heavy marijuana users²² have not been replicated with more sophisticated techniques.^{28,89}

Nevertheless, recent studies^{14,122} have found subtle defects in cognitive tasks in heavy marijuana users after a brief period (19–24 hours) of marijuana abstinence. Longer term cognitive deficits in heavy marijuana

users have also been reported.¹⁴⁰ Although these studies have attempted to match heavy marijuana users with subjects of similar cognitive abilities before exposure to marijuana use, the adequacy of this matching has been questioned.¹³³ The complex methodological issues facing research in this area are well reviewed in an article by Pope and colleagues.¹²¹ Care must be exercised so that studies are designed to differentiate between changes in brain function caused the effects of marijuana and by the illness for which marijuana is being given. AIDS dementia is an obvious example of this possible confusion. It is also important to determine whether repeated use of marijuana at therapeutic dosages produces any irreversible cognitive effects.

Psychomotor Performance

Marijuana administration has been reported to affect psychomotor performance on a number of tasks. The review by Chait and Pierri²³ not only details the studies that have been done but also points out the inconsistencies among studies, the methodological shortcomings of many studies, and the large individual differences among the studies attributable to subject, situational, and methodological factors. Those factors must be considered in studies of psychomotor performance when participants are involved in a clinical trial of the efficacy of marijuana. The types of psychomotor functions that have been shown to be disrupted by the acute administration of marijuana include body sway, hand steadiness, rotary pursuit, driving and flying simulation, divided attention, sustained attention, and the digit-symbol substitution test. A study of experienced airplane pilots showed that even 24 hours after a single marijuana cigarette their performance on flight simulator tests was impaired.¹⁶³ Before the tests, however, they told the study investigators that they were sure their performance would be unaffected.

Cognitive impairments associated with acutely administered marijuana limit the activities that people would be able to do safely or productively. For example, no one under the influence of marijuana or THC should drive a vehicle or operate potentially dangerous equipment.

Amotivational Syndrome

One of the more controversial effects claimed for marijuana is the production of an "amotivational syndrome." This syndrome is not a medical diagnosis, but it has been used to describe young people who drop out of social activities and show little interest in school, work, or other goal-directed activity. When heavy marijuana use accompanies these symptoms, the drug is often cited as the cause, but no convincing data demon-

strate a causal relationship between marijuana smoking and these behavioral characteristics.²³ It is not enough to observe that a chronic marijuana user lacks motivation. Instead, relevant personality traits and behavior of subjects must be assessed before and after the subject becomes a heavy marijuana user. Because such research can only be done on subjects who become heavy marijuana users on their own, a large population study—such as the Epidemiological Catchment Area study described earlier in this chapter—would be needed to shed light on the relationship between motivation and marijuana use. Even then, although a causal relationship between the two could, in theory, be dismissed by an epidemiological study, causality could not be proven.

Summary

Measures of mood, cognition, and psychomotor performance should be incorporated into clinical trials evaluating the efficacy of marijuana or cannabinoid drugs for a given medical condition. Ideally, participants would complete mood assessment questionnaires at various intervals throughout the day for a period before; every week during; and, where appropriate, after marijuana therapy. A full psychological screening of research participants should be conducted to determine whether there is an interaction between the mood-altering effects of chronic marijuana use and the psychological characteristics of the subjects. Similarly, the cognitive and psychomotor functioning should be assessed before and regularly during the course of a chronic regimen of marijuana or cannabinoid treatment to determine the extent to which tolerance to the impairing effects of marijuana develops and to monitor whether new problems develop.

When compared with changes produced by either placebo or an active control medication, the magnitude of desirable therapeutic effects and the frequency and magnitude of adverse psychological side effects of marijuana could be determined. That would allow a more thorough assessment of the risk:benefit ratio associated with the use of marijuana for a given indication.

CONCLUSION: The psychological effects of cannabinoids, such as anxiety reduction, sedation, and euphoria, can influence their potential therapeutic value. Those effects are potentially undesirable in some patients and situations and beneficial in others. In addition, psychological effects can complicate the interpretation of other aspects of the drug's effect.

RECOMMENDATION: Psychological effects of cannabinoids, such as anxiety reduction and sedation, which can influence medical benefits, should be evaluated in clinical trials.

PHYSIOLOGICAL HARMS: TISSUE AND ORGAN DAMAGE

Many people who spoke to the IOM study team in favor of the medical use of marijuana cited the absence of marijuana overdoses as evidence that it is safe. Indeed, epidemiological data indicate that in the general population marijuana use is not associated with increased mortality.¹³⁸ However, other serious health outcomes should be considered, and they are discussed below.

It is important to keep in mind that most of the studies that report physiological harm resulting from marijuana use are based on the effects of marijuana smoking. Thus, we emphasize that the effects reported cannot be presumed to be caused by THC alone or even in combination with other cannabinoids found in marijuana. It is likely that smoke is a major cause of the reported effects. In most studies the methods used make it impossible to weigh the relative contributions of smoke versus cannabinoids.

Immune System

The relationship between marijuana and the immune system presents many facets, including potential benefits and suspected harms. This section reviews the evidence on suspected harms to the immune system caused by marijuana use.

Despite the many claims that marijuana suppresses the human immune system, the health effects of marijuana-induced immunomodulation are still unclear. Few studies have been done with animals or humans to assess the effects of marijuana exposure on host resistance to bacteria, viruses, or tumors.

Human Studies

Several approaches have been used to determine the effects of marijuana on the human immune system. Each has serious limitations, which are discussed below.

Assays of Leukocytes from Marijuana Smokers. One of the more common approaches has been to isolate peripheral blood leukocytes from people who have smoked marijuana in order to evaluate the immune

response of those cells *in vitro*—most often by measuring mitogen-induced cell proliferation, a normal immune response. Almost without exception, this approach has failed to demonstrate any reduction in leukocyte function. The major problem with the approach is that after blood samples are drawn from the study subjects the leukocytes must be isolated from whole blood before they are tested. That is done by high-speed centrifugation followed by extensive washing of the cells, which removes the cannabinoid; perhaps for this reason no adverse effects have been demonstrated in peripheral blood leukocytes from marijuana smokers.^{75,91,123,160}

Leukocyte Responses to THC. Another approach is to isolate peripheral blood leukocytes from healthy control subjects who do not smoke marijuana and then to measure the effect of THC on the ability of these cells to proliferate in response to mitogenic stimulation *in vitro*. One important difference between leukocytes isolated from a marijuana smoker, as described above, and leukocyte cell cultures to which THC has been added directly is in the cannabinoid composition. Marijuana smoke contains many distinct cannabinoid compounds of which THC is just one. Moreover, the immunomodulatory activity of many of the other cannabinoid compounds has never been tested, and it is now known that at least one of those—cannabinol (CBN)—has greater activity on the immune system than on the central nervous system,⁶⁴ so it is unclear whether the profile of activity observed with THC accurately represents the effects of marijuana smoke on immune competence. Likewise, the extent to which different cannabinoids in combination exhibit additive, synergistic, or antagonistic effects with respect to immunomodulatory activity is unclear. The issue is complicated by the fact that leukocytes express both types of cannabinoid receptors: CB₁ and CB₂.

An additional factor that might affect the immunomodulatory activity of cannabinoids in leukocytes is metabolism. Leukocytes have very low levels of the cytochrome P-450 drug-metabolizing enzymes,²⁰ so the metabolism of cannabinoids is probably different between *in vivo* and *in vitro* exposure. That last point is pertinent primarily to investigations of chronic, not acute, cannabinoid exposure.

Human-Derived Cell Lines. A third approach for investigating the effects of cannabinoids on human leukocytes has been to study human-derived cell lines.* As described above, the cell lines are treated *in vitro* with cannabinoids to test their responses to different stimuli. Although cell lines

*Cell lines are created by removing cells from an organism and then treating them so they are “immortalized,” meaning they will continue to divide and multiply indefinitely in culture. Cellular processes can then be studied in isolation from their original source.

are a convenient source of human cells, the problems described above apply here as well. In addition, the cell lines might not be the same as the original cells. For example, cell lines do not necessarily have the same number of cannabinoid receptors as the original human cells.

Rodent Studies

The most widely used approach is to evaluate the effects of cannabinoids in rodents, using rodent-derived cells *in vitro*. The rationale is that the human and rodent immune systems are remarkably similar, and it is assumed that the effects produced by cannabinoids on the rodent immune system will be similar to those produced in humans. Although no substantial species differences in immune system sensitivity to cannabinoids have been reported, the possibility should be considered.

Summary

The complete effect of marijuana smoking on immune function remains unknown. More important, it is not known whether smoking leads to increased rates of infections, tumors, allergies, or autoimmune responses. The problem is how to duplicate the “normal” marijuana smoking pattern while removing other potential immunomodulating lifestyle factors, such as alcohol and tobacco use. Epidemiological studies are needed to determine whether marijuana users have a higher incidence of such diseases, as infections, tumors, allergies, and autoimmune diseases. Studies on resistance to bacterial and viral infection are clearly needed and should involve the collaboration of immunologists, infectious disease specialists, oncologists, and pharmacologists.

Marijuana Smoke

Tobacco is the predominant cause of such lung diseases as cancer and emphysema, and marijuana smoke contains many of the components of tobacco smoke.⁶⁹ Thus, it is important to consider the relationship between habitual marijuana smoking and some lung diseases.

Given a cigarette of comparable weight, as much as four times the amount of tar can be deposited in the lungs of marijuana smokers as in the lungs of tobacco smokers.¹⁶² The difference is due primarily to the differences in filtration and smoking technique between tobacco and marijuana smokers. Marijuana cigarettes usually do not have filters, and marijuana smokers typically develop a larger puff volume, inhale more deeply, and hold their breath several times longer than tobacco smokers.¹¹⁹ However, a marijuana cigarette smoked recreationally typically is not packed

as tightly as a tobacco cigarette, and the smokable substance is about half that in a tobacco cigarette. In addition, tobacco smokers generally smoke considerably more cigarettes per day than do marijuana smokers.

Cellular Damage

Lymphocytes: T and B Cells. Human studies of the effect of marijuana smoking on immune cell function are not all consistent with cannabinoid cell culture and animal studies. For example, antibody production was decreased in a group of hospitalized patients who smoked marijuana for four days (12 cigarettes/day), but the decrease was seen in only one subtype of humoral antibody (IgG), whereas two other subtypes (IgA and IgM) remained normal and one (IgE) was increased.¹⁰⁸ In addition, T cell proliferation was normal in the blood of a group of marijuana smokers, although closer evaluation showed an increase in one subset of T cells¹⁶¹ and a decrease in a different subset (CD8).¹⁵⁷ It appears that marijuana use is associated with intermittent disturbances in T and B cell function, but the magnitude is small and other measures are often normal.⁸⁷

Macrophages. Alveolar macrophages are the principal immune-effector cells in the lung and are primarily responsible for protecting the lung against infectious microorganisms, inhaled foreign substances, and tumor cells. They are increased during tissue inflammation. In a large sample of volunteers, habitual marijuana smokers had twice as many alveolar macrophages as nonsmokers, and smokers of both marijuana and tobacco had twice as many again.¹¹ Marijuana smoking also reduced the ability of alveolar macrophages to kill fungi, such as *Candida albicans*;^{*} pathogenic bacteria, such as *Staphylococcus aureus*; and tumor target cells. The reduction in ability to destroy fungal organisms was similar to that seen in tobacco smokers. The inability to kill pathogenic bacteria was not seen in tobacco smokers.¹⁰ Furthermore, marijuana smoking depressed production of proinflammatory cytokines, such as TNF-I and IL-6, but not of immunosuppressive cytokines.¹⁰ Cytokines are important regulators of macrophage function, so this marijuana-related decrease in inflammatory cytokine production might be a mechanism whereby marijuana smokers are less able to destroy fungal and bacterial organisms, as well as tumor cells.

The inability of alveolar macrophages from habitual marijuana smokers without apparent disease to destroy fungi, bacteria, and tumor cells

**Candida albicans* is a yeast infection that is particularly prevalent among people whose immune systems are suppressed, such as in AIDS patients.

and to release proinflammatory cytokines, suggests that marijuana might be an immunosuppressant with clinically significant effects on host defense. Therefore, the risks of smoking marijuana should be seriously weighed before recommending its use in any patient with preexisting immune deficits—including AIDS patients, cancer patients, and those receiving immunosuppressive therapies (for example, transplant or cancer patients).

Bronchial and Pulmonary Damage

Animal Studies. A number of animal studies have revealed respiratory tract changes and diseases associated with marijuana smoking, but others have not. Extensive damage to the smaller airways, which are the major site of chronic obstructive pulmonary disease (COPD),* and acute and chronic pneumonia have been observed in various species exposed to different doses of marijuana smoke.^{41,42,128} In contrast, rats exposed to increasing doses of marijuana smoke for one year did not show any signs of COPD, whereas rats exposed to tobacco smoke did.⁶⁷

Chronic Bronchitis and Respiratory Illness. Results of human studies suggest that there is a greater chance of respiratory illness in people who smoke marijuana. In a survey of outpatient medical visits at a large health maintenance organization (HMO), marijuana users were more likely to seek help for respiratory illnesses than people who smoked neither marijuana or tobacco.¹²⁰ However, the incidence of seeking help for respiratory illnesses was not higher in those who smoked marijuana for 10 years or more than in those who smoked for less than 10 years. One explanation for this is that people who experience respiratory symptoms are more likely to quit smoking and that people who continue to smoke constitute a set of survivors who do not develop or are indifferent to such symptoms. One limitation of this study is that no data were available on the use of cocaine, which when used with marijuana could contribute to the observed differences. Another limitation is that the survey relied on self-reporting; tobacco, alcohol, and marijuana use might have been underreported (S. Sidney, IOM workshop).

When marijuana smokers were compared with nonsmokers and tobacco smokers in a group of 446 volunteers, 15–20% of the marijuana smokers reported symptoms of chronic bronchitis, including chronic

*COPD is a slow progressive obstruction of the airways, loss of their elasticity, and loss of lung volume, characterized by chronic shortness of breath, chronic bronchitis, and reduced oxygenation of blood.

cough and phlegm production,¹⁴⁶ and 20–25% of the tobacco smokers reported symptoms of chronic bronchitis. Despite a marked disparity in the amount of each substance smoked per day (three or four joints of marijuana versus more than 20 cigarettes of tobacco), the difference in the percentages of tobacco smokers and marijuana smokers experiencing symptoms of chronic bronchitis was statistically insignificant.¹⁴⁶ Similar findings were reported by Bloom and co-workers,¹⁵ who noted an additive effect of smoking both marijuana and tobacco.

Bronchial Tissue Changes. Habitual marijuana smoking is associated with changes in the lining of the human respiratory tract. Many marijuana or tobacco smokers have increased redness (erythema) and swelling (edema) of the airway tissues and increased mucous secretions.^{43,56} In marijuana smokers the number and size of small blood vessels in the bronchial wall are increased, tissue edema is present, and the normal ciliated cells* lining the inner surface of the bronchial wall are largely replaced by mucous-secreting goblet cells. The damage is greater in people who smoke both marijuana and tobacco.¹³⁰ Overproduction of mucus by the increased numbers of mucous-secreting cells in the presence of decreased numbers of ciliated cells tends to leave coughing as the only major mechanism to remove mucus from the airways; this might explain the relatively high proportion of marijuana smokers who complain of chronic cough and phlegm production.¹⁴⁸

A 1998 study has shown that both marijuana and tobacco smokers have significantly more cellular and molecular abnormalities in bronchial epithelium cells than nonsmokers; these changes are associated with increased risk of cancer.¹² The tobacco-only smokers in that study smoked an average of 25 cigarettes per day, whereas the marijuana-only smokers smoked an average of 21 marijuana cigarettes per week. Although the marijuana smokers smoked far fewer cigarettes, their cellular abnormalities were equivalent to or greater than those seen in tobacco smokers. This and earlier studies have shown that such abnormalities are greatest in people who smoke both marijuana and tobacco; hence, marijuana and tobacco smoke might have additive effects on airway tissue.^{12,43,56} Tenant¹⁵⁰ found similar results in U.S. servicemen who suffered from respiratory symptoms and were heavy hashish smokers. (Hashish is the resin from the marijuana plant.)

Chronic Obstructive Pulmonary Disease. In the absence of epidemiological data, indirect evidence, such as nonspecific airway hyperrespon-

*Ciliated cells have hair-like projections that function to transport mucus toward the mouth by rapid wave-like motion.

siveness and measures of lung function, offers an indicator of the vulnerability of marijuana smokers to COPD.¹⁵⁴ For example, the methacholine provocative challenge test, used to evaluate airway hyperresponsiveness, showed that tobacco smokers develop more airway hyperresponsiveness. But no such correlation has been shown between marijuana smoking and airway hyperresponsiveness.

There is conflicting evidence on whether regular marijuana use harms the small airways of the lungs. Bloom and co-workers found that an average of one joint smoked per day significantly impaired the function of small airways.¹⁵ But Tashkin and co-workers¹⁴⁶ did not observe such damage among heavier marijuana users (three to four joints per day for at least 10 years), although they noted a narrowing of large central airways. Tashkin and co-workers' long-term study, which adjusted for age-related decline in lung function (associated with an increased risk for developing COPD), showed an accelerated rate of decline in tobacco smokers but not in marijuana smokers.¹⁴⁷ Thus, the question of whether usual marijuana smoking habits are enough to cause COPD remains open.

Conclusion. Chronic marijuana smoking might lead to acute and chronic bronchitis and extensive microscopic abnormalities in the cells lining the bronchial passageways, some of which may be premalignant. These respiratory symptoms are similar to those of tobacco smokers, and the combination of marijuana and tobacco smoking augments these effects. At the time of this writing, it had not been established whether chronic smoking marijuana causes COPD, but there is probably an association.

HIV/AIDS Patients

The relationship between marijuana smoking and the natural course of AIDS is of particular concern because HIV patients are the largest group who report using marijuana for medical purposes. Marijuana use has been linked both to increased risk of progression to AIDS in HIV-seropositive patients and to increased mortality in AIDS patients.

For unknown reasons, marijuana use is associated with increased mortality among men with AIDS but not among the general population.¹³⁸ (The relative risk of AIDS mortality for current marijuana users in this 12-year study was 1.90, indicating that almost twice as many marijuana users died of AIDS as did noncurrent marijuana users.) Never-married men used twice as much marijuana as married men and accounted for 83% of the AIDS deaths in the study. The authors of the study note that, while marital status is insufficient to adjust for lifestyle factors—particularly, homosexual behavior—a substantial proportion of the never-married men with AIDS were probably homosexuals or bisexuals. That raises the pos-

sibility that the association of marijuana use with AIDS deaths might be related to indirect factors, such as use of other drugs or high-risk sexual behavior, both of which increase risks of infection to which AIDS patients are more susceptible. The higher mortality of AIDS patients who were current marijuana users also raises the question of whether this was because patients increased their use of marijuana at the endstages of the disease to treat their symptoms. However, the association between marijuana use and AIDS deaths was similar even when the subjects who died earliest in the first five years of this 12-year study, and who were presumably the most sick, were excluded from the analysis. In summary, it is premature to conclude what the underlying causes of this association might be.

For the general population, the mortality associated with marijuana use was lower than that associated with cigarette smoking, and tobacco smoking was not an independent risk factor in AIDS mortality. The authors of the study described above concluded that therapeutic use of marijuana did not contribute to the increased mortality among men with AIDS.

Marijuana use has been associated with a higher prevalence of HIV seropositivity in cross-sectional studies,⁸⁴ but the relationship of marijuana to the progression to AIDS in HIV-seropositive patients is a reasonable question. It remains unclear whether marijuana smoking is an independent risk factor in the progression of AIDS in HIV-seropositive men. Marijuana use did not increase the risk of AIDS in HIV-seropositive men in the Multicenter AIDS Cohort Study, in which 1,795 HIV-seropositive men were studied for 18 months,⁸⁴ or in the San Francisco Men's Health Study, in which 451 HIV-seropositive men were studied for six years.³⁴ In contrast, the Sydney AIDS Project in Australia, in which 386 HIV-seropositive men were studied for 12 months,¹⁵² reported that marijuana use was associated with increased risk of progression to AIDS. The results of the Sydney study are less reliable than those of the other two studies noted; it was the shortest of the studies and, according to the 1993 definition of AIDS, many of the subjects probably already had AIDS at the beginning of the study.*

The most compelling concerns regarding marijuana smoking in HIV/AIDS patients are the possible effects of marijuana on immunity.¹¹¹ Reports of opportunistic fungal and bacterial pneumonia in AIDS patients who used marijuana suggest that marijuana smoking either suppresses the immune system³³ or exposes patients to an added burden of patho-

*In 1993 the diagnosis of AIDS was expanded to include anyone with a CD4 count of less than 200. Prior to 1993 this alone would have been insufficient for a diagnosis of AIDS.

gens.²¹ In summary, patients with preexisting immune deficits due to AIDS should be expected to be vulnerable to serious harm caused by smoking marijuana. The relative contribution of marijuana smoke versus THC or other cannabinoids is not known.

Carcinogenicity

The gas and tar phases of marijuana and tobacco smoke contain many of the same compounds. Furthermore, the tar phase of marijuana smoke contains higher concentrations of polycyclic aromatic hydrocarbons (PAHs), such as the carcinogen benzopyrene. The higher content of carcinogenic PAHs in marijuana tar and the greater deposition of this tar in the lung might act in conjunction to amplify the exposure of a marijuana smoker to carcinogens. For those reasons the carcinogenicity of marijuana smoke is an important concern.

It is more difficult to collect the epidemiological data necessary to establish or refute the link between marijuana smoke and cancer than that between tobacco smoke and cancer. Far fewer people smoke only marijuana than only tobacco, and marijuana smokers are more likely to underreport their smoking.

Case Studies. Results of several case series suggest that marijuana might play a role in the development of human respiratory cancer. Reports indicate an unexpectedly large proportion of marijuana users among people with lung cancer^{141,149} and cancers of the upper aerodigestive tract—that is, the oral cavity, pharynx, larynx, and esophagus—that occur before the age of 45.^{36,39,149} Respiratory tract cancers associated with heavy tobacco and alcohol consumption are not usually seen before the age of 60,¹⁵⁴ and the occurrence of such cancers in marijuana users younger than 60 suggests that long-term marijuana smoking potentiates the effects of other risk factors, such as tobacco smoking, and is a more potent risk factor than tobacco and alcohol use in the early development of respiratory cancers. Most studies lack the necessary comparison groups to calculate the isolated effect of marijuana use on cancer risk. Many marijuana smokers also smoke tobacco, so when studies lack information regarding cigarette smoking status, there is no way to separate the effects of marijuana smoke and tobacco smoke.

Epidemiological Evidence. As of this writing, Sidney and co-workers¹³⁹ had conducted the only epidemiological study to evaluate the association between marijuana use and cancer. The study included a cohort of about 65,000 men and women 15–49 years old. Marijuana users were defined as those who had used marijuana on six or more occasions. Among the 1,421

cases of cancer in this cohort, marijuana use was associated only with an increased risk of prostate cancer in men who did not smoke tobacco. In these relatively young HMO clients, no association was found between marijuana use and other cancers, including all tobacco-related cancers, colorectal cancer, and melanoma. The major limitation associated with interpreting this study is that the development of lung cancer requires a long exposure to smoking, and most marijuana users quit before this level of exposure is achieved. In addition, marijuana use has been widespread in the United States only since the late 1960s; therefore, despite the large cohort size there might not have been a sufficient number of heavy or long-term marijuana smokers to reveal an effect.

Cellular and Molecular Studies. In contrast with clinical studies, cellular and molecular studies have provided strong evidence that marijuana smoke is carcinogenic. Cell culture studies implicate marijuana smoke in the development of cancer. Prolonged exposure of hamster lung cell cultures to marijuana smoke led to malignant transformations,⁹⁴ and exposure of human lung explants to marijuana smoke resulted in chromosomal and DNA alterations.¹⁵⁴ The tar from marijuana smoke also induced mutations similar to those produced by tar from the same quantity of tobacco in a common bacterial assay for mutagenicity.¹⁵⁸

Molecular studies also implicate marijuana smoke as a carcinogen. Proto-oncogenes and tumor suppressor genes are a group of genes that affect cell growth and differentiation. Normally, they code for proteins that control cellular proliferation. Once mutated or activated, they produce proteins that cause cells to multiply rapidly and out of control, and this results in tumors or cancer.* When the production of these proteins was evaluated in tissue biopsies taken from marijuana, tobacco, and marijuana plus tobacco smokers, and nonsmokers, two of them (EGFR and Ki-67) were markedly higher in the marijuana smokers than in the nonsmokers and the tobacco smokers. Moreover, the effects of marijuana and tobacco were additive.¹³¹ Thus, in relatively young smokers of marijuana, particularly those who smoke both marijuana and tobacco, marijuana is implicated as a risk factor for lung cancer.

DNA alterations are known to be early events in the development of cancer, and have been observed in the lymphocytes of pregnant marijuana smokers and in those of their newborns.⁴ This is an important study

*Some of the genes involved in the development of lung cancer include those that encode for Ki-67 (a nuclear proliferation protein responsible for cell division), the p53 tumor suppressor (a protein that normally suppresses cell growth), and epidermal growth factor receptor (EGFR) (a receptor found on a variety of cell types, especially epithelial cells, that promotes cellular growth and proliferation when bound to epidermal growth factor).

because the investigators were careful to exclude tobacco smokers—a problem in previous studies that cited mutagenic effects of marijuana smoke.^{26,53,63,142} The same investigators found similar effects in previous studies among tobacco smokers,^{5,6} so the effects cannot be attributed solely to THC or other cannabinoids. Although it can be determined only by experiment, it is likely that the smoke contents—other than cannabinoids—are responsible for a large part of the mutagenic effect.

Preliminary findings suggest that marijuana smoke activates cytochrome P4501A1 (CYP1A1), the enzyme that converts PAHs, such as benz[α]pyrene, into active carcinogens.⁹⁹ Bronchial epithelial cells in tissue biopsies taken from marijuana smokers show more binding to CYP1A1 antibodies than do comparable cells in biopsies from nonsmokers (D. Tashkin, IOM workshop). That suggests that there is more of CYP1A1 itself in the bronchial cells of marijuana smokers, but different experimental methods will be needed to establish that possibility.

Conclusions

There is no conclusive evidence that marijuana causes cancer in humans, including cancers usually related to tobacco use. However, cellular, genetic, and human studies all suggest that marijuana smoke is an important risk factor for the development of respiratory cancer. More definitive evidence that habitual marijuana smoking leads or does not lead to respiratory cancer awaits the results of well-designed case control epidemiological studies. It has been 30 years since the initiation of widespread marijuana use among young people in our society, and such studies should now be feasible.

The following studies or activities would be useful in providing data that could more precisely define the health risks of smoking marijuana.

1. Case control studies to determine whether marijuana use is associated with an increased risk of respiratory cancer. Despite the lack of compelling epidemiological evidence, findings from the biochemical, cellular, immunological, genetic, tissue, and animal studies cited above strongly suggest that marijuana is a risk factor for human cancer. What is required to address that hypothesis more convincingly is a population-based case control study of sufficiently large numbers of people with lung cancer and upper aerodigestive tumors (cancers of the oral cavity and pharynx, larynx, and esophagus), as well as noncancer controls, to demonstrate a statistically significant association, if one exists. Because of the long period required for induction of human carcinomas and the infrequent use of marijuana in the general U.S. population before 1966, no epidemiological studies so far have been extensive enough to measure the

association between marijuana and cancer adequately. However, epidemiological investigation of this association is probably possible now in that some 30 years have elapsed since the start of widespread marijuana use in the United States among teenagers and young adults.

2. Molecular markers of respiratory cancer progression in marijuana smokers. If an epidemiological association between marijuana use and risk of respiratory cancer is demonstrated, studies would be warranted to explore the presence of molecular markers—such as TP53, p16, NAT2, and GSTM1—that could be predictive of genetically increased risk of carcinogenesis in marijuana users.

3. Prospective epidemiological studies of populations with HIV seropositivity or at high risk for HIV infection.* Because HIV/AIDS patients constitute the largest group that reports smoking marijuana for medical purposes and they are particularly vulnerable to immunosuppressive effects, there is a pressing need for a better understanding of the relative risk posed by and the rewards of smoking marijuana. Such studies should include history of marijuana use in the analysis of potential risk factors for seroconversion and acquisition of opportunistic infections or progression to AIDS. The studies could be carried out in the context of any federally approved clinical trials of medical marijuana in immunocompromised patients and should provide a follow-up period long enough to capture potential adverse events.

4. Regularized recording of marijuana use by patients. Although marijuana is the most commonly used illicit drug, medical providers often do not question patients about marijuana use and rarely document its use.¹⁰² Among 452 Kaiser Permanente patients who reported daily or almost daily marijuana use, physicians recorded marijuana use in only 3% of their medical records (S. Sidney, IOM workshop).

5. Additional cellular, animal, and human studies to investigate the effects of THC and marijuana on immune function. The effects studied should include effects on proinflammatory versus immunosuppressive cytokines and on the function of leukocytes that present antigen to T cells.

The question that needs to be addressed is whether THC or marijuana is a risk factor for HIV infection, for progression to more severe stages of

*A *prospective study* is one in which a group of subjects is identified and then studied over the course of time. Such a study allows an experimenter to balance different factors that may contribute to the study outcome. For example, age, family history, and smoking are risk factors for lung cancer. In a prospective study, these factors can be balanced to measure how much smoking increases the risk of lung cancer. A *retrospective study* is one in which people with a particular disease are identified and their histories are studied. Such studies are easier and less expensive to conduct, but they generally lack the explanatory power of prospective studies.

AIDS, or for opportunistic infection among HIV-positive patients. Studies are needed to determine the effects of marijuana use on the function of alveolar macrophages. It would be important to compare the HIV infectivity and replication of alveolar macrophages harvested from habitual marijuana users with those harvested from nonusers or infrequent marijuana users. Cell culture studies could be used to compare the susceptibility of HIV-infected alveolar macrophages to additional infection with opportunistic pathogens. Similarly, further studies on cell cultures of peripheral blood mononuclear cells could be used to assess the effects of exposure to THC on HIV infectivity and replication.

Cardiovascular System

Marijuana smoke and oral THC can cause tachycardia (rapid heart beat) in humans, 20–100% above baseline.^{57,85} The increase in heart rate is greatest in the first 10–20 minutes after smoking and decreases sharply and steadily; depending on whether smoked marijuana or oral THC is used, this can last three or five hours, respectively.^{68,95} In some cases, blood pressure increases while a person is in a reclining position but decreases inordinately on standing, resulting in postural hypotension (decreased blood pressure due to changing posture from a lying or sitting position to a standing position, which can cause dizziness and faintness). In contrast with acute administration of THC, chronic oral ingestion of THC reduces heart rate in humans.¹³

In animals, THC decreases heart rate and blood pressure.^{57,156} However, most of the animal studies have been conducted in anesthetized animals, and anesthesia causes hypertension. Thus, those studies should be interpreted as reports on the effects of cannabinoids in hypertensive subjects. The results of the animal and human studies are consistent with the conclusion that cannabinoids are hypotensive at high doses in animals, as well as humans.¹⁵⁶

Tolerance can appear after a few days of frequent daily administration (two or three doses per day) of oral THC or marijuana extract, with heart rate decreasing, reclining blood pressure falling, and postural hypotension disappearing.⁷³ Thus, the intensity of the effects depends on frequency of use, dose, and even body position.

The cardiovascular changes have not posed a health problem for healthy, young users of marijuana or THC. However, such changes in heart rate and blood pressure could present a serious problem for older patients, especially those with coronary arterial or cerebrovascular disease. Cardiovascular diseases are the leading causes of death in the United States (coronary heart disease is first; stroke is third), so any effect of mari-

juana use on cardiovascular disease could have a substantial impact on public health (S. Sidney, IOM workshop). The magnitude of the impact remains to be determined as chronic marijuana users from the late 1960s enter the age when coronary arterial and cerebrovascular diseases become common. Smoking marijuana is also known to decrease maximal exercise performance. That, with the increased heart rate, could theoretically induce angina (S. Sidney, IOM workshop), so, this raises the possibility that patients with symptomatic coronary artery disease should be advised not to smoke marijuana, and THC might be contraindicated in patients with restricted cardiovascular function.

Reproductive System

Animal Studies. Marijuana and THC can inhibit many reproductive functions on a short-term basis. In both male and female animals, THC injections suppress reproductive hormones and behavior.^{107,159} Studies have consistently shown that injections of THC result in rapid, dose-dependent suppression of serum luteinizing hormone (LH).⁷⁰ (LH is the pituitary hormone that stimulates release of the gonadal hormones, testosterone and estrogen.) Embryo implantation also appears to be inhibited by THC. But it does not necessarily follow that marijuana use will interfere with human reproduction. With few exceptions, the animal studies are based on acute treatments (single injections) or short-term treatments (THC injections given over a series of days). The results are generally observed for only several hours or in females sometimes for only one ovulatory cycle.

Acute treatments with cannabinoids—including THC, CBD, cannabinol, and anandamide—can decrease the fertilizing capacity of sea urchin sperm.¹³⁵⁻¹³⁷ The sea urchin is only a distant relative of humans, but the cellular processes that regulate fertilization are similar enough that one can expect a similar effect in humans. However, the effect of cannabinoids on the capacity of sperm to fertilize eggs is reversible and is observed at concentrations of 6–100 μM ,^{136,137} which are higher than those likely to be experienced by marijuana smokers. The presence of cannabinoid receptors in sperm suggests the possibility of a natural role for anandamide in modulating sperm function during fertilization. However, it remains to be determined whether smoked marijuana or oral THC taken in prescribed doses has a clinically significant effect on the fertilizing capacity of human sperm.

Exposure to THC *in utero* can result in long-term changes. Many *in utero* effects interfere with embryo implantation (see review by Wenger and co-workers¹⁵⁹). Exposure to THC shortly before or after birth can result in impaired reproductive behavior in mice when they reach adult-

hood: females are slower to show sexual receptivity, and males are slower to mount.¹⁰⁷

Although THC can act directly on endocrine tissues, such as the testes and ovaries, it appears to affect reproductive physiology through its actions on the brain, somewhere other than the pituitary. Some of the effects of THC are exerted through its action on stress hormones, such as cortisol.⁷⁰

Human Studies. The few human studies are consistent with the acute animal studies: THC inhibits reproductive functions. However, studies of men and women who use marijuana regularly have yielded conflicting results and show either depression of reproductive hormones, no effect, or only a short-term effect. Overall, the results of human studies are consistent with the hypothesis that THC inhibits LH on a short-term basis but not in long-term marijuana users. In other words, long-term users develop tolerance to the inhibitory effect of THC on LH. The results in men and women are similar, with the added consideration of the menstrual cycle in women; the acute effects of THC appear to vary with cycle stage. THC appears to have little effect during the follicular phase (the phase after menses and before ovulation) and to inhibit the LH pulse during the luteal phase (the phase after ovulation and before menses).¹⁰³ In brief, although there are no data on fertility itself, marijuana or THC would probably decrease human fertility—at least in the short term—for both men and women. And it is reasonable to predict that THC can interfere with early pregnancy, particularly with implantation of the embryo. Like tobacco smoke, marijuana smoke is highly likely to be harmful to fetal development and should be avoided by pregnant women and those who might become pregnant in the near future. Nevertheless, although fertility and fetal development are important concerns for many, they are unlikely to be of much concern to people with seriously debilitating or life-threatening diseases. The well-documented inhibition of reproductive functions by THC is thus not a serious concern for evaluating the short-term medical use of marijuana or specific cannabinoids.

The results of studies of the relationship between prenatal marijuana exposure and birth outcome have been inconsistent (reviewed in 1995 by Cornelius and co-workers³⁰). Except for adolescent mothers, there is little evidence that gestation is shorter in mothers who smoke marijuana.³⁰ Several studies of women who smoked marijuana regularly during pregnancy show that they tend to give birth to lower weight babies.^{46,65} Mothers who smoke tobacco also give birth to lower weight babies, and the relative contributions of smoking and THC are not known from these studies.

Babies born to mothers who smoked marijuana during pregnancy

weighed an average of 3.4 ounces less than babies born to a control group of mothers who did not smoke marijuana; there was no statistically significant difference in either gestational age or frequency of congenital abnormalities.¹⁶⁴ Those results were based on women whose urine tests indicated recent marijuana exposure. However, when the analysis was based only on self-reports of marijuana use (without verification by urine tests), there was no difference in weight between babies born to women who reported themselves as marijuana smokers and those born to women who reported that they did not smoke marijuana. That raises an important concern about the methods used to measure the effects of marijuana smoking in any study, perhaps even more so in studies on the effects of marijuana during pregnancy, when subjects might be less likely to admit to smoking marijuana. (The study was conducted in the last trimester of pregnancy, and there was no information about the extent of marijuana use earlier in pregnancy.)

For most of these studies, much of the harm associated with marijuana use is consistent with that associated with tobacco use, and smoking is an important factor, so the contribution of cannabinoids cannot be confirmed. However, Jamaican women who use marijuana rarely smoke it; but instead prepare it as tea.³⁷ In a study of neonates born to Jamaican women who did or did not ingest marijuana during pregnancy, there was no difference in neurobehavioral assessments made at three days after birth and at one month.³⁸ A limitation of the study is that there was no direct measure of marijuana use. Estimates of marijuana use were based on self-reports, which might be more accurate in Jamaica than in the United States because less social stigma is associated with marijuana use in Jamaica but still are less reliable than direct measures.

Newborns of mothers who smoke either marijuana or tobacco have statistically significantly higher mutation rates than those of non-smokers.^{4,5}

Since 1978, the Ottawa Prenatal Prospective Study has measured the cognitive functions of children born to mothers who smoked marijuana during pregnancy.⁴⁷ Children of mothers who smoked either moderately (one to six marijuana cigarettes per week) or heavily (more than six marijuana cigarettes per week) have been studied from the age of four days to 9–12 years. It is important to keep in mind that studies like this provide important data about the risks associated with marijuana use during pregnancy, but they do not establish the *causes* of any such association.

The children in the different marijuana exposure groups showed no lasting differences in global measures of intelligence, such as language development, reading scores, and visual or perceptual tests. Moderate cognitive deficits were detectable among these children when they were

four days old and again at four years, but the deficits were no longer apparent at five years.

Prenatal marijuana exposure was not, however, without lasting effect. At ages 5–6 years and 9–12 years, children in the same study who were prenatally exposed to tobacco smoke scored lower on tests of language skills and cognitive functioning.⁴⁸ In another study,^{49,50} 9 to 12 year olds who were exposed to marijuana prenatally scored lower than control subjects on tasks associated with “executive function,” a term used by psychologists to describe a person’s ability to plan, anticipate, and suppress behaviors that are incompatible with a current goal.⁵⁰ It was reflected in how the mothers described their children. Mothers of the marijuana-exposed children were more likely to describe their offspring as hyperactive or impulsive than were mothers of control children. The alteration in executive function was not seen in children born to tobacco smokers. The underlying causes might be the marijuana exposure or might be more closely related to the reasons underlying the mothers’ use of marijuana during pregnancy.

Mice born to dams injected with the endogenous cannabinoid, anandamide, during the last trimester of pregnancy also showed delayed effects. No effect of anandamide treatment during pregnancy was detected until the mice were adults (40 days old), at which time they showed behavioral changes that are common to the effects of other psychotropic drugs or prenatal stress.⁴⁵ As with the children born to mothers who smoked marijuana, it is not known what aspect of the treatment caused the effect. The dams might have found the dose (20 mg/kg of body weight) of anandamide aversive, in which case the effect could have resulted from generalized stress, as opposed to a cannabinoid-specific effect. Either is possible. Despite the uncertainty as to the underlying causes of the effects of prenatal exposure to cannabinoid drugs, it is prudent to advise against smoking marijuana during pregnancy.

SUMMARY AND CONCLUSIONS

This chapter summarizes the harmful effects of marijuana on individual users and, to a lesser extent, on society. The harmful effects on individuals were considered from the perspective of possible medical use of marijuana and can be divided into acute and chronic effects. The vast majority of evidence on harmful effects of marijuana is based on *smoked* marijuana, and, except for the psychoactive effects that can be reasonably attributed to THC, it is not possible to distinguish the drug effects from the effects of inhaling smoke from burning plant material.

For most people the primary adverse effect of *acute* marijuana use is diminished psychomotor performance; it is inadvisable for anyone under

the influence of marijuana to operate any equipment that might put the user or others in danger (such as driving or operating complex equipment). Most people can be expected to show impaired performance of complex tasks, and a minority experience dysphoria. People with or at risk of psychiatric disorders (including substance dependence) are particularly vulnerable to developing marijuana dependence, and marijuana use would be generally contraindicated for them. The short-term immunosuppressive effects are not well established; if they exist at all, they are probably not great enough to preclude a legitimate medical use. The acute side effects of marijuana use are within the risks tolerated for many medications.

The *chronic* effects of marijuana are of greater concern for medical use and fall into two categories: the effects of chronic smoking and the effects of THC. Marijuana smoke is like tobacco smoke in that it is associated with increased risk of cancer, lung damage, and poor pregnancy outcome. Smoked marijuana is unlikely to be a safe medication for any chronic medical condition. The second category is that associated with dependence on the psychoactive effects of THC. Despite past skepticism, it has been established that, although it is not common, a vulnerable subpopulation of marijuana users can develop dependence. Adolescents, particularly those with conduct disorders, and people with psychiatric disorders, or problems with substance abuse appear to be at greater risk for marijuana dependence than the general population.

As a cannabinoid drug delivery system, marijuana cigarettes are not ideal in that they deliver a variable mixture of cannabinoids and a variety of other biologically active substances, not all of which are desirable or even known. Unknown substances include possible contaminants, such as fungi or bacteria.

Finally, there is the broad social concern that sanctioning the medical use of marijuana might lead to an increase in its use among the general population. No convincing data support that concern. The existing data are consistent with the idea that this would not be a problem if the medical use of marijuana were as closely regulated as the use of other medications that have abuse potential, but we acknowledge a lack of data that directly address the question. Even if there were evidence that the medical use of marijuana would decrease the perception that it can be a harmful substance, this is beyond the scope of laws regulating the approval of therapeutic drugs. Those laws concern scientific data related to the safety and efficacy of drugs for individual use; they do not address perceptions or beliefs of the general population.

Marijuana is not a completely benign substance. It is a powerful drug with a variety of effects. However, except for the harm associated with smoking, the adverse effects of marijuana use are within the range toler-

ated for other medications. Thus, the safety issues associated with marijuana do not preclude some medical uses. But the question remains: Is it effective? That question is covered here in two chapters: chapter 2 summarizes what has been learned about the biological activity of cannabinoids in the past 15 years through research in the basic sciences, and chapter 4 reviews clinical data on the effectiveness of marijuana and cannabinoids for the treatment of various medical conditions.

Three factors influence the safety of marijuana or cannabinoid drugs for medical use: the delivery system, the use of plant material, and the side effects of cannabinoid drugs. (1) Smoking marijuana is clearly harmful, especially in people with chronic conditions, and is not an ideal drug delivery system. (2) Plants are of uncertain composition, which renders their effects equally uncertain, so they constitute an undesirable medication. (3) The side effects of cannabinoid drugs are within the acceptable risks associated with approved medications. Indeed, some of the side effects, such as anxiety reduction and sedation, might be desirable for some patients. As with many medications, there are people for whom they would probably be contraindicated.

CONCLUSION: Present data on drug use progression neither support nor refute the suggestion that medical availability would increase drug abuse. However, this question is beyond the issues normally considered for medical uses of drugs, and it should not be a factor in the evaluation of the therapeutic potential of marijuana or cannabinoids.

CONCLUSION: A distinctive marijuana withdrawal syndrome has been identified, but it is mild and short lived. The syndrome includes restlessness, irritability, mild agitation, insomnia, sleep EEG disturbance, nausea, and cramping.

CONCLUSION: Numerous studies suggest that marijuana smoke is an important risk factor in the development of respiratory disease.

RECOMMENDATION: Studies to define the individual health risks of smoking marijuana should be conducted, particularly among populations in which marijuana use is prevalent.

4

The Medical Value of Marijuana and Related Substances

During the course of drug development, a typical compound is found to have some medical benefit and then extensive tests are undertaken to determine its safety and proper dosage for medical use. In contrast, marijuana has been widely used in the United States for decades.¹⁶² In 1996, 68.6 million people—32% of the U.S. population over 12 years old—had tried marijuana or hashish at least once; 5% were current users.¹⁶²

The data on the adverse effects of marijuana are more extensive than the data on its effectiveness. Clinical studies of marijuana are difficult to conduct: researchers interested in clinical studies of marijuana face a series of barriers, research funds are limited, and there is a daunting thicket of regulations to be negotiated at the federal level (those of the Food and Drug Administration, FDA, and the Drug Enforcement Agency, DEA) and state levels (see chapter 5). Consequently, the rapid growth in basic research on cannabinoids contrasts with the paucity of substantial clinical studies on medical uses.

This chapter is devoted to an analysis of the therapeutic value of marijuana and cannabinoids for specific symptoms associated with various conditions. The risks associated with the medical use of marijuana are discussed in chapter 3. It should be noted that THC, the primary active ingredient in marijuana, is an FDA-approved drug referred to as dronabinol and marketed as Marinol. Marijuana is advocated primarily for relief from the symptoms of disease rather than as a cure.

For the most part, the logical categories for the medical use of mari-

juana are not based on particular diseases but on symptoms—such as nausea, appetite loss, or chronic pain—each of which can be caused by various diseases or even by treatments for diseases. This chapter is therefore organized by symptoms rather than by diseases. There are eight sections. The first section explains clinical trials, the following five deal with specific symptoms and conditions, and the last two summarize the medical benefits of marijuana and cannabinoids. The five sections on symptoms and conditions are as follows: pain, nausea and vomiting, wasting syndrome and appetite stimulation, neurological symptoms (including muscle spasticity), and glaucoma.

The Institute of Medicine (IOM) study team received reports of more than 30 different medical uses of marijuana, more than could be carefully reviewed in a report of this length; even more uses are reported elsewhere.^{62,63} For most of the infrequently mentioned medical uses of marijuana there are only a few anecdotal reports. This report reviews only the most prominent symptoms that are reportedly relieved by marijuana. However, many of those diseases not reviewed here share common symptoms, such as pain, nausea and vomiting, and muscle spasms, which might be relieved by cannabinoid drugs.

STANDARDS FOR EVALUATING CLINICAL TRIALS

Before evaluating individual clinical trials concerning the efficacy and safety of medical uses of marijuana and cannabinoids, it is useful to review the general qualities of clinical trials. Clinical trials involve groups of individuals in which different treatments are compared among different groups. Such trials measure the efficacy of a medication and are required by the FDA for approval of any new drug or new use of a drug (discussed further in chapter 5).

The degree of assurance that the outcome of a clinical trial is due to the treatment being tested depends on how well the trial is designed. Three important factors to consider in evaluating the design of a clinical trial are sample selection, subjective effects, and effects that are independent of the treatment. For *sample selection* it is important to ensure that patients are allocated to different treatment groups in such a way that the groups are not biased toward a particular treatment outcome. For example, the health status, gender, and ages of different treatment groups should be equivalent. *Subjective effects* must be controlled because they influence experimental results in two important ways. First, a patient's expectation that a treatment will be effective can influence the degree of its effect (for example, in the control of nausea). Second, the investigator's expectation can influence his or her interpretation of the treatment effect (for example, when assessing the level of pain experienced by a patient).

For these reasons, double blinding, in which neither the subject nor the person who assesses the drug's effect is aware of the subject's treatment group, is particularly important in cannabinoid drug studies. Another important control for subjective effects includes the use of placebo drugs, which are inert substances, or the use of comparison drugs that have effects similar to the experimental drug. Finally, the quality of the experimental design depends on controlling for factors that are unrelated to the test drug but that might nonetheless influence the treatment outcome. *Sequencing effects* are one example of such factors. For example, patients might react differently to the same medication depending on whether the medication was administered after an effective or an ineffective treatment. Likewise, a patient whose symptoms are initially mild might react differently to a drug than would a patient whose symptoms are initially severe. Because psychological effects are associated with cannabinoid drugs, it is important to consider how such side effects might influence the therapeutic value of the treatment. Conditions such as pain and nausea are especially susceptible to subjective influences. For example, depending on the person, THC can reduce or increase anxiety; it is important to determine to what extent this "side effect" contributes to the therapeutic effect.

While double-blind, randomized, controlled clinical trials offer the highest degree of assurance of drug efficacy, such trials are not always feasible. Vulnerable populations, such as children, older patients, and women of child-bearing age, are often excluded from experimental drug trials for safety reasons. Nonetheless, such patients are part of everyday clinical practice. The challenge of integrating the ideal of standardized and rigorous processes for treatment evaluation with everyday clinical practice has encouraged interest in single-patient trials.⁶⁷ Methods for such trials have been established and tested in a variety of clinical settings, usually under everyday conditions.^{66,105,159} They are particularly valuable when physicians or patients are uncertain about the efficacy of treatment for symptomatic diseases. Controls can be incorporated even in this kind of trial. Such trials can be double blinded and can involve cross-over designs in which the patient is treated with alternating treatments, such as placebo-drug-placebo or one drug followed by another drug. As with any other clinical trial, a single-patient trial should be designed to permit objective comparison between treatments.

ANALGESIA

Pain is the most common symptom for which patients seek medical assistance.⁵ Pain associated with structural or psychophysiological disorders can arise from somatic, visceral, or neural structures. *Somatic pain* results from activation of receptors outside the brain and is transmitted to

the brain via peripheral nerves. *Visceral pain* results from activation of specific pain receptors in the intestine (visceral nociceptive receptors); it is characterized as a deep aching or cramping sensation, but its source is often experienced at sites remote from the site of receptor activation, a phenomenon known as referred pain. *Neuropathic pain* results from injury to peripheral receptors, nerves, or the central nervous system; it is typically burning, the skin feels abnormally unpleasant when gently touched (dysesthesia), and it often occurs in an area of sensory loss, as in the case of postherpetic neuralgia (shingles).

All of the currently available analgesic (pain-relieving) drugs have limited efficacy for some types of pain. Some are limited by dose-related side effects and some by the development of tolerance or dependence. A cannabinoid, or other analgesic, could potentially be useful under any of the following circumstances:

- There is a medical condition for which it is more effective than any currently available medication.
- It has a broad clinical spectrum of efficacy and a unique side effect profile.
- It has synergistic interactions with other analgesics.
- It exhibits “side effects” that are considered useful in some clinical situations.
- Its efficacy is enhanced in patients who have developed tolerance to opioids.

There have not been extensive clinical studies of the analgesic potency of cannabinoids, but the available data from animal studies indicate that cannabinoids could be useful analgesics. In general, cannabinoids seem to be mild to moderate analgesics. Opiates, such as morphine and codeine, are the most widely used drugs for the treatment of acute pain, but they are not consistently effective in chronic pain; they often induce nausea and sedation, and tolerance occurs in some patients. Recent research has made it clear that CB₁ receptor agonists act on pathways that partially overlap with those activated by opioids but through pharmacologically distinct mechanisms (see chapter 2). Therefore, they would probably have a different side effect profile and perhaps additive or synergistic analgesic efficacy.

In light of the evidence that cannabinoids can reduce pain in animals, it is important to re-evaluate the evidence of analgesic efficacy in humans and to ask what clinical evidence is needed to decide whether cannabinoids have any use in the treatment of pain.

Clinical Studies of Cannabinoids

There have been three kinds of studies of the effects of cannabinoids on pain in human volunteers: studies of experimentally induced acute pain, studies of postsurgical acute pain, and studies of chronic pain. Overall, there have been very few studies—only one since 1981—and they have been inconclusive.

Experimentally Induced Acute Pain

Early studies of cannabinoids on volunteers did not demonstrate consistent analgesia when experimental pain models were used. In fact, three early volunteer studies of THC and experimental pain caused by a variety of pain modalities—electrical stimulation, tourniquet pain, and thermal pain—resulted in an *increase* in pain sensitivity (hyperalgesia).^{22,84,108}

Other studies also failed to show an analgesic effect of THC, but they were not well designed. Raft and co-workers found no evidence of THC effect on pain thresholds and pain tolerance following electrical stimulation and noxious pressure.¹⁵⁰ But their study suffers from two major methodological problems. First, they measured only the extremes of pain sensation—*threshold* (the lowest intensity at which a particular stimulus is perceived as painful) and *tolerance* (the maximum intensity of pain that a subject can withstand). However, most pain is experienced in an intermediate range, where effects on pain suppression are most detectable. Modern methods of pain assessment in humans typically use ratings of the intensity of the sensation of pain; those methods are superior to assessing the effects of a drug on the extremes of pain.¹⁹² Second, Raft and co-workers did not include a positive control; that is, they did not demonstrate the adequacy of their method by showing that an established analgesic, such as an opiate or narcotic, was effective under their study conditions.

Clark and co-workers²² tested the effect of smoked marijuana on thermal pain in volunteers and failed to observe an analgesic effect. However, because of the study design, the results are inconclusive. First, there was no positive control to demonstrate the adequacy of their methods; second, the study subjects were habitual marijuana users. During the study, they were hospitalized and allowed free access to marijuana cigarettes for a period of four weeks, consuming an average of four to 17 marijuana cigarettes per day. Pain was tested “approximately every one to two weeks.” Thus, it is quite likely that the subjects were tolerant to THC at the time of testing.

Surgical Acute Pain

Raft and co-workers¹⁵⁰ found no analgesic effect of THC on surgical pain induced by tooth extraction. However, that study suffered from several serious limitations: the tooth extraction included treatment with the local anesthetic lidocaine, the pain during the procedure was assessed 24 hours later, and there was no positive control. Levonantradol (a synthetic THC analogue) was tested in 56 patients who had moderate to severe postoperative or trauma pain.⁸⁹ They were given intramuscular injections of levonantradol or placebo 24 hours after surgery. To control for previous drug exposure, patients with a history of drug abuse or addiction and those who received an analgesic, antiinflammatory, tranquilizer, sedative, or anesthetic agent within 24 hours of the test drug were excluded from the study. On average, pain relief was significantly greater in the levonantradol-treated patients than in the placebo-treated patients. Because the authors did not report the number or percentage of people who responded, it is not clear whether the average represents consistent pain relief in all levonantradol-treated patients or whether some people experienced great relief and a few experienced none.

Chronic Pain

The most encouraging clinical data on the effects of cannabinoids on chronic pain are from three studies of cancer pain. Cancer pain can be due to inflammation, mechanical invasion of bone or other pain-sensitive structure, or nerve injury. It is severe, persistent, and often resistant to treatment with opioids. In one study, Noyes and co-workers found that oral doses of THC in the range of 5–20 mg produced analgesia in patients with cancer pain.^{139,140} The first experiment was a double-blind, placebo-controlled study of 10 subjects and measured both pain intensity and pain relief.¹⁴⁰ Each subject received all drug treatments: placebo and 5, 10, 15, and 20 mg of THC in pill form; each pill was identical in appearance and given on successive days. The 15- and 20-mg doses of THC produced significant analgesia. There were no reports of nausea or vomiting. In fact, at least half the patients reported increased appetite. With a 20-mg dose of THC, patients were heavily sedated and exhibited “depersonalization,” characterized by a state of dreamy immobility, a sense of unreality, and disconnected thoughts. Five of 36 patients exhibited adverse reactions (extreme anxiety) and were eliminated from the study. Only one patient experienced this effect at the 10-mg dose of THC. The mean age of the patients was 51 years, and they were probably not experienced marijuana smokers. A limitation of this study is that there were no positive con-

trols—that is, other analgesics that could provide a better measure of the degree of analgesia produced by THC.

In a later larger single-dose study, the same investigators reported that the analgesic effect of 10 mg of THC was equivalent to that of 60 mg of codeine; the effect of 20 mg of THC was equivalent to that of 120 mg of codeine.¹³⁹ (Note that codeine is a relatively weak analgesic.) The side effect profiles were similar, though THC was more sedating than codeine. In a separate publication the same authors published data indicating that patients had improved mood, a sense of well-being, and less anxiety.¹³⁹

The results of the studies mentioned above on cancer pain are consistent with the results of using a nitrogen analogue of THC. Two trials were reported: one compared this analogue with codeine in 30 patients, and a second compared it with placebo or secobarbital, a short-acting barbiturate.¹⁷⁵ For mild, moderate, and severe pain, the THC analogue was equivalent to 50 mg of codeine and superior to placebo and to 50 mg of secobarbital.

Case Reports and Surveys

The few case reports of clinical analgesia trials of cannabinoids are not convincing.^{85,120} There are, however, anecdotal surveys that raise the possibility of a role for cannabinoids in some patients who have chronic pain with prominent spasticity. A recent survey of over 100 patients with multiple sclerosis reported that a large number obtained relief from spasticity and limb pain (discussed further under the section on multiple sclerosis).²⁸ Several said that it relieved their phantom pain and headache.⁴¹

Migraine Headaches

There is clearly a need for improved migraine medications. Sumatriptan (Imitrex) is the best available medication for migraine headaches, but it fails to abolish migraine symptoms in about 30% of migraine patients.^{118,147} Marijuana has been proposed numerous times as a treatment for migraine headaches, but there are almost no clinical data on the use of marijuana or cannabinoids for migraine. Our search of the literature since 1975 yielded only one scientific publication on the subject. It presents three cases of cessation of daily marijuana smoking followed by migraine attacks—not convincing evidence that marijuana relieves migraine headaches.⁴³ The same result could have been found if migraine headaches were a consequence of marijuana withdrawal. While there is no evidence that marijuana withdrawal is followed by migraines, when analyzing the strength of reports such as these it is important to consider

all logical possibilities. Various people have claimed that marijuana relieves their migraine headaches, but at this stage there are no conclusive clinical data or published surveys about the effect of cannabinoids on migraine.

However, a possible link between cannabinoids and migraine is suggested by the abundance of cannabinoid receptors in the periaqueductal gray (PAG) region of the brain. The PAG region is part of the neural system that suppresses pain and is thought to be involved in the generation of migraine headaches.⁵² The link or lack thereof between cannabinoids and migraine might be elucidated by examining the effects of cannabinoids on the PAG region.¹¹⁰ Recent results indicating that both cannabinoid receptor subtypes are involved in controlling peripheral pain¹⁵ suggest that the link is possible. Further research is warranted.

Conclusions: Analgesia

A key question to address is whether there is any receptor selectivity for the analgesic efficacy of cannabinoids. Are the unwanted side effects (amnesia and sedation) caused by the same receptors in the same brain regions as those producing the analgesia? If the answer is *yes*, enhancing efficacy will not solve the problem of sedation. Similarly, are the pleasant side effects due to an action at the same receptor? Can the feelings of well-being and appetite stimulation be separated by molecular design? Recent results indicating that both cannabinoid receptor subtypes are independently involved in controlling peripheral pain¹⁵ (discussed in chapter 2) strongly suggest that this is possible and that further research is warranted.

Further research into the basic circuitry underlying cannabinoid analgesia should be valuable. The variety of neural pathways that underlie the control of pain suggests that a synergistic analgesia “cocktail” would be effective. For example, Lichtman and Martin have shown the involvement of an $\alpha 2$ adrenoceptor in cannabinoid analgesia.¹¹¹ Perhaps a combination of a CB₁ agonist and an $\alpha 2$ agonist (such as clonidine) would provide enhanced analgesia with less severe side effects.

Clinical studies should be directed at pain patients for whom there is a demonstrated need for improved management and where the particular side effect profile of cannabinoids promises a clear benefit over current approaches. The following patient groups should be targeted for clinical studies of cannabinoids in the treatment of pain:

- Chemotherapy patients, especially those being treated for the mucositis, nausea, and anorexia.

- Postoperative pain patients (using cannabinoids as an opioid adjunct to determine whether nausea and vomiting from opioids are reduced).
- Patients with spinal cord injury, peripheral neuropathic pain, or central poststroke pain.
- Patients with chronic pain and insomnia.
- AIDS patients with cachexia, AIDS neuropathy, or any significant pain problem.

In any patient group an essential question to be addressed is whether the analgesic efficacy of opioids can be augmented. The strategy would be to find the ceiling analgesic effect with an opioid (as determined by pain intensity and tolerability of side effects) and then add a cannabinoid to determine whether additional pain relief can be obtained. That would begin the investigation of potential drug combinations. As with any clinical study on analgesic drugs, it will be important to investigate the development of tolerance and physical dependence; these are not themselves reasons to exclude the use of cannabinoids as analgesics, but such information is essential to the management of many drugs that are associated with tolerance or physical dependence.

A secondary question would be whether THC is the only or the best component of marijuana for analgesia. How does the analgesic effect of the plant extract compare with that of THC alone? If there is a difference, it will be important to identify the combinations of cannabinoids that are the most effective analgesics.

In conclusion, the available evidence from animal and human studies indicates that cannabinoids can have a substantial analgesic effect. One exception is the lack of analgesic effect in studies on experimentally induced acute pain, but because of limitations in the design of those studies they were inconclusive. Further clinical work is warranted to establish the magnitude of the effect in different clinical conditions and to determine whether the effect is sustained. Although the usefulness of cannabinoids appears to be limited by side effects, notably sedation, other effects such as anxiolysis, appetite stimulation, and perhaps antinausea and antispasticity effects should be studied in randomized, controlled clinical trials. These very "special" effects might warrant development of cannabinoid drugs for particular clinical populations.

NAUSEA AND VOMITING

Nausea and vomiting (emesis) occur under a variety of conditions, such as acute viral illness, cancer, radiation exposure, cancer chemotherapy, postoperative recovery, pregnancy, motion, and poisoning. Both

are produced by excitation of one or a combination of triggers in the gastrointestinal tract, brain stem, and higher brain centers (Figure 4.1, Emesis-stimulating pathways).¹²⁷ There are numerous cannabinoid receptors in the nucleus of the solitary tract, a brain center that is important in the control of emesis.^{79,80} Although the same mechanisms appear to be involved in triggering both nausea and vomiting, either can occur without the other. Much more is known about the neural mechanisms that produce vomiting than about those that produce nausea, in large part because vomiting is a complex behavior involving coordinated changes in the gastrointestinal tract, respiratory muscles, and posture, whereas nausea is a sensation involving primarily higher brain centers and lacks a discrete observable action.^{104,128} Most reports on the antiemetic effects of marijuana or cannabinoids are based on chemotherapy-induced emesis; they are the subject of the following section.

Chemotherapy-Induced Nausea and Vomiting

The use of effective chemotherapeutic drugs has produced cures in some malignancies and retarded the growth of others, but nausea and

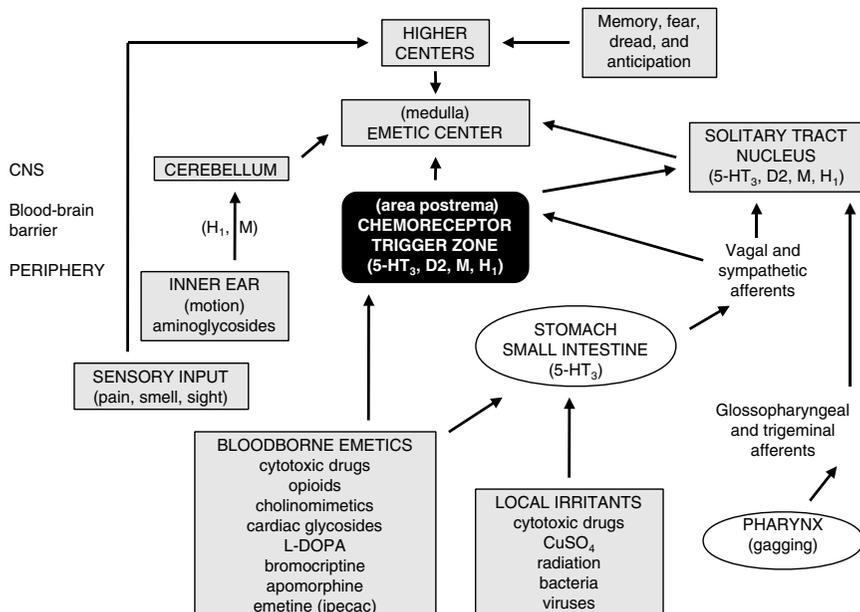

FIGURE 4.1 Emesis-stimulating pathways. SOURCE: Bruton, L.L. 1996. P. 929 in Hardman et al., eds., *The Pharmacological Basis of Therapeutics*, 9th edition. New York: McGraw-Hill. Reprinted with permission.

vomiting are frequent side effects of these drugs. Nausea ranks behind only hair loss as a concern of patients on chemotherapy, and many patients experience it as the worst side effect of chemotherapy. The side effects can be so devastating that patients abandon therapy or suffer diminished quality of life. As a result, the development of effective strategies to control the emesis induced by many chemotherapeutic agents is a major goal in the supportive care of patients with malignancies.

The mechanism by which chemotherapy induces vomiting is not completely understood. Studies suggest that emesis is caused by stimulation of receptors in the central nervous system or the gastrointestinal tract. This stimulation appears to be caused by the drug itself, a metabolite of the drug, or a neurotransmitter.^{6,12,35} In contrast with an emetic like apomorphine, there is a delay between the administration of chemotherapy and the onset of emesis. This delay depends on the chemotherapeutic agent; emesis can begin anywhere from a few minutes after the administration of an agent like mustine to an hour for cisplatin.¹²

The most desirable effect of an antiemetic is to control emesis completely, which is currently the primary standard in testing new antiemetic agents (R. Gralla, IOM workshop). Patients recall the number of emetic episodes accurately, even if their antiemetics are sedating or affect memory;¹⁰¹ thus, the desired end point of complete control is also a highly reliable method of evaluation. The degree of nausea can be estimated through the use of established visual analogue scales.^{*21,55,101}

Another consideration in using antiemetic drugs is that the frequency of emesis varies from one chemotherapeutic agent to another. For example, cisplatin causes vomiting in more than 99% of patients who are not taking an antiemetic (with about 10 vomiting episodes per dose), whereas methotrexate causes emesis in less than 10% of patients.^{55,82,83} Among chemotherapeutic agents, cisplatin is the most consistent emetic known and has become the benchmark for judging antiemetic efficacy. Antiemetics that are effective with cisplatin are at least as effective with other chemotherapeutic agents. Controlling for the influence of prior chemotherapy and balancing predisposing factors such as, sex, age, and prior heavy alcohol use among study groups are vital for reliability. Reliable randomization of patients and blinding techniques (easier when there are no psychoactive effects) are also necessary to evaluate the control of vomiting and nausea.

*The *visual analogue scale* is a continuous line representing all possible levels of a particular sensation. It is an estimation of a patient's subjective evaluation and not a true measurement. Patients select a point anywhere on the line to demonstrate the level of sensation they are experiencing, with one end representing one extreme, such as no sensations, and the other end representing the opposite extreme, such as a maximum level of that sensation.

THC and Marijuana Therapy for Chemotherapy-Induced Nausea and Vomiting

Cannabinoids are mildly effective in preventing emesis in some patients who are receiving cancer chemotherapy. Several cannabinoids have been tested as antiemetics, including THC (both Δ^9 -THC and Δ^8 -THC) and the synthetic cannabinoids nabilone and levonantradol. Smoked marijuana has also been examined.

Antiemetic Properties of THC

The quality and usefulness of antiemetic studies depend on adherence to the methodological considerations outlined above. Many of the reported clinical experiences with cannabinoids are not based on definitive experimental methods. In studies that compared THC with a placebo, THC was usually found to possess antiemetic properties. However, the chemotherapeutic drug varied in most trials, and some studies included small numbers of patients. In one study THC was found to be superior to a placebo in patients receiving methotrexate, an agent that is not a strong emetic.¹⁸ When the same investigators studied THC in a small number of patients who were receiving a chemotherapeutic drug that is more likely to cause emesis than anthracycline, the antiemetic effect was poor.¹⁹

Other trials were designed to compare THC with that of Compazine (prochlorperazine).^{143,160} In the 1980s, prochlorperazine was one of the more effective antiemetics available, but it was not completely satisfactory, and the search for better agents continued. THC and prochlorperazine given orally showed similar degrees of efficacy, but the studies often used various chemotherapeutic agents. Even when administered in combination, THC and prochlorperazine failed to stop vomiting in two-thirds of patients.⁵⁰

In a carefully controlled double-blind study comparing THC with the antiemetic drug metoclopramide, in which no patient had previously received chemotherapy and in which anticipatory emesis was therefore not a factor, all patients received the same dose of cisplatin and were randomly assigned to the THC group or the metoclopramide group. Complete control of emesis occurred in 47% of those treated with metoclopramide and 13% of those treated with THC.⁵⁸ Major control (two or fewer episodes) occurred in 73% of the patients given metoclopramide compared to 27% of those given THC. There were many flaws in experimental methods, but those results suggest that THC has some, but not great, efficacy in reducing chemotherapy-induced emesis.^{18,19,50,161} The studies also indicate that the degree of efficacy is not high. In 1985, the

FDA approved THC in the form of dronabinol for this treatment (discussed in chapter 5).

The THC metabolite, 11-OH-THC, is more psychoactive than THC but is a weaker antiemetic.¹²¹ Thus, it might be possible to design antiemetic cannabinoids without the psychological effects associated with marijuana or THC. Δ^8 -THC is less psychoactive than THC¹⁵¹ but was found to completely block both acute and delayed chemotherapy-induced emesis in a study of eight children, ages 3–13 years.* Two hours before the start of each cancer treatment and every six hours thereafter for 24 hours, the children were given Δ^8 -THC as oil drops on the tongue or in a bite of bread (18 mg/m² body surface area). The children received a total of 480 treatments. The only side effects reported were slight irritability in two of the youngest children (3.5 and 4 years old). Based on the prediction that the THC-induced anxiety effects would be less in children than in adults, the authors used doses that were higher than those recommended for adults (5–10 mg/m² body surface area).

Antiemetic Properties of Synthetic THC Analogues

Nabilone (Cesamet) and levonantradol were tested in various settings; the results were similar to those with THC. Efficacy was observed in several trials, but no advantage emerged for these agents.^{176,185} As in the THC trials, nabilone and levonantradol reduced emesis but not as well as other available agents in moderately to highly emetogenic settings. Neither is commercially available in the United States.

Antiemetic Properties of Marijuana

Among the efforts to study marijuana was a preliminary study conducted in New York state on 56 cancer patients who were unresponsive to conventional antiemetic agents.¹⁸⁸ The patients were asked to rate the effectiveness of marijuana compared with results during prior chemotherapy cycles. In this survey, 34% of patients rated marijuana as moderately or highly effective. The authors concluded that marijuana had antiemetic efficacy, but its relative value was difficult to determine because no control group was used and the patients varied with respect to previous experiences, such as marijuana use and THC therapy.

*Note that the authors of this study chose to use Δ^8 -THC because it is more stable and easier to produce than Δ^9 -THC; it does not follow from this particular study that marijuana, with its mixture of cannabinoids, should be a more powerful antiemetic than Δ^9 -THC.

A Canadian oncology group conducted a double-blind, cross-over, placebo-controlled study comparing smoked marijuana with THC in pill form in 20 patients who were receiving various chemotherapeutic drugs.¹⁰⁷ The degree of emetic control was similar: only 25% of patients achieved complete control of emesis; 35% of the patients indicated a slight preference for the THC pills over marijuana, 20% preferred marijuana, and 45% expressed no preference.¹⁰⁷

Neither study showed a clear advantage for smoked marijuana over oral THC, but neither reported data on the time course of antiemetic control, possible advantages of self-titration with the smoked marijuana, or the degree to which patients were able to swallow the pills. Patients with severe vomiting would have been unlikely to be able to swallow or keep the pills down long enough for them to take effect. The onset of drug effect is much faster with inhaled or injected THC than it is for oral delivery.^{87,112,141} Although many marijuana users have claimed that smoked marijuana is a more effective antiemetic than oral THC, no controlled studies have yet been published that analyze this in sufficient detail to estimate the extent to which this is the case.

Side Effects Associated with THC and Marijuana in Antiemetic Therapy

Frequent side effects associated with THC or marijuana are dizziness, dry mouth, hypotension, moderate sedation, and euphoria or dysphoria.^{18,19,50,107,143,160,176,185} To patients, dry mouth and sedation are the least troubling side effects. Perhaps the most troubling side effects are orthostatic hypotension and dizziness, which could increase the patient's distress.

There is disagreement as to whether the psychoactive effects of THC correlate with its antiemetic activity. In the prospective double-blind trial comparing THC with metoclopramide, the authors reported no relationship between the occurrence of complete antiemetic control and euphoria or dysphoria.⁵⁸ Other investigators believe that the occurrence of euphoria or dysphoria is often associated with improved antiemetic control.¹⁶⁰ Nevertheless, there is a consensus among investigators that dysphoric effects are more common among patients who have had no prior experience with cannabinoids. An important and unexpected problem encountered in the New York state open trial with marijuana was the inability of nearly one-fourth of the patients to tolerate the administration of marijuana by smoking.¹⁸⁸ The intolerance could have been due to inexperience with smoking marijuana and is an important consideration.

Therapy for Chemotherapy-Induced Nausea and Vomiting

Present Therapy

New classes of antiemetics that have emerged over the past 10 years have dramatically reduced the nausea and vomiting associated with cancer chemotherapy and transformed the acceptance of cisplatin by cancer patients. The new antiemetics—including selective serotonin type 3 receptor antagonists, substituted benzamides, corticosteroids, butyrophenones, and phenothiazines—have few side effects when given over a short term and are convenient in various clinical settings.

The most effective commonly used antiemetics are serotonin receptor antagonists (ondansetron and granisetron) with or without corticosteroids.^{37,56,88,145,155} In a combination trial of dexamethasone (a corticosteroid) and a serotonin antagonist, complete control of acute cisplatin-induced emesis was observed in about 75% of patients. If the chemotherapy was only moderately emetogenic, up to 90% of the patients who received the combination achieved complete control of emesis. Side effects of those antiemetic agents include headache, constipation, and alterations in liver function, but they are generally well tolerated by most patients.¹³

Other commonly used antiemetics are phenothiazines—prochlorperazine (Compazine) and haloperidol—and metoclopramide. Metoclopramide is somewhat less effective than the serotonin antagonists and has more side effects, including acute dystonic reactions, drowsiness, diarrhea, and depression.^{13,37} Side effects associated with phenothiazines are severe or acute dystonic reactions, hypotension, blurred vision, drowsiness, dry mouth, urinary retention, allergic reactions, and occasional jaundice.¹³

The cost of effective antiemetic regimens can vary markedly, depending on the agent, dose, schedule, and route of administration. Overall, oral regimens cost less than intravenous regimens because of lower pharmacy and administration costs, as well as lower acquisition costs in many countries. Regimens with a cost to the pharmacy as low as about \$30 to \$35 per treatment session have been shown to be effective;⁵⁷ these costs are for treatment of acute emesis and delayed emesis with generic agents where available.

Although it is generally not well known by the public, major progress in controlling chemotherapy-induced acute nausea and vomiting has been made since the 1970s. Patients receiving the most difficult to control emetic agents now have no more than about a 20–30% likelihood of experiencing acute emesis,¹⁵⁵ whereas in the 1970s the likelihood was nearly 100% despite antiemetics.^{55,86} As has been seen, most antiemetic studies with

BOX 4.1

Attitudes of Oncologists Toward Prescribing Marijuana

In the 1990s, two groups of investigators conducted three surveys on the attitudes of clinical oncologists toward prescribing marijuana as an antiemetic. These studies are arguably out of date in that the antiemetics available now are much more effective than those available when the studies were conducted. Nonetheless, the studies merit attention because they are still often cited as evidence for or against the use of marijuana as an antiemetic.

The two groups' results were contradictory. In 1994, by which time serotonin receptor antagonists (5-HT receptors) had become available, Schwartz and Beveridge¹⁷¹ concluded that oncologists had little interest in prescribing marijuana to control emesis, whereas Doblin and Kleiman³⁹ had concluded in 1991 that interest was great. Since 1994, the two groups have debated in the literature as to which study represents the true sentiment among oncologists.^{38,172,177} In fact, numerous methodological differences between the two studies might explain the different results.^{38,172} Ultimately, these studies are irrelevant. Both deal with perceptions rather than pharmacological realities based on well-designed outcome studies.¹⁷⁷

cannabinoids had methodological difficulties and are inconclusive. The evidence from the well-conducted trials indicate that cannabinoids reduce emesis in about one-fourth of patients receiving cancer chemotherapy. Cannabinoids are not as effective as several other classes of agents, such as substituted benzamides, serotonin receptor antagonists, and corticosteroids. The side effects associated with cannabinoid use are generally tolerable. Like cannabinoids, smoked marijuana, was apparently effective, but the efficacy was no greater than that of available antiemetic agents now considered to be marginally satisfactory. At present, the most effective antiemetic regimens are combinations of oral serotonin receptor antagonists with dexamethasone in single-dose regimens given before chemotherapy. Neither multiple-dose regimens nor intravenous antiemetics provide better control, and both add unnecessary costs.^{59,81}

Future Therapy

Advances in therapy for chemotherapy-induced nausea and vomiting will require discovery of agents that work through mechanisms dif-

ferent from those of existing antiemetics, including the serotonin antagonists. Among the proposed new pathways, neurokinin-1 (NK-1) receptor antagonists appear to be the most promising. Neurokinin receptors are found in brain and intestine and are thought to be involved in motor activity, mood, pain and reinforcement. They might well be involved in mediating intestinal sensations, including nausea. In animal models, agents that block the NK-1 receptor prevent cisplatin-induced emesis. At the time of this writing, clinical trials with NK-1 receptor antagonists were under way (phase II or small phase III comparison studies). Preliminary results indicated that these agents have useful activity in both acute and delayed chemotherapy-induced emesis (that is, beginning or persisting 24 or more hours after chemotherapy) and are safe to administer orally.^{102,135}

It is theoretically possible, considering that the mechanism of cannabinoid action appears to differ from that of the serotonin receptor antagonists and of corticosteroids, that THC added to more effective regimens might enhance control of emesis. Such combinations should aim to be as convenient as possible and have few additional side effects. The critical issue is not whether marijuana or cannabinoid drugs might be superior to the new drugs, but whether some group of patients might obtain added or better relief from marijuana or cannabinoid drugs.

Even with the best antiemetic drugs, the control of nausea and vomiting that begins or persists 24 hours after chemotherapy remains imperfect. The pathophysiology of delayed emesis appears different from that of acute emesis, and it is more likely to occur with a strong emetic agent, but it varies from patient to patient. Treatment to prevent this emesis requires dosing both before and after chemotherapy.¹⁰³

Conclusions: Chemotherapy-Induced Nausea

Most chemotherapy patients are unlikely to want to use marijuana or THC as an antiemetic. In 1999, there are more effective antiemetic agents available than were available earlier. By comparison, cannabinoids are only modest antiemetics. However, because modern antiemetics probably act through different mechanisms, cannabinoids might be effective in people who respond poorly to currently used antiemetic drugs, or cannabinoids might be more effective in combination with a new drug than is either alone. For both reasons, studies of the effects of adjunctive cannabinoids on chemotherapy-induced emesis are worth pursuing for patients whose emesis is not optimally controlled with other agents.

While some people who spoke to the IOM study team described the mood-enhancing and anxiety-reducing effects of marijuana as a positive contribution to the antiemetic effects of marijuana, one-fourth of the

patients in the New York state study described earlier were unable to tolerate smoked marijuana. Overall, the effects of oral THC and smoked marijuana are similar, but there are differences. For example, in the residential studies of experienced marijuana users by Haney and co-workers, subjects reported that marijuana made them feel "mellow,"⁷¹ whereas comparable doses of oral THC did not.⁷⁰ Such differences might be due to the different routes of delivery of THC, as well as the different mixture of cannabinoids found in the marijuana plant. As of this writing, no studies had been published that weighed the relative contributions of those different factors.

The goal of antiemetic medications is to prevent nausea and vomiting. Hence, antiemetics are typically given before chemotherapy, in which case a pill is an effective form of drug delivery. However, in patients already experiencing severe nausea or vomiting, pills are generally ineffective because of the difficulty in swallowing or keeping a pill down and slow onset of the drug effect. Thus, an inhalation (but preferably not smoking) cannabinoid drug delivery system would be advantageous for treating chemotherapy-induced nausea.

Until the development of rapid-onset antiemetic drug delivery systems, there will likely remain a subpopulation of patients for whom standard antiemetic therapy is ineffective and who suffer from debilitating emesis. It is possible that the harmful effects of smoking marijuana for a limited period of time might be outweighed by the antiemetic benefits of marijuana, at least for patients for whom standard antiemetic therapy is ineffective and who suffer from debilitating emesis. Such patients should be evaluated on a case-by-case basis and treated under close medical supervision.

WASTING SYNDROME AND APPETITE STIMULATION

Wasting syndrome in acquired immune deficiency syndrome (AIDS) patients is defined by the Centers for Disease Control and Prevention as the involuntary loss of more than 10% of baseline average body weight in the presence of diarrhea or fever of more than 30 days that is not attributable to other disease processes.¹⁷ Anorexia (loss of appetite) can accelerate wasting by limiting the intake of nutrients. Wasting (cachexia) and anorexia are common end-stage features of some fatal diseases, such as AIDS, and of some types of metastatic cancers. In AIDS, weight loss of as little as 5% is associated with decreased survival, and a body weight about one-third below ideal body weight results in death.^{99,158}

There are two forms of malnutrition: starvation and cachexia. Starvation, the deprivation of essential nutrients, results from famine or poverty, malabsorption, eating disorders such as anorexia nervosa, and so on. Star-

vation leads to metabolic adaptations that deplete body fat before losses of lean tissue. Cachexia results from tissue injury, infection, or tumor and is characterized by a disproportionate loss of lean body mass, such as skeletal muscle. The effects of starvation regardless of the cause can usually be reversed by providing food, whereas the effects of cachexia can be reversed only through control of the underlying disease and—at least for some patients—drugs that stimulate metabolism, such as growth hormone or androgenic-anabolic hormones.

Malnutrition in HIV-Infected Patients

By 1997 more than 30 million people worldwide were infected with human immunodeficiency virus (HIV), and the number is predicted to increase to almost 40 million by the year 2000.^{126,186} Malnutrition is common among AIDS patients and plays an independent and important role in their prognosis.^{95,100,158} Because treatment for malnutrition depends on whether it is caused by starvation or cachexia, one needs to know the effects of HIV infection on metabolic processes. The answer depends on the clinical situation and can be either or both.⁹⁴

The development of malnutrition in HIV infection has many facets. Malnutrition in HIV-infected patients results in a disproportionate depletion of body cell mass,* total body nitrogen, and skeletal muscle mass; all are consistent with cachexia.^{97,194} Body composition studies show that the depletion of body cell mass precedes the progression to AIDS (falling CD4 lymphocyte counts); this suggests that malnutrition is a consequence of the inflammatory response to the underlying viral infection, rather than a general complication of AIDS.¹⁴⁴ In contrast, weight loss is often episodic and related to acute complications, such as febrile opportunistic infections.¹¹³ Mechanisms underlying wasting in HIV-infected patients depend on the stage of HIV infection and on specific associated complications.

The many reasons for decreased food intake among AIDS patients include mouth, throat, or esophageal infections or ulcers (oropharyngeal and esophageal pathology); adverse effects of medications;¹⁹⁶ diarrhea; enteric infection; malabsorption; serious systemic infection; focal or diffuse neurological disease; HIV enteropathy; depression; fatigue; and poverty. Nutrient malabsorption is often the result of microorganism overgrowth or infection in the intestine, especially in the later stages of AIDS.^{95,157}

*Body cell mass is the fat-free cellular mass. It is composed of the cells of the muscle and organs, plus circulating hematopoietic cells and the aqueous compartment of adipocytes. It is not fat, extracellular water, or extracellular solids (such as tendons).

Marijuana and THC for Malnutrition in HIV-Infected Patients

Despite their frequency of use, little has been published about the effectiveness of marijuana or cannabinoids for the treatment of malnutrition and wasting syndrome in HIV-infected patients. The only cannabinoid evaluated in controlled clinical studies is THC, or dronabinol. Short-term (six-week) and long-term (one-year) therapy with dronabinol was associated with an increase in appetite and stable weight, and in a previous short-term (five-week) clinical trial in five patients, dronabinol was shown to increase body fat by 1%.^{8,9,179} In 1992, the FDA approved THC, under the trade name Marinol (dronabinol), as an appetite stimulant for the treatment of AIDS-related weight loss. Megestrol acetate (Megace) is a synthetic derivative of progesterone that can stimulate appetite and cause substantial weight gain when given in high doses (320–640 mg/day) to AIDS patients. Megestrol acetate is more effective than dronabinol in stimulating weight gain, and dronabinol has no additive effect when used in combination with megestrol acetate.¹⁸³ HIV/AIDS patients are the largest group of patients who use dronabinol. However, some reject it because of the intensity of neuropsychological effects, an inability to titrate the oral dose easily, and the delayed onset and prolonged duration of its action.³ There is evidence that cannabinoids modulate the immune system (see chapter 2, “Cannabinoids and the Immune System”), and this could be a problem in immunologically compromised patients. No published studies have formally evaluated use of any of the other cannabinoids for appetite stimulation in wasting.

Anecdotes abound that smoked marijuana is useful for the treatment of HIV-associated anorexia and weight loss.^{23,62} Some people report a preference for smoked marijuana over oral THC because it gives them the ability to titrate the effects, which depend on how much they inhale. In controlled laboratory studies of healthy adults, smoked marijuana was shown to increase body weight, appetite, and food intake.^{47,119} Unfortunately, there have been no controlled studies of the effect of smoked marijuana on appetite, weight gain, and body composition in AIDS patients. At the time of this writing, Donald Abrams, of the University of California, San Francisco, was conducting the first clinical trial to test the safety of smoked marijuana in AIDS patients, and the results were not yet available.

A major concern with marijuana smoking in HIV-infected patients is that they might be more vulnerable than other marijuana users to immunosuppressive effects of marijuana or to the exposure of infectious organisms associated marijuana plant material (see chapter 3, “Marijuana Smoke”).

Therapy for Wasting Syndrome in HIV-Infected Patients

Present Therapy

Generally, therapy for wasting in HIV-infected people focuses on appetite stimulation. Few therapies have proved successful in treatment of the AIDS wasting syndrome. The stimulant studied most is megestrol acetate, which has been shown to increase food intake by about 30% over baseline for reasons that remain unknown. Its effect in producing substantial weight gain is dose dependent, but most of the weight gained is in fat tissue, not lean body mass. Although the findings are still preliminary, anabolic compounds, such as testosterone or growth hormone, might be useful in preventing the loss of or in restoring lean body mass in AIDS patients.^{10,44,64,170} Enteral and parenteral nutrition have also been evaluated and shown to increase weight, but again the increase is due more to body fat than to lean body mass.^{96,98}

Encouraging advances in the antiviral treatment of HIV infection and developments in the prophylaxis of and therapy for opportunistic infections have recently changed the outlook for the long-term health of HIV-infected people. Death rates have been halved, and the frequency of serious complications, including malnutrition, has fallen markedly.^{94,133}

Future Therapy

The primary focus of future therapies for wasting in HIV-infected patients is to increase lean body mass as well as appetite. Active systemic infections are associated with profound anorexia, which is believed to be mediated by cytokines that stimulate inflammation through their actions in and outside the brain.¹³² Cytokine inhibitors, such as thalidomide, have been under investigation as potential treatments to increase lean body mass and reduce malnutrition. Even though cannabinoids do not appear to restore lean body mass, they might be useful as adjunctive therapy. For example, cannabinoids could be used as appetite stimulants, in patients with diminished appetite who are undergoing resistance exercises or anabolic therapy to increase lean body mass. They could also be beneficial for a variety of effects, such as increased appetite, while reducing the nausea and vomiting caused by protease inhibitors and the pain and anxiety associated with AIDS.

Considering current knowledge about malnutrition in HIV infection, cannabinoids, by themselves, will probably not constitute primary therapy for this condition but might be useful in combination with other therapies, such as anabolic agents. Specifically, the proposed mechanism of action of increasing food intake would most likely be ineffective in pro-

moting an increase in skeletal muscle mass and functional capacity—the goal in the treatment of cachexia in AIDS patients.

Malnutrition in Cancer Patients

Malnutrition compromises the quality of life of many cancer patients and contributes to the progression of their disease. About 30% of Americans will develop cancer in their lifetimes, and two-thirds of those who get cancer will die as a result of it.⁵ Depending on the type of cancer, 50–80% of patients will develop cachexia and up to 50% of them will die, in part, as a result of cachexia.^{11,40} The cachexia appears to result from the tumor itself, and cytokines (proteins secreted by the host during an immune response to tumor) are probably important factors in this development. Cachexia does not occur in all cancer patients, but generally occurs in the late stages of advanced cancer of the pancreas, lung, and prostate.

The only cannabinoid evaluated for treating cachexia in cancer patients is dronabinol, which has been shown to improve appetite and promote weight gain.⁵⁴ Present treatments for cancer cachexia are similar to that for cachexia in AIDS patients. These treatments are usually indicated in late stages of advanced disease and include megestrol acetate and enteral and parenteral nutrition. Megestrol acetate stimulates appetite and promotes weight gain in cancer patients, although the gain is mostly in fat mass (reviewed by Bruera 1998¹⁴). Both megestrol acetate and dronabinol have dose-related side effects that can be troublesome for patients: megestrol acetate can cause hyperglycemia and hypertension, and dronabinol can cause dizziness and lethargy. Cannabinoids have also been shown to modulate the immune system (see chapter 2, “Cannabinoids and the Immune System”), and this could be contraindicated in some cancer patients (both the chemotherapy and the cancer can be immunosuppressive).

Future treatments will probably depend on the development of methods that block cytokine actions and the use of selective β_2 -adrenergic receptor agonists to increase muscle mass.^{14,73} Treatments for cancer cachexia will also most likely need to identify individual patients' needs. Some patients might need only a cytokine inhibitor, whereas others could benefit from combined approaches, such as an appetite stimulant and β_2 -adrenergic receptor agonists. In this respect, such cannabinoids as THC might prove useful as part of a combination therapy as an appetite stimulant, antiemetic, analgesic, and anxiolytic, especially for patients in late stages of the disease.

Anorexia Nervosa

Anorexia nervosa, a psychiatric disorder characterized by distorted body image and self-starvation, affects an estimated 0.6% of the U.S. population, with a greater prevalence in females than males.⁵ Its mortality is high, and response to standard treatments is poor.

THC appears to be ineffective in treating this disease. In one study it caused severe dysphoric reactions in three of 11 patients.⁶⁵ One possible explanation of the dysphoria is that THC increases appetite and thus intensifies the mental conflict between hunger and food refusal.¹³ Furthermore, such patients might have underlying psychiatric disorders, such as schizophrenia and depression, in which cannabinoids might be hazardous (see chapter 3, "Psychological Harms").

Current treatments include psychological techniques to overcome emotional or behavioral problems and dietary intervention to reverse the malnutrition.¹⁹⁵ Pharmacological treatments, such as antidepressants, have been used in addition to psychotherapy but tend to lack the desired level of efficacy.³³ Recently, alterations in a gene for one of the serotonin receptors have been identified in some patients with anorexia nervosa.⁴⁵ The possibility of a genetic component suggests a pathway for the development of new drugs to treat this disease.

Conclusions: Wasting Syndrome and Appetite Stimulation

The profile of cannabinoid drug effects suggests that they are promising for treating wasting syndrome in AIDS patients. Nausea, appetite loss, pain, and anxiety are all afflictions of wasting, and all can be mitigated by marijuana. Although some medications are more effective than marijuana for these problems, they are not equally effective in all patients. A rapid-onset (that is, acting within minutes) delivery system should be developed and tested in such patients. Smoking marijuana is not recommended. The long-term harm caused by smoking marijuana makes it a poor drug delivery system, particularly for patients with chronic illnesses.

Terminal cancer patients pose different issues. For those patients the medical harm associated with smoking is of little consequence. For terminal patients suffering debilitating pain or nausea and for whom all indicated medications have failed to provide relief, the medical benefits of smoked marijuana might outweigh the harm.

NEUROLOGICAL DISORDERS

Neurological disorders affect the brain, spinal cord, or peripheral nerves and muscles in the body. Marijuana has been proposed most often

as a source of relief for three general types of neurological disorders: muscle spasticity, particularly in multiple sclerosis patients and spinal cord injury victims; movement disorders, such as Parkinson's disease, Huntington's disease, and Tourette's syndrome; and epilepsy. Marijuana is not proposed as a cure for such disorders, but it might relieve some associated symptoms.

Muscle Spasticity

Spasticity is the increased resistance to passive stretch of muscles and increased deep tendon reflexes. Muscles may also contract involuntarily (flexor and extensor spasms). In some cases these contractions are debilitating and painful and require therapy to relieve the spasms and associated pain.

There are numerous anecdotal reports that marijuana can relieve the spasticity associated with multiple sclerosis or spinal cord injury, and animal studies have shown that cannabinoids affect motor areas in the brain—areas that might influence spasticity.^{51,78,130,168}

Multiple Sclerosis

Multiple sclerosis (MS) is a condition in which multiple areas of the central nervous system (CNS) are affected. Many nerve fibers become demyelinated, some are destroyed, and scars (sclerosis) form, resulting in plaques scattered throughout the white matter of the CNS. (Myelin is the lipid covering that surrounds nerve cell fibers and facilitates the conduction of signals along nerve cells and ultimately between the brain, the spinal cord, and the rest of the body.) MS exacerbations appear to be caused by abnormal immune activity that causes inflammation and myelin destruction in the brain (primarily in the periventricular area), brain stem, or spinal cord. Demyelination slows or blocks transmission of nerve impulses and results in an array of symptoms such as fatigue, depression, spasticity, ataxia (inability to control voluntary muscular movements), vertigo, blindness, and incontinence. About 90% of MS patients eventually develop spasticity. There are an estimated 2.5 million MS patients worldwide, and spasticity is a major concern of many patients and physicians.¹³⁴ Spasticity is variably experienced as muscle stiffness, muscle spasms, flexor spasms or cramps, muscle pain or ache. The tendency for the legs to spasm at night (flexor spasms) can interfere with sleep.

Marijuana is often reported to reduce the muscle spasticity associated with MS.^{62,123} In a mail survey of 112 MS patients who regularly use marijuana, patients reported that spasticity was improved and the associated pain and clonus decreased.²⁸⁷ However, a double-blind placebo-controlled

study of postural responses in 10 MS patients and 10 healthy volunteers indicated that marijuana smoking impaired posture and balance in both MS patients and the volunteers.⁶¹ Nevertheless, the 10 MS patients felt that they were clinically improved. The subjective improvement, while intriguing, does not constitute unequivocal evidence that marijuana relieves spasticity. Survey data do not measure the degree of placebo effect, estimated to be as great as 30 percent in pain treatments.^{122,131} Furthermore, surveys do not separate the effects of marijuana or cannabinoids on mood and anxiety from the effects on spasticity.

The effects of THC on spasticity were evaluated in a series of three clinical trials testing a total of 30 patients.^{24,148,187} They were "open trials," meaning that the patients were informed before treatment that they would be receiving THC. Based on patient report or clinical exam by the investigator, spasticity was less severe after the THC treatment. However, THC was not effective in all patients and frequently caused unpleasant side effects. Spasticity was also reported to be less severe in a single case study after nabilone treatment (Figure 4.2).¹¹⁷

In general, the abundant anecdotal reports are not well supported by the clinical data summarized in Table 4.1. But this is due more to the limitation of the studies than to negative results. There are no supporting animal data to encourage clinical research in this area, but there also are no good animal models of the spasticity of MS. Without an appropriate model, studies to determine the physiological basis for how marijuana or THC might relieve spasticity cannot be conducted. Nonetheless, the survey results suggest that it would be useful to investigate the potential therapeutic value of cannabinoids in relieving symptoms associated with MS. Such research would require the use of objective measures of spasticity, such as the pendulum test.* Since THC is mildly sedating, it is also important to distinguish this effect from antispasticity effects in any such investigations. Mild sedatives, such as Benadryl or benzodiazepines, would be useful controls for studies on the ability of cannabinoids to relieve muscle spasticity. The regular use of smoked marijuana, however, would be contraindicated in a chronic condition like MS.

Spinal Cord Injury

In 1990, there were about 15 million patients worldwide with spinal cord injury, and an estimated 10,000 new cases are reported each year in

*The *pendulum test* is an objective and accurate measure of MS-induced spasticity. It is done by videotaping a patient who lies supine on a table with his or her leg extending off the edge. The leg is dropped and the resulting motion is mathematically analyzed by computer to provide a quantitative measure of spasticity.

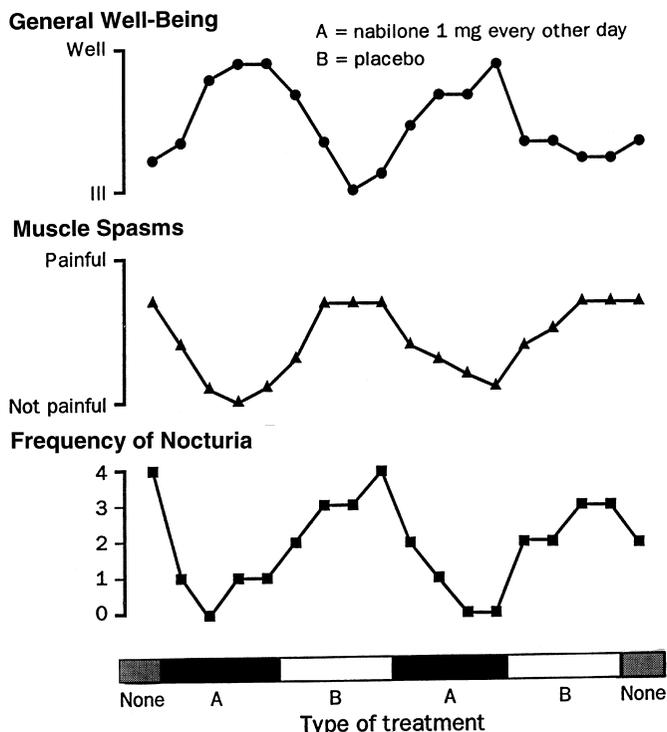

FIGURE 4.2 Effect of nabilone on multiple sclerosis symptoms. This figure shows the results of a trial in which a 45-year-old man with MS was given four-week treatments alternately with placebo and nabilone. The patient served as both experimental subject and control; his treatment sequence was nabilone-placebo-nabilone-placebo. That pattern of alternating treatments reduces the possibility that the observed changes are unrelated to the drug and are not simply due to other factors that changed with time. The results of the trial are consistent with the possibility that THC might relieve spasticity, but although more rigorous than many self-report studies of psychoactive substances, it has problems. First, the patient could not distinguish the treatments at the time of taking them, but after the nabilone treatment he felt sedated. Thus, it is not possible to know how much the expectation of relief contributed to his perception of relief. Second, the study measured his perception of pain, in which spasticity is an important factor but not the only factor. It is not possible to know the extent to which the perception of pain was affected by nabilone and how much by the stimulus that generated the pain—in this case, involuntary muscle contractions. Because it is unaffected by conscious control, the frequency of nocturia is clearer evidence of the effect of THC, although it might also represent how well the patient slept. This trial with a single person is intriguing but not definitive proof that THC can reliably relieve spasticity. SOURCE: Martyn et al. (1995).¹¹⁷ Reprinted with permission.

TABLE 4.1 Studies on the Effects of Marijuana and Cannabinoids in Multiple Sclerosis

Drug and Dose	Study Design	Results	Reference
Marijuana	Mail survey 112/233 MS patients	Survey was mailed to 233 MS patients, of whom 112 (48%) responded; 97% of respondents reported improved spasticity and reduced pain.	Consroe and co-workers (1997) ²⁸
Marijuana	Clinical trial 1 MS patient	Reduction in spasticity and improved ataxia.	Meinck and co-workers (1989) ¹²³
Marijuana	Double-blind, placebo-controlled 10 MS patients; 10 normal individuals	MS patients felt they were improved, but posture and balance were impaired.	Greenberg and co-workers (1994) ⁶¹
Oral THC 5–15 mg every 6 hrs, up to 18 hrs	Open trial 8 MS patients	5 patients experienced subjective but not objective improvement in motor coordination; objective improvement in tremor demonstrated in 2 of the 8 patients.	Clifford (1983) ²⁴
Oral THC 5 and 10 mg, single doses	Double-blind, placebo controlled 9 MS patients	Spasticity was improved based on examiner ratings.	Petro and Ellenberger (1981) ¹⁴⁸
Oral THC 2.5–15 mg, once or twice daily for 5 days	Double-blind, placebo controlled, crossover 13 MS patients	Patients reported subjective decreases in spasticity at doses of 7.5 mg or greater, but no changes in objective measures of spasticity or weakness were observed.	Ungerleider and co-workers (1987) ¹⁸⁷
Nabilone (THC analogue)	Placebo-controlled 1 MS patient	The patient reported increased well-being, less frequent nocturia, and reduced severity of muscle spasticity during nabilone treatment (Figure 4.2).	Martyn and co-workers (1995) ¹¹⁷

the United States alone.^{134,138} About 60% of spinal cord injuries occur in people younger than 35 years old. Most will need long-term care and some lifelong care.¹¹⁶

Many spinal cord injury patients report that marijuana reduces their muscle spasms.¹¹⁴ Twenty-two of 43 respondents to a 1982 survey of

people with spinal cord injuries reported that marijuana reduced their spasticity.¹¹⁴ One double-blind study of a paraplegic patient with painful spasms in both legs suggested that oral THC was superior to codeine in reducing muscle spasms.^{72,120} Victims of spinal cord injury reporting at IOM workshops noted that smoking marijuana reduces their muscle spasms, their nausea, and the frequency of their sleepless nights. The caveats described for surveys of spasticity relief in MS patients also apply here.

Therapy for Muscle Spasticity

Present Therapy. Present therapy for spasticity includes the various medications listed in Table 4.2. Baclofen and tizanidine, the most commonly prescribed antispasticity drugs, relieve spasticity and spasms with various degrees of success. The benefit of these agents is generally only partial. Their use is complicated by the side effects of drowsiness, dry mouth, and increased weakness.

Future Therapy. The discovery of agents that work through mechanisms different from those of existing antispasticity drugs will be an important advance in the treatment of spasticity. The aim of new treatments will be to relieve muscle spasticity and pain without substantially increasing muscle weakness in conditions that result in spasticity. The treatment for MS itself will likely be directed at immunomodulation. Various immunomodulating agents, such as beta-interferon and glatiramer acetate, have been shown to reduce the frequency of symptomatic attacks, the progression of disability, and the rate of appearance of demyelinated lesions as detected by magnetic resonance imaging.⁵

Conclusion: Muscle Spasticity

Basic animal studies described in chapter 2 have shown that cannabinoid receptors are particularly abundant in areas of the brain that control

TABLE 4.2 Classes of Antispasticity Drugs

Drug Class	Drug
GABA _B -receptor agonists	Baclofen
α-Receptor agonists	Tizanidine
Noncompetitive GABA _A -receptor agonists	Benzodiazepines, including diazepam
Calcium blockers in skeletal muscle	Dantrolene

movement and that cannabinoids affect movement and posture in animals as well as humans. The observations are consistent with the possibility that cannabinoids have antispastic effects, but they do not offer any direct evidence that cannabinoids affect spasticity, even in animals. The available clinical data are too meager to either accept or dismiss the suggestion that marijuana or cannabinoids relieve muscle spasticity. But the few positive reports of the ability of THC and related compounds to reduce spasticity, together with the prevalence of anecdotal reports of the relief provided by marijuana, suggest that carefully designed clinical trials testing the effects of cannabinoids on muscle spasticity should be considered (see chapter 1).^{25,62} Such trials should be designed to assess the degree to which the anxiolytic effects of cannabinoids contribute to any observed antispastic effects.

Spasticity occurring at night can be very disruptive to sleep. Thus, a long-lasting medication would be especially useful for MS patients at bedtime—when drowsiness would be a beneficial rather than an unwanted side effect and mood-altering effects would be less of a problem. One caution is related to the effects of THC on the stages of sleep, which should be evaluated in MS patients who have sleep disturbances. If THC is proven to relieve spasticity, a pill might be the preferred route of delivery for nighttime use because of its long duration of action. Compared to the currently available therapies, the long half-life of THC might allow for a smoother drug effect throughout the day. The intensity of the symptoms resulting from spasticity, particularly in MS, can rapidly increase in an unpredictable fashion such that the patient develops an “attack” of intense muscle spasms lasting minutes to hours. An inhaled form of THC (if it were shown to be efficacious) might be appropriate for those patients.

Movement Disorders

Movement disorders are a group of neurological conditions caused by abnormalities in the basal ganglia and their subcortical connections through the thalamus with cortical motor areas. The brain dysfunctions ultimately result in abnormal skeletal muscle movements in the face, limbs, and trunk. The movement disorders most often considered for marijuana or cannabinoid therapy are dystonia, Huntington’s disease, Parkinson’s disease, and Tourette’s syndrome. Movement disorders are often transiently exacerbated by stress and activity and improved by factors that reduce stress. This is of particular interest because for many people marijuana reduces anxiety.

Dystonia

Dystonia can be a sign of other basal ganglion disorders, such as Huntington's disease and tardive dyskinesia (irreversible development of involuntary dyskinesic movements) and can be a primary basal ganglion disorder. Primary dystonias are a heterogeneous group of chronic slowly progressive neurological disorders characterized by dystonic movements—slow sustained involuntary muscle contractions that often result in abnormal postures of limbs, trunk, and neck. Dystonias can be confined to one part of the body, such as spasmodic torticollis (neck) or Meige's syndrome (facial muscles), or can affect many parts of the body, such as dystonia musculorum deformans.⁵ Dystonia can cause mild to severe disability and sometimes pain secondary to muscle aching or arthritis. Some dystonias are genetic; others are caused by drugs. The specific neuropathological changes in these diseases have not been determined.

No controlled study of marijuana in dystonic patients has been published, and the only study of cannabinoids was a preliminary open trial of cannabidiol (CBD) that suggested modest dose-related improvements in the five dystonic patients studied.³⁰ In mutant dystonic hamsters, however, the cannabinoid receptor agonist, WIN 55,212-2, can produce antidystonic effects.¹⁵³

Huntington's Disease

Huntington's disease is an inherited degenerative disease that usually appears in middle age and results in atrophy or loss of neurons in the caudate nucleus, putamen, and cerebral cortex. It is characterized by arrhythmic, rapid muscular contractions (chorea), emotional disturbance, and dementia (impairment in intellectual and social ability). Animal studies suggest that cannabinoids have antichoreic activity, presumably because of stimulation of CB₁ receptors in the basal ganglia.^{129,168}

On the basis of positive results in one of four Huntington's disease patients, CBD and a placebo were tested in a double-blind crossover study of 15 Huntington's disease patients who were not taking any antipsychotic drugs. Their symptoms neither improved nor worsened with CBD treatment.^{27,164}

The effects of other cannabinoids on patients with Huntington's disease are largely unknown. THC and other CB₁ agonists are more likely candidates than CBD, which does not bind to the CB₁ receptor. Those receptors are densely distributed on the very neurons that perish in Huntington's disease.¹⁵² Thus far there is little evidence to encourage clinical studies of cannabinoids in Huntington's disease.

Parkinson's Disease

Parkinson's disease, a degenerative disease, affects about 1 million Americans over the age of 50.⁵³ It is characterized by bradykinesia (slowness in movement), akinesia (abrupt stoppage of movement), resting tremor, muscular rigidity, and postural instability.

Theoretically, cannabinoids could be useful for treating Parkinson's disease patients because cannabinoid agonists specifically inhibit the pathways between the subthalamic nucleus and substantia nigra and probably also the pathways between the subthalamic nucleus and globus pallidus (these structures shown in Figure 2.6).^{165,169} The latter effect was not directly tested but is consistent with what is known about these neural pathways. Hyperactivity of the subthalamic neurons, observed in both Parkinson's patients and animal models of Parkinson's disease, is hypothesized to be a major factor in the debilitating bradykinesia associated with the disease.³⁶ Furthermore, although cannabinoids oppose the actions of dopamine in intact rats, they augment dopamine activation of movement in an animal model of Parkinson's disease. This suggests the potential for adjunctive therapy with cannabinoid agonists.^{165-167,169}

At the time of this writing, we could find only one published clinical trial of marijuana involving five cases of idiopathic Parkinson's disease.⁴⁸ That trial was prompted by a patient's report that smoking marijuana reduced tremor, but the investigators found no improvement in tremor after the five patients smoked marijuana—whereas all subjects benefited from the administration of standard medications for Parkinson's disease (levodopa and apomorphine).⁴⁸ Although new animal data might someday indicate a use for cannabinoids in treating Parkinson's disease, current data do not recommend clinical trials of cannabinoids in patients with Parkinson's disease.

Tourette's Syndrome

Tourette's syndrome usually begins in childhood and is characterized by motor and vocal tics (involuntary rapid repetitive movements or vocalizations). It has been suggested that the symptoms might be mediated by a reduction in the activity of limbic-basal ganglia-thalamocortical circuits (shown in Figure 2.4).⁴² These circuits, while not well understood, appear to be responsible for translating a person's intentions to move into actual movements. Damage to these structures leads to either involuntary increases in movement (as in Huntington's disease) or the inability to make voluntary movements (as in Parkinson's disease). The nature of the deficit in Tourette's syndrome is unknown.

No clear link has been established between symptoms of Tourette's

syndrome and cannabinoid sites or mechanism of action. Pimozide and haloperidol, two widely used treatments for Tourette’s syndrome, inhibit effects mediated by the neurotransmitter dopamine, whereas cannabinoids can increase dopamine release.^{154,181} The physiological relevance, if any, of these two observations has not been established.

Clinical reports consist of four case histories indicating that marijuana use can reduce tics in Tourette’s patients.^{75,163} In three of the four cases the investigators suggest that beneficial effects of marijuana might have been due to anxiety-reducing properties of marijuana rather than to a specific antitic effect.¹⁶³

Therapy for Movement Disorders

Various drugs are available (Table 4.3) to treat the different movement disorders. Common side effects of many of these drugs are sedation, lethargy, school and work avoidance, social phobia, and increased risk of parkinsonism and tardive dyskinesia. With some of the medications, like those used for dystonia, efficacy is lacking in up to 50% of the patients. In addition to medications, surgical interventions, such as pallidotomy and neurosurgical transplantation of embryonic substantia nigra tissue into the patient’s striatum, have been tried in Parkinson’s disease patients. Surgery is generally palliative and is still considered to be in the developmental phase.

TABLE 4.3 Drugs Used to Treat Movement Disorders

Dystonia	Parkinson’s disease
Benzodiazepines	Levodopa
Tetrabenazine	Carbidopa+levodopa combination
Intramuscular botulinum toxin	Amantadine
Anticholinergics	Bromocriptine
Baclofen	Pergolide
	Pramipexole
Huntington’s disease	Ropinirole
Reserpine	Selegiline
Tetrabenazine	Trihexyphenidyl
Haloperidol	Benztropine
Tourette’s syndrome tics	
Pimozide	
Clonidine	
Haloperidol	

Conclusion: Movement Disorders

The abundance of CB₁ receptors in basal ganglia and reports of animal studies showing the involvement of cannabinoids in the control of movement suggest that cannabinoids would be useful in treating movement disorders in humans. Marijuana or CB₁ receptor agonists might provide symptomatic relief of chorea, dystonia, some aspects of parkinsonism, and tics. However, clinical evidence is largely anecdotal; there have been no well-controlled studies of adequate numbers of patients. Furthermore, nonspecific effects might confound interpretation of results of studies. For example, the anxiolytic effects of cannabinoids might make patients feel that their condition is improved, despite the absence of measurable change in their condition.

Compared to the abundance of anecdotal reports concerning the beneficial effects of marijuana on muscle spasticity, there are relatively few claims that marijuana is useful for treating movement disorders. This might reflect a lack of effect or a lack of individuals with movement disorders who have tried marijuana. In any case, while there are a few isolated reports of individuals with movement disorders who report a benefit from marijuana, there are no published surveys indicating that a substantial percentage of patients with movement disorders find relief from marijuana. Existing studies involve too few patients from which to draw conclusions. The most promising reports involve symptomatic treatment of spasticity. If the reported neuroprotective effects of cannabinoids discussed in chapter 2 prove to be therapeutically useful, this could benefit patients with movement disorders, but without further data such a benefit is highly speculative. Since stress often transiently exacerbates movement disorders, it is reasonable to hypothesize that the anxiolytic effects of marijuana or cannabinoids might be beneficial to some patients with movement disorders. However, chronic marijuana smoking is a health risk that could increase the burden of chronic conditions, such as movement disorders.

Cannabinoids inhibit both major excitatory and inhibitory inputs to the basal ganglia. This suggests that a cannabinoid agonist could produce opposite effects on movement, depending on the type of transmission (excitatory or inhibitory) that is most active at the time of drug administration. This property could be used to design treatments in basal ganglia movement disorders, such as Parkinson's disease where either the excitatory subthalamic input becomes hyperactive or the inhibitory striatal input becomes hypoactive. The dose employed would be a major factor in the therapeutic uses of cannabinoids in movement disorders; low doses should be desirable, while higher doses could be expected to aggravate pathological conditions. Thus, there is a clear reason to recommend pre-

clinical studies; that is, animal studies to test the hypothesis that cannabinoids play an important role in movement disorders.

With the possible exception of multiple sclerosis, the evidence to recommend clinical trials of cannabinoids in movement disorders is relatively weak. Ideally, clinical studies would follow animal research that provided stronger evidence than is currently available on the potential therapeutic value of cannabinoids in the treatment of movement disorders. Unfortunately, there are no good animal models for these disorders. Thus, double-blind, placebo-controlled clinical trials of isolated cannabinoids that include controls for relevant side effects should be conducted. Such effects include anxiolytic and sedative effects, which might either mask or contribute to the potential therapeutic effects of cannabinoids.

Epilepsy

Epilepsy is a chronic seizure disorder that affects about 2 million Americans and 30 million people worldwide.¹⁵⁶ It is characterized by recurrent sudden attacks of altered consciousness, convulsions, or other motor activity. A seizure is the synchronized excitation of large groups of brain cells. These abnormal electrical events have a wide array of possible causes, including injury to the brain and chemical changes derived from metabolic faults of exposure to toxins.¹⁵⁶

Seizures are classified as partial (focal) or generalized. Partial seizures are associated with specific sensory, motor, or psychic aberrations that reflect the function of the part of the cerebral cortex from which the seizures arise. Generalized seizures are usually the result of pathological conditions of brain sites that project to widespread regions of the brain. Such pathology can produce petit mal seizures or major grand mal convulsions.

Cannabinoids in Epilepsy

There are anecdotal and individual case reports that marijuana controls seizures in epileptics (reviewed in a 1997 British Medical Association report¹³), but there is no solid evidence. While there are no studies indicating that either marijuana or THC worsen seizures, there is no scientific basis to justify such studies.

In the only known case-controlled study that was designed to evaluate illicit drug use and the risk of first seizure, Ng and co-workers¹³⁷ concluded that marijuana is a protective factor for first-time seizures in men but not women. Men who used marijuana reportedly had fewer first-time seizures than men who did not use marijuana. That report was based on a comparison of 308 patients who had been admitted to a hospital after

their first seizure with a control group of 294 patients. The control group was made up of patients who had not had seizures and were admitted for emergency surgery, such as surgery for appendicitis, intestinal obstruction, or acute cholecystitis. Compared to men who did not use marijuana, the odds ratio of first seizure for men who had used marijuana within 90 days of hospital admission was 0.36 (95% confidence interval = 0.18–0.74). An odds ratio of less than one is consistent with the suggestion that marijuana users are less likely to have seizures. The results for women were not statistically significant. However, this was a weak study. It did not include measures of health status prior to hospital admissions for the patients' serious conditions, and differences in their health status might have influenced their drug use rather than—as suggested by the authors—that differences in their drug use influenced their health.

The potential antiepileptic activity of CBD has been investigated but is not promising. Three controlled trials were conducted in which CBD was given orally to patients who had had generalized grand mal seizures or focal seizures (Table 4.4). Two of these studies were never published, but information about one was published in a letter to the *South African Medical Journal*, and the other was presented at the 1990 Marijuana International Conference on Cannabis and Cannabinoids.¹⁸⁴

TABLE 4.4 Clinical Trials of Cannabidiol (CBD) in Epileptics

Study Design	Results	Reference
Double-blind placebo-controlled trial 8 epileptic patients were given CBD at 200–300 mg/day in conjunction with standard antiepileptic therapies.	4 of 8 remained almost free of convulsions. Three of the 4 were partially improved for up to 4.5 months.	Cunha and co-workers ³⁴
Double-blind placebo-controlled study 12 epileptic patients were given CBD at 200–300 mg/day along with standard antiepileptic drugs.	CBD had no effect on seizure frequency.	Ames ⁴
Double-blind placebo-controlled, add-on crossover trial 10 epileptic patients were given CBD at 300 mg/day for 6 months.	CBD had no effect on seizures.	Trembly and Sherman, 1990 ¹⁸⁴ (reviewed in Consroe and Sandyk, 1992 ²⁹)
Open trial One patient was given CBD at 900–1,200 mg/day for 10 months.	Seizure frequency was reduced in the patient.	Trembly and Sherman, 1990 ¹⁸⁴ (reviewed in Consroe and Sandyk, 1992 ²⁹)

Even if CBD had antiepileptic properties, these studies were likely too small to demonstrate efficacy. Proving efficacy of anticonvulsants generally requires large numbers of patients followed for months because the frequency of seizures is highly variable and the response to therapy varies depending on seizure type.^{4,49}

Therapy for Epilepsy

Present Therapy. Standard pharmacotherapy for partial and generalized seizures, listed in Table 4.5, involves a variety of anticonvulsant drugs. These drugs suppress seizures completely in approximately 60% of patients who have chronic epilepsy and improve seizures in another 15% of patients. All of the anticonvulsants listed in Table 4.5 have side effects, some of the more common of which are drowsiness, mental slowing, ataxia, tremor, hair loss, increased appetite, headache, insomnia, and rash. Nevertheless, recurrent seizures are physically dangerous and emotionally devastating, and preventing them outweighs many undesirable side effects of anticonvulsant drugs.

Future Therapy. The goal of epilepsy treatment is to halt the seizures with minimal or no side effects and then to eradicate the cause. Most of the anticonvulsant research on cannabinoids was conducted before 1986. Since then, many new anticonvulsants have been introduced and cannabinoid receptors have been discovered. At present, the only biological evidence of antiepileptic properties of cannabinoids is that CB₁ receptors are abundant in the hippocampus and amygdala. Both regions are involved in partial seizures but are better known for their role in functions unrelated to seizures.²⁶ Basic research might reveal stronger links between cannabinoids and seizure activity, but this is not likely to be as fruitful a

TABLE 4.5 Anticonvulsant Drugs for Various Types of Seizures

Generalized grand mal seizures	Partial (focal) seizures

subject of cannabinoid research as others. Given the present state of knowledge, clinical studies of cannabinoids in epileptics are not indicated.

Alzheimer's Disease

Food refusal is a common problem in patients who suffer from Alzheimer's type dementia. The causes of anorexia in demented people are not known but may be a symptom of depression. Antidepressants improve eating in some but not all patients with severe dementia. Eleven Alzheimer's patients were treated for 12 weeks on an alternating schedule of dronabinol and placebo (six weeks of each treatment). The dronabinol treatment resulted in substantial weight gains and declines in disturbed behavior.¹⁹⁰ No serious side effects were observed. One patient had a seizure and was removed from the study, but the seizure was not necessarily caused by dronabinol. Recurrent seizures without any precipitating events occur in 20% of patients who have advanced dementia of Alzheimer's type.¹⁸⁹ Nevertheless, these results are encouraging enough to recommend further clinical research with cannabinoids.

The patients in the study discussed above were in long-term institutional care, and most were severely demented with impaired memory. Although short-term memory loss is a common side effect of THC in healthy patients, it was not a concern in this study. However, the effect of dronabinol on memory in Alzheimer's patients who are not as severely disturbed as those in the above study would be an important consideration.

GLAUCOMA

After cataracts, glaucoma is the second-leading cause of blindness in the world; almost 67 million people are expected to be affected worldwide by the year 2000¹⁴⁹ (for an excellent review, see Alward, 1998²). The most common form of glaucoma, primary open-angle glaucoma (POAG), is a slowly progressive disorder that results in loss of retinal ganglion cells and degeneration of the optic nerve, causing deterioration of the visual fields and ultimately blindness. The mechanisms behind the disease are not understood, but three major risk factors are known: age, race, and high intraocular pressure (IOP). POAG is most prevalent among the elderly, with 1% affected in those over 60 years old and more than 9% in those over 80. In African Americans over 80, there is more than a 10% chance of having the disease, and older African Caribbeans (who are less racially mixed than African Americans) have a 20–25% chance of having the disease.¹⁰⁶

The eye's rigid shape is normally maintained in part by IOP, which is

regulated by the circulation of a clear fluid, the aqueous humor,* between the front of the lens and the back of the cornea. Because of impaired outflow of aqueous humor from the anterior chamber of the eye, a high IOP is a risk factor for glaucoma, but the mechanism by which it damages the optic nerve and retinal ganglion cells remains unclear.¹⁷⁴ The two leading possibilities are that high IOP interferes with nutrient blood flow to the region of the optic nerve or that it interferes with transport of nutrients, growth factors, and other compounds within the optic nerve axon (P. Kaufman, IOM workshop). If the interference continues, the retinal ganglion cells and optic nerve will permanently atrophy; the result is blindness.⁶⁸ Because high IOP is the only known major risk factor that can be controlled, most treatments have been designed to reduce it. However, reducing it does not always arrest or slow the progression of visual loss.^{20,109}

Marijuana and Cannabinoids in Glaucoma

Marijuana and THC have been shown to reduce IOP by an average of 24% in people with normal IOP who have visual-field changes. In a number of studies of healthy adults and glaucoma patients, IOP was reduced by an average of 25% after smoking a marijuana cigarette that contained approximately 2% THC—a reduction as good as that observed with most other medications available today.^{1,16,32,76,77,125,193} Similar responses have been observed when marijuana was eaten or THC was given in pill form (10–40 mg) to healthy adults or glaucoma patients.^{76,91} But the effect lasts only about three to four hours. Elevated IOP is a chronic condition and must be controlled continuously.

Intravenous administration of Δ^9 -THC, Δ^8 -THC, or 11-OH-THC to healthy adults substantially decreased IOP, whereas cannabiol, CBD, and β -OH-THC had little effect.^{31,146} The cause for the reduction in IOP remains unknown, but the effect appears to be independent of the frequently observed drop in arterial systolic blood pressure (Keith Green, Medical College of Georgia, personal communication).

Three synthetic cannabinoids were investigated; BW29Y, BW146Y, and nabilone. They were given orally to patients who had high IOP. BW146Y and nabilone were as effective as ingesting THC or smoking

*The cornea and lens must be optically clear, which means that there cannot be blood circulation in these tissues. The aqueous humor is a clear fluid that functions as alternative circulation across the rear of the cornea and to the lens, providing nutrients and removing waste from these tissues.

marijuana but again with a very short duration of action; BW29Y was ineffective.^{136,182}

Topical treatments with cannabinoids have been ineffective in reducing IOP. When Δ^9 -THC was applied topically as eye drops, whether once or four times a day, there was no decrease in IOP.^{60,90} Suspensions of lipophilic THC tended to be irritating to the eye.

In summary, cannabinoids and marijuana can reduce IOP when administered orally, intravenously, or by inhalation but not when administered topically. Even though a reduction in IOP by standard medications or surgery clearly slows the rate of glaucoma symptom progression, there is no direct evidence of benefits of cannabinoids or marijuana in the natural progression of glaucoma, visual acuity, or optic nerve atrophy.^{92,115}

In addition to lowering IOP, marijuana reduces blood pressure and has many psychological effects. Merritt and co-workers reported hypotension, palpitations, and psychotropic effects in glaucoma patients after inhalation of marijuana.¹²⁵ Cooler and Gregg³¹ also reported increased anxiety and tachycardia after intravenous infusion of THC (1.5–3 mg). All those side effects are problematic, particularly for elderly glaucoma patients who have cardiovascular or cerebrovascular disease. The reduction in blood pressure can be substantial and might adversely affect blood flow to the optic nerve.¹²⁴ Many people with systemic hypertension have their blood pressure reduced to manageable and acceptable levels through medication, but this does not seem to affect their IOP. In contrast, there is evidence that reduction in blood pressure to considerably below-normal levels influences IOP and ocular blood flow.^{46,74,142} Hence, in the case of an eye with high IOP or an optic nerve in poor condition and susceptibility to high IOP, reduced blood flow to the optic nerve could compromise a functional retina and be a factor in the progression of glaucoma.

Because it is not known how these compounds work, it is also not known how they might interact with other drugs used to treat glaucoma. If the mechanism involves a final common pathway, the effects of cannabinoids might not be additive and might even interfere with effective drugs.

Therapy for Glaucoma

Present Therapy

Six classes of drugs are used to treat glaucoma; all reduce IOP (Table 4.6).⁹³ In the late 1970s, when early reports of the effects of marijuana on IOP surfaced, only cholinomimetics, epinephrine, and oral carbonic anhydrase inhibitors were available. They are not popular today because of their side effects, such as pupil constriction or dilation, brow ache, tachycardia, and diuresis; all of them have been superseded by the other classes

TABLE 4.6 Classes of Drugs Used to Treat Glaucoma

Cholinergic agonists Pilocarpine	α_2-Adrenergic agonists Apraclonidine Brimonidine
β_2-Adrenergic agonists Epinephrine Dipivefrin	Carbonic anhydrase inhibitors Acetazolamide Dorzolamide (Trusopt)
β_2-Adrenergic antagonists Timolol Betaxolol (Betoptic)	Prostaglandin-F_{2a} analogues Latanoprost Unoprostone

of drugs.⁹³ Surgical options are also available today to lower IOP, including laser trabeculoplasty, trabeculectomy/sclerostomy, drainage implantation, and cyclodestruction of fluid-forming tissues.¹⁷³ Thus, there are now many effective options to slow the progression of glaucoma by reducing IOP.

One important factor in slowing the progression of glaucoma via medications that reduce IOP is patient compliance with dosing regimens. With respect to compliance, the ideal glaucoma drug is one that is applied at most twice a day (P. Kaufman, IOM workshop). If the dose must be repeated every three to four hours, patient compliance becomes a problem; for this reason, marijuana and the cannabinoids studied thus far would not be highly satisfactory treatments for glaucoma. Present therapies, especially combinations of approved topical drugs, can control IOP when administered once or twice a day, at a cost of about \$60 per month.

Future Therapy

In all likelihood the next generation of glaucoma therapies will deal with neural protection, neural rescue, neural regeneration, or blood flow, and the optic nerve and neural retina will be treated directly rather than just by lowering IOP (P. Kaufman, IOM workshop). There is some evidence that a synthetic cannabinoid, HU-211, might have neuroprotective effects *in vitro*; this presents a potential approach that has nothing to do with IOP.¹⁹⁷ HU-211 is commonly referred to as a cannabinoid because its chemical structure is similar to THC; however, it does not bind to cannabinoid receptor.

It is known that cannabinoids lower IOP fairly substantially but not how. No one has tested whether the effect is receptor mediated (B. Martin, IOM workshop). To do so, one could test whether a receptor antagonist

blocked the effects of THC or other cannabinoids. If the decrease were shown to be receptor mediated, it would be important to know whether it was through CB₁, which mediates central nervous system effects, or CB₂, which is not involved in CNS effects. If it were CB₂, it might be possible to reduce IOP without the CNS side effects. Finally, it is not known whether the endogenous cannabinoid system is a natural regulator of IOP.

Conclusion: Glaucoma

Although glaucoma is one of the most frequently cited medical indications for marijuana, the data do not support this indication. High intraocular pressure (IOP) is a known risk factor for glaucoma and can, indeed, be reduced by cannabinoids and marijuana. However, the effect is too and short lived and requires too high doses, and there are too many side effects to recommend lifelong use in the treatment of glaucoma. The potential harmful effects of chronic marijuana smoking outweigh its modest benefits in the treatment of glaucoma. Clinical studies on the effects of smoked marijuana are unlikely to result in improved treatment for glaucoma.

Future research might reveal a therapeutic effect of isolated cannabinoids. For example, it might be possible to design a cannabinoid drug with longer-lasting effects on IOP and with less psychoactivity than THC.

SUMMARY

Advances in cannabinoid science of the past 16 years have given rise to a wealth of new opportunities for the development of medically useful cannabinoid-based drugs. The accumulated data suggest a variety of indications, particularly for pain relief, antiemesis, and appetite stimulation. For patients such as those with AIDS or who are undergoing chemotherapy, and who suffer simultaneously from severe pain, nausea, and appetite loss, cannabinoid drugs might offer broad-spectrum relief not found in any other single medication. The data are weaker for muscle spasticity but moderately promising. The least promising categories are movement disorders, epilepsy, and glaucoma. Animal data are moderately supportive of a potential for cannabinoids in the treatment of movement disorders and might eventually yield stronger encouragement. The therapeutic effects of cannabinoids are most well established for THC, which is the primary psychoactive ingredient of marijuana. But it does not follow from this that smoking marijuana is good medicine.

Although marijuana smoke delivers THC and other cannabinoids to the body, it also delivers harmful substances, including most of those found in tobacco smoke. In addition, plants contain a variable mixture of

biologically active compounds and cannot be expected to provide a precisely defined drug effect. For those reasons there is little future in smoked marijuana as a medically approved medication. If there is any future in cannabinoid drugs, it lies with agents of more certain, not less certain, composition. While clinical trials are the route to developing approved medications, they are also valuable for other reasons. For example, the personal medical use of smoked marijuana—regardless of whether or not it is approved—to treat certain symptoms is reason enough to advocate clinical trials to assess the degree to which the symptoms or course of diseases are affected. Trials testing the safety and efficacy of marijuana use are an important component to understanding the course of a disease, particularly diseases such as AIDS for which marijuana use is prevalent. The argument against the future of smoked marijuana for treating any condition is not that there is no reason to predict efficacy but that there is risk. That risk could be overcome by the development of a nonsmoked rapid-onset delivery system for cannabinoid drugs.

There are two caveats to following the traditional path of drug development for cannabinoids. The first is timing. Patients who are currently suffering from debilitating conditions unrelieved by legally available drugs, and who might find relief with smoked marijuana, will find little comfort in a promise of a better drug 10 years from now. In terms of good medicine, marijuana should rarely be recommended unless all reasonable options have been eliminated. But then what? It is conceivable that the medical and scientific opinion might find itself in conflict with drug regulations. This presents a policy issue that must weigh—at least temporarily—the needs of individual patients against broader social issues. Our assessment of the scientific data on the medical value of marijuana and its constituent cannabinoids is but one component of attaining that balance.

The second caveat is a practical one. Although most scientists who study cannabinoids would agree that the scientific pathways to cannabinoid drug development are clearly marked, there is no guarantee that the fruits of scientific research will be made available to the public. Cannabinoid-based drugs will become available only if there is either enough incentive for private enterprise to develop and market such drugs or sustained public investment in cannabinoid drug research and development. The perils along this pathway are discussed in chapter 5. Although marijuana is an abused drug, the logical focus of research on the therapeutic value of cannabinoid-based drugs is the treatment of specific symptoms or diseases, not substance abuse. Thus, the most logical research sponsors would be the several institutes within the National Institutes of Health or organizations whose primary expertise lies in the relevant symptoms or diseases.

CONCLUSION: Scientific data indicate the potential therapeutic value of cannabinoid drugs, primarily THC, for pain relief, control of nausea and vomiting, and appetite stimulation; smoked marijuana, however, is a crude THC delivery system that also delivers harmful substances.

RECOMMENDATION: Clinical trials of cannabinoid drugs for symptom management should be conducted with the goal of developing rapid-onset, reliable, and safe delivery systems.

RECOMMENDATION: Clinical trials of marijuana use for medical purposes should be conducted under the following limited circumstances: trials should involve only short-term marijuana use (less than six months), should be conducted in patients with conditions for which there is reasonable expectation of efficacy, should be approved by institutional review boards, and should collect data about efficacy.

RECOMMENDATION: Short-term use of smoked marijuana (less than six months) for patients with debilitating symptoms (such as intractable pain or vomiting) must meet the following conditions:

- failure of all approved medications to provide relief has been documented,
- the symptoms can reasonably be expected to be relieved by rapid-onset cannabinoid drugs,
- such treatment is administered under medical supervision in a manner that allows for assessment of treatment effectiveness, and
- involves an oversight strategy comparable to an institutional review board process that could provide guidance within 24 hours of a submission by a physician to provide marijuana to a patient for a specified use.

Until a nonsmoked rapid-onset cannabinoid drug delivery system becomes available, we acknowledge that there is no clear alternative for people suffering from *chronic* conditions that might be relieved by smoking marijuana, such as pain or AIDS wasting. One possible approach is to treat patients as *n-of-1* clinical trials, in which patients are fully informed of their status as experimental subjects using a harmful drug delivery system and in which their condition is closely monitored and documented under medical supervision, thereby increasing the knowledge base of the risks and benefits of marijuana use under such conditions. We recom-

mend these *n*-of-1 clinical trials using the same oversight mechanism as that proposed in the above recommendations.

OTHER REPORTS ON MARIJUANA AS MEDICINE

Since 1996, five important reports pertaining to the medical uses of marijuana have been published, each prepared by deliberative groups of medical and scientific experts (Appendix E). They were written to address different facets of the medical marijuana debate, and each offers a somewhat different perspective. With the exception of the report by the Health Council of the Netherlands, each concluded that marijuana can be moderately effective in treating a variety of symptoms. They also agree that current scientific understanding is rudimentary; indeed, the sentiment most often stated is that more research is needed. And these reports record the same problem with herbal medications as noted here: the uncertain composition of plant material makes for an uncertain, and hence often undesirable, medicine.

The 1996 report by the Health Council of the Netherlands concluded that there is insufficient evidence to justify the medical use of marijuana or THC, despite the fact that the latter is an approved medication in the United States and Britain. However, that committee addressed only whether there was sufficient evidence to warrant the prescription of marijuana or cannabinoids, not whether the data are sufficient to justify clinical trials. Conclusions of the Health Council of the Netherlands contrast with that country's tolerance of marijuana use. The health council's report noted that marijuana use by patients in the terminal stages of illness is tolerated in hospitals. It also said that the council did "not wish to judge patients who consume marihuana (in whatever form) because it makes them feel better. . . ."

In contrast, the American Medical Association House of Delegates, National Institutes of Health (NIH), and the British Medical Association recommend clinical trials of smoked marijuana for a variety of symptoms. The NIH report, however, was alone in recommending clinical studies of marijuana for the treatment of glaucoma—and even then there was disagreement among the panel members (William T. Beaver, chair, NIH Ad Hoc Expert Panel on the Medical Use of Marijuana, personal communication, 1998).

Recent reviews that have received extensive attention from those who follow the medical marijuana debate have been written by strong advocates *for* (Grinspoon and Bakalar, 1993⁶²; Zimmer and Morgan, 1997¹⁹⁸) or *against* (Voth and Schwartz, 1997¹⁹¹) the medical use of marijuana. Those reports represent the individual views of their authors, and they are not reviewed here but have been reviewed in major scientific journals.^{7,69,178,180}

Development of Cannabinoid Drugs

Medicines today are expected to be of known composition and quality. Even in cases where marijuana can provide relief of symptoms, the crude plant mixture does not meet this modern expectation. The future of medical marijuana lies in classical pharmacological drug development, and indeed there has been a resurgence of scientific, as well as public, interest in the therapeutic applications of cannabinoids. After an initial burst of scientific activity in the 1970s, today's renewed interest has been fueled by major scientific discoveries discussed in previous chapters: the identification and cloning of endogenous cannabinoid receptors, the discovery of endogenous substances that bind to these receptors, and the emergence of synthetic cannabinoids that also bind to cannabinoid receptors. These scientific accomplishments have propelled interest in developing new drugs that can treat more effectively or more safely the constellation of symptoms for which cannabinoids might have therapeutic benefit (see chapter 4). Through the process of what is referred to as "rational drug design," scientists manipulate the chemical structures of known cannabinoids to design better therapeutic agents. Several new cannabinoids are being developed for human use, but none has reached the stage of human testing in the United States.

The purpose of this chapter is to describe the process of and analyze the prospects for development of cannabinoid drugs. It first discusses the regulatory hurdles that every new drug encounters en route to market. It then proceeds to describe the regulatory and market experiences of

dronabinol (tetrahydrocannabinol, or THC, in sesame oil), the only approved cannabinoid in the United States. These sections serve as a road map to determine whether the therapeutic potential of cannabinoids is likely to be exploited commercially to meet patient needs. Finally, the chapter describes what would be needed to bring marijuana to market as a medicinal plant.

The term *cannabinoids* is used in this chapter to refer to a group of substances that are structurally related to THC—by virtue of a tricyclic chemical structure—or that bind to cannabinoid receptors, such as the natural ligand anandamide. From a chemist's point of view, this definition encompasses a variety of distinct chemical classes. But because the purpose of this chapter is to explore prospects for drug development, both chemical structure and pharmacological activity are important; therefore, the broader definition of cannabinoids is used.

FEDERAL DRUG DEVELOPMENT POLICY

Like controlled substances, cannabinoids developed for medical use encounter a gauntlet of public health regulatory controls administered by two federal agencies: the Food and Drug Administration (FDA) of the U.S. Department of Health and Human Services (DHHS) and the Drug Enforcement Administration (DEA) of the U.S. Department of Justice. The FDA regulates human testing and the introduction of new drugs into the marketplace, whereas the DEA determines the schedule of and establishes production quotas for drugs with potential for abuse to prevent their diversion to illicit channels. The DEA also authorizes registered physicians to prescribe controlled substances. Some drugs, such as marijuana, are labeled Schedule I in the Controlled Substance Act, and this adds considerable complexity and expense to their clinical evaluation. It is important to point out that Schedule I status does not necessarily apply to all cannabinoids.

Food and Drug Administration

Under the Federal Food, Drug, and Cosmetic (FD&C) Act, the FDA approves new drugs for entry into the marketplace after their safety and efficacy are established through controlled clinical trials conducted by the drugs' sponsors.²³ FDA approval of a drug is the culmination of a long, research intensive process of drug development, which often takes well over a decade.^{19,44} Drug development is performed largely by pharmaceutical companies, but some targeted drug development programs are sponsored by the National Institutes of Health (NIH) to stimulate further development and marketing by the private sector. The NIH's drug devel-

opment programs—including those for AIDS, cancer, addiction, and epilepsy—have been instrumental in ushering new drugs to market in collaboration with pharmaceutical companies.³³ In fact, as noted later, most of the preclinical and clinical research on dronabinol was supported by NIH.

Drug development begins with discovery, that is, the synthesis and purification of a new compound with expected biological activity and therapeutic value. The next major step is the testing of the compound in animals to learn more about its safety and efficacy and to predict its utility for humans. Those early activities are collectively referred to as the pre-clinical phase. When evidence from the preclinical phase suggests a promising role in humans, the manufacturer submits an Investigational New Drug (IND) application to the FDA. The IND submission contains a plan for human clinical trials and includes the results of preclinical testing and other information.²⁰ Absent FDA objection, the IND becomes effective after 30 days, allowing the manufacturer to conduct clinical testing (testing in humans), which generally involves three phases (see Figure 5.1). The three stages of clinical testing are usually the most time-consuming phases of drug development, lasting five years on average.²² The actual time depends on the complexity of the drug, availability of patients, duration of use, difficulty of measuring clinical end points, therapeutic class, and indication (the disease or condition for which the drug has purported benefits).³¹

Drug development is a long and financially risky process. For every drug that ultimately reaches clinical testing through an IND, thousands of drugs are synthesized and tested in the laboratory. And only about one in five drugs initially tested in humans successfully secures FDA approval for marketing through a new drug application (NDA).¹⁹

The manufacturer submits an NDA to the FDA to gain approval for marketing when clinical testing is complete. An NDA is a massive document, the largest portion of which contains the clinical data from Phase I–III testing. The other technical sections of an NDA include chemistry, manufacturing, and controls; nonclinical pharmacology and toxicology; and human pharmacokinetics and bioavailability.²³ In the case of a new cannabinoid, an abuse liability assessment would also probably be part of an NDA submission. In 1996 the median time for FDA review of an NDA, from submission to approval, was 15.1 months, a review period considerably shorter than that in 1990, when the figure was 24.3 months.²² The shortening of approval time is an outgrowth of the Prescription Drug User Fee Act of 1992, which authorized the FDA to hire additional review staff with so-called user fees paid by industry and imposed clear deadlines for FDA action on an NDA. With respect to the cost of a single drug's development, a number of recent studies have provided a range of estimates of

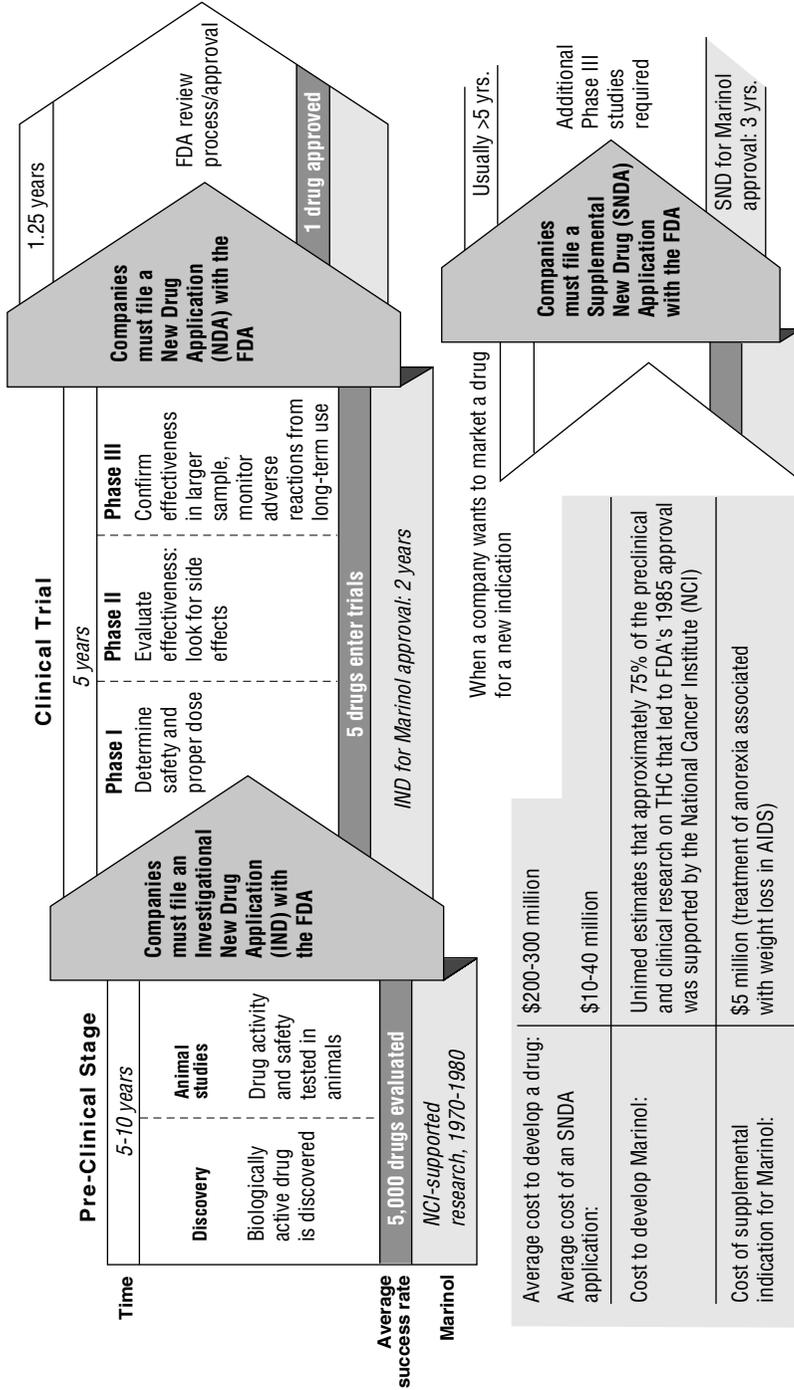

FIGURE 5.1 Stages of clinical testing.

about \$200–\$300 million, depending on the method and year of calculation.^{33,44}

With FDA approval of an NDA, the manufacturer is permitted to market the drug for the *approved indication*. At that point, although any physician is at liberty to prescribe the approved drug for another indication (an “off-label use”), the manufacturer cannot promote it for that indication unless the new indication is granted separate marketing approval by the FDA.* To obtain such approval, the manufacturer is required to compile another application to the FDA for what is known variously as an “efficacy supplement,” a “supplemental application,” or a “supplemental new drug application.” Those terms connote that the application is supplemental to the NDA. In general, collecting new data for FDA approval of an efficacy supplement is not as intensive a process as that for an NDA; it generally requires the firm to conduct two additional Phase III studies, although under some circumstances only one additional study of the drug’s efficacy is needed.²⁴ The preclinical studies, for example, ordinarily need not be replicated. The average cost to the manufacturer for obtaining approval for the new indication is typically about \$10–\$40 million.³³ The review time to obtain FDA approval for the new indication can be considerable; a recent study of supplemental indications approved by the FDA in 1989–1994 found the approval time to exceed that for the original NDA,¹⁸ a reflection, in part, of the lower priority that the FDA accords to the review of efficacy supplements as opposed to new drugs.²³

The manufacturer also must apply to the FDA to receive marketing approval for a new formulation of a previously approved drug. A new formulation is a new dosage form, including a new route of administration. An example of such a new formulation is an inhaled version of Marinol, which is currently approved only in capsule form. The manufacturer is required to establish bioequivalence, safety, and efficacy of the new formulation. The amount of evidence required for approval is highly variable, depending on the similarities between the new formulation and the approved formulation. New formulations are evaluated case by case by the FDA. In the case of Marinol, for example, an inhaled version is likely to require not only new studies of efficacy but also new studies of abuse liability. There appear to be no published peer-reviewed studies of the average cost and time for approval of a new formulation.

Two other FDA programs might be relevant to the potential availabil-

*FDA policies for off-label use are being transformed as a result of the Food and Drug Administration Modernization Act of 1997. The FDA recently promulgated new rules to give manufacturers greater flexibility to disseminate information about off-label uses (FDA, 1998b^{24a}). As of this writing, however, court decisions have left the status of the new rules somewhat unclear.

ity of new cannabinoids. One program is authorized under the Orphan Drug Act of 1983, which provides incentives to manufacturers to develop drugs to treat “orphan diseases.” An orphan disease, as defined in an amendment to the act, is one that affects 200,000 or fewer people in the United States.* The act’s most important incentive is a period of exclusive marketing protection of seven years, during which time the FDA is prohibited from approving the same drug for the same indication.^{5,6} Some of the medical conditions for which cannabinoids have been advocated—Huntington’s disease, multiple sclerosis, and spinal cord injury (see chapter 4)—might meet the definition of an orphan disease and thus enable manufacturers to take advantage of the act’s financial incentives to bring products to market. If a disease affects more than 200,000 people, the manufacturer sometimes subdivides the patient population into smaller units to qualify. For example, a drug for the treatment of Parkinson’s disease is not likely to receive an orphan designation because its prevalence exceeds 200,000, but orphan designation has been accorded to drugs for subsets of Parkinson’s patients, such as those suffering from early-morning motor dysfunction in the late stages of the disease.²⁵

The other program is the Treatment-IND program, which was established by regulation in 1987 (and codified into law in 1997) to allow patients with serious and life-threatening diseases to obtain experimental medications, such as marijuana, before their general marketing.[†] Treatment INDs may be issued during Phase III studies to patients who are not enrolled in clinical trials, provided among other requirements that no comparable alternative drug is available.^{22,32,33} Thus, the treatment IND program can provide a mechanism for some patients to obtain a promising new cannabinoid before its widespread commercial availability if it reached the late stages of clinical testing for a serious or life-threatening disease.

Drug Enforcement Administration

The DEA is responsible for scheduling controlled substances, that is, drugs and other agents that possess a potential for abuse. *Abuse* is generally defined as nonmedical use that leads to health and safety hazards, diversion from legitimate channels, self-administration, and other untoward results.^{15,21} The legislation that gives DEA the authority to regulate

*The FDA can grant orphan designation to a drug intended for a condition that affects a larger population if the manufacturer’s estimated expenses are unlikely to be recovered by sales in the United States (Public Law 98-551).

[†]Marijuana cigarettes were available under a special FDA-sponsored Compassionate Investigational New Drug Program for desperately ill patients until March 1992, when the program was closed to new participants.⁴⁸

drugs of abuse is the Controlled Substances Act, which was passed in 1970 and amended several times. The overall purpose of the CSA is to restrict or control the availability of drugs to prevent their abuse.

Under the CSA, the DEA places each drug that has abuse potential into one of five categories. The five categories, referred to as Schedules I–V, carry different degrees of restriction. Schedule I is the most restrictive, covering drugs that have “no accepted medical use” in the United States and that have high abuse potential. The definitions of the categories and examples of drugs in each are listed in Appendix C. Each schedule is associated with a distinct set of controls that affect manufacturers, investigators, pharmacists, practitioners, patients, and recreational users. The controls include registration with the DEA, labeling and packaging, production quotas, security, recordkeeping, and dispensing.¹⁵ For instance, patients with a legitimate medical need for drugs in Schedule II, the most restrictive schedule for drugs “currently with accepted medical use,” can neither refill their prescriptions nor have them telephoned to a pharmacy (except in an emergency).

The scheduling of substances under the CSA is handled case by case. It may be initiated by DEA, by DHHS, or by petition from an interested party, including the drug’s manufacturer or a public-interest group.¹⁵ The final decision for scheduling rests with the DEA, but for this purpose the secretary of DHHS is mandated to provide a recommendation. The secretary’s recommendation* to DEA is based in part on results from abuse liability testing that the FDA requires of the manufacturer seeking approval of a new drug. Abuse liability testing is not a single test; it is a compilation of several *in vitro* human and animal studies, of which some of the best known are drug self-administration and drug discrimination studies.^{21,34} The secretary’s recommendation for scheduling is formally guided by eight legal criteria, including the drug’s actual or relative potential for abuse, scientific evidence of its pharmacological effect, risk to public health, and its psychic or physiological dependence liability (21 U.S.C. § 811 (b), (c)). Once the DEA receives a scheduling recommendation, its scheduling decision, including the requirement for obtaining public comment, usually takes weeks to months.³³ In practice, the DEA usually adheres to the recommendation of the secretary.[†] Beyond the DEA,

*The FDA and the National Institute of Drug Abuse, two agencies of DHHS, work jointly to develop the medical and scientific analysis that is forwarded to the secretary, who makes a recommendation to the administrator of the DEA (DEA, 1998¹⁵).

†Under the CSA, “the recommendations of the Secretary to the Attorney General shall be binding on the Attorney General as to such scientific and medical matters, and if the Secretary recommends that a drug or other substance not be controlled, the Attorney General shall not control the drug or other substance” (21 U.S.C. § 811 (b)).

various state scheduling laws also affect the manufacture and distribution of controlled substances.^{33,50}

Under the CSA, marijuana and THC* are in Schedule I, the most restrictive schedule. The scheduling of any other cannabinoid under this act first hinges on whether it is found *in the plant*. All cannabinoids in the plant are automatically in Schedule I because they fall under the act's definition of marijuana (21 U.S.C. § 802 (16)). In addition, under DEA's regulations, synthetic equivalents of the substances contained in the plant and "synthetic substances, derivatives, and their isomers" whose "chemical structure and pharmacological activity" are "similar" to THC also are automatically in Schedule I (21 CFR § 1308.11(d)(27). Based on the examples listed in the regulations, the word *similar* probably limits the applicability of the regulation to isomers of THC, but DEA's interpretation of its own regulations would carry significant weight in any specific situation.

Prompted by a 1995 petition from Jon Gettman, a former president of the National Organization for the Reform of Marijuana Laws (NORML), to remove marijuana and THC from Schedule I, DEA gathered information which was then submitted to DHHS for a medical and scientific recommendation and scheduling recommendation, as required by the CSA. For the reasons noted above, any changes in scheduling of marijuana and THC would also affect other plant cannabinoids. For the present, however, any cannabinoid found in the plant is automatically controlled in Schedule I.

Investigators are affected by Schedule I requirements even if their research is being conducted *in vitro* or on animals. For example, researchers studying cannabinoids found in the plant are required under the CSA to submit their research protocol to DEA, which issues a registration that is contingent on FDA's evaluation and approval of the protocol (21 CFR § 1301.18). DEA also inspects the researcher's security arrangements. However, the regulatory implications are quite different for cannabinoids *not found in the plant*. Such cannabinoids appear to be uncontrolled unless the FDA or DEA decides that they are sufficiently similar to THC to be placed automatically into Schedule I under the regulatory definition outlined above or the FDA or the manufacturer deems them to have potential for abuse, thereby triggering *de novo* the scheduling process noted above. Thus far, the cannabinoids most commonly used in preclinical research (Table 5.1) appear to be sufficiently distinct from THC that they are not currently considered controlled substances by definition (F. Sapienza, DEA, personal communication, 1998). No new cannabinoids other than

*Technically, the CSA and the regulations use the term "tetrahydrocannabinols."

THC have yet been clinically tested in the United States, so scheduling experience is limited. The unscheduled status of some cannabinoids might change as research progresses. Results of early clinical research could lead a manufacturer to proceed with or lead the FDA to require abuse liability testing. Depending on the results of such studies, DHHS might or might not recommend scheduling *de novo* to DEA, which makes the final decision case by case.

Will newly discovered cannabinoids be subject to scheduling? That is a complex question that has no simple answer. The answer depends entirely on each new cannabinoid—whether it is found in the plant, its chemical and pharmacological relationship to THC, and its potential for abuse. Novel cannabinoids with strong similarity to THC are likely to be scheduled at some point before marketing, whereas those with weak similarity might not be. The manufacturer's submission to FDA, which contains its own studies and its request for a particular schedule, can also shape the outcome. Cannabinoids found in the plant are automatically in Schedule I until the manufacturer requests and provides justification for rescheduling. The CSA does permit DEA to reschedule a substance (move it to a different schedule) and to deschedule a substance (remove it from control under the CSA) according to the scheduling criteria (see Appendix F) and the process outlined above.

The possibility of scheduling is a major determinant of whether a manufacturer proceeds with drug development.³³ In general, pharmaceutical firms perceive scheduling to be a deterrent because it limits their ability to achieve market share for the following reasons: restricted access,

physician disinclination to prescribe scheduled substances, stigma, the additional expense for abuse liability studies, and expensive delays in reaching the market due to federal and state scheduling processes.³³ Empirical evidence to support that widely held perception is difficult to find, but at least one large survey of physicians found them to have moderate concerns about prescribing opioids because of actual or perceived pressure from regulatory agencies, such as DEA.⁵⁷ On the basis of a legal analysis and widespread complaints from researchers and pharmaceutical executives, the Institute of Medicine (IOM, 1995)³³ recommended changes in the CSA to eliminate the act's barriers to undertaking clinical research and development of controlled substances; this position was supported in a later report on marijuana.⁴⁰

DEVELOPMENT AND MARKETING OF MARINOL

The following material is based on the published literature (where cited), workshops sponsored by the IOM, and an interview with Robert Dudley, senior vice president of Unimed Pharmaceuticals, Inc., the manufacturer of Marinol and the holder of the NDA. Unimed markets Marinol jointly with Roxane Laboratories, Inc.

Marinol (dronabinol) is the only cannabinoid with approval for marketing in the United States.* The following description covers its development, regulatory history, pharmacokinetics, adverse effects, abuse liability, and market growth. The experience with Marinol can serve as a possible bellwether for the regulatory and commercial fate of new cannabinoids being considered for development.

Development and Regulatory History

Marinol is manufactured as a capsule containing THC in sesame oil; it is taken orally. It was approved by the FDA in 1985 for the treatment of nausea and vomiting associated with cancer chemotherapy. In 1992, the FDA approved marketing of dronabinol for the treatment of anorexia associated with weight loss in patients with AIDS.⁴⁵ The preclinical and clinical research on THC that culminated in the FDA's 1985 approval was supported primarily by the National Cancer Institute (NCI), whose research support goes back to the 1970s. NCI's contribution appears pivotal, considering that Unimed, the pharmaceutical company that holds

*The only cannabinoid licensed outside the United States is nabilone (Cesamet), which is an analogue of THC available in the United Kingdom for the management of nausea and vomiting associated with cancer chemotherapy (Pertwee, 1997).⁴⁶

the NDA, estimates its contribution to have been only about 25% of the total research effort. The FDA's review and approval of Marinol took about two years after submission of the NDA, according to Unimed. To obtain approval for Marinol's second indication (through an efficacy supplement), the FDA required two more relatively small Phase III studies. The studies lasted three years and cost \$5 million to complete.

Physical Properties, Pharmacokinetics, and Adverse Events

Marinol is synthesized in the laboratory rather than extracted from the plant. Its manufacture is complex and expensive because of the numerous steps needed for purification. The poor solubility of Marinol in aqueous solutions and its high first-pass metabolism in the liver account for its poor bioavailability; only 10–20% of an oral dose reaches the systemic circulation.^{45,60} The onset of action is slow; peak plasma concentrations are not attained until two to four hours after dosing.^{45,56} In contrast, inhaled marijuana is rapidly absorbed. In a study comparing THC administered orally, by inhalation, and intravenously, plasma concentration peaked almost instantaneously after both inhalation and intravenous administration; most participants' peak plasma concentrations after oral administration occurred at 60 or 90 minutes. Variation in individual responses is highest for oral THC and bioavailability is lowest.⁴²

Marinol's most common adverse events are associated with the central nervous system (CNS): anxiety, confusion, depersonalization, dizziness, euphoria, dysphoria, somnolence, and thinking abnormality.^{8,9,45,59} In two recent clinical trials, CNS adverse events occurred in about one-third of patients, but only a small percentage discontinued the drug because of adverse effects.^{8,9} Lowering the dose of dronabinol can minimize side effects, especially dysphoria (disquiet or malaise).⁴⁷

Abuse Potential and Scheduling

On commercial introduction in 1985, Marinol was placed in Schedule II. This schedule, the second most restrictive, is reserved for medically approved substances that have "high potential for abuse" (21 U.S.C. § 812 (b) (2)). Unimed did not encounter any delays in marketing as a result of the scheduling process because the scheduling decision was made by the DEA before FDA's approval for marketing. Nor did Unimed encounter any marketing delays as a result of state scheduling laws. Unimed was not specifically asked by the FDA to perform abuse liability studies for the first approval, presumably because such studies had been conducted earlier.

Unimed later petitioned the DEA to reschedule Marinol from Sched-

ule II to Schedule III, which is reserved for medically approved substances that have some potential for abuse (21 U.S.C. § 812 (b) (3)). To buttress its request for rescheduling, Unimed supported an analysis of Marinol's abuse liability by researchers at the Haight Ashbury Free Clinic of San Francisco, which treats many cannabis-dependent patients and people who have HIV/AIDS. The analysis found no evidence of abuse or diversion of Marinol after a literature review and surveys and interviews of medical specialists in addiction, oncology, cancer research, and treatment of HIV, and people in law enforcement. The authors attribute Marinol's low abuse potential to its slow onset of action, its dysphoric effects, and other factors.¹² On November 5, 1998, the DEA announced a proposal to reschedule Marinol to Schedule III.¹⁷ As of this writing, no formal action on that proposal had been taken.

The rescheduling of a drug from Schedule II to Schedule III is considered important because it lifts some of the restrictions on availability. For example, Unimed expects a sales increase of about 15–20% as a result of rescheduling. In its judgment and that of many other pharmaceutical companies,³³ scheduling limits market penetration; the more restrictive the schedules, the greater the limitation. The reasons are that physicians and other providers are reluctant to prescribe Schedule II drugs; patients are deterred from seeking prescriptions because of Schedule II prohibition of refills, as opposed to other commercially available scheduled substances; additional restrictions are imposed by several states, such as quantity restrictions (for example, 30-day supply limits) and triplicate prescriptions;⁵⁰ and some Schedule II drugs are excluded from hospital formularies because of onerous security and paperwork requirements under federal and state controlled substances laws.

Market Growth and Transformation

Annual sales of Marinol are estimated at \$20 million, according to Unimed. Of Marinol's patient population 80% use it for HIV, 10% for cancer chemotherapy, and about 5–10% for other reasons. The latter group is thought to consist of Alzheimer's patients drawn to the drug by a recently published clinical study indicating Marinol's promise for the treatment of their anorexia and disturbed behavior.⁵⁸ As noted earlier, Unimed cannot promote Marinol for this unlabeled indication, but physicians are free to prescribe it for such an indication. Unimed is conducting additional research in pursuit of FDA approval of a new indication for Marinol in the treatment of Alzheimer disease.

The 1992 approval of Marinol for the treatment of anorexia in AIDS patients marked a major transformation in the composition of the patient population. Marinol's use had been restricted to oncology patients. The

oncology market for Marinol gradually receded as a result of the introduction of newer medications, including such serotonin antagonists as ondansetron, which are more effective (see chapter 4, "Nausea and Vomiting") and are not scheduled. Much of the recent growth of the market for Marinol (which is about 10% per year) is attributed to its increasing use by HIV patients being treated with combination antiretroviral therapy. Marinol appears to have a dual effect, not only stimulating appetite but also combating the nausea and vomiting associated with combination therapy. Unimed is supporting a Phase II study to examine this combined effect and, with promising results, plans to seek FDA approval for this new indication.

Unimed has two forms of market protection for Marinol. In December 1992, the FDA granted Marinol seven years of exclusive marketing under the Orphan Drug Act. The market exclusivity is related to Marinol's use in anorexia associated with AIDS. Because of the designated orphan indication, the active ingredient, THC, cannot be marketed by another manufacturer for the same indication until December 1999. Other pharmaceutical manufacturers are not constrained from manufacturing and marketing THC for its *other* indication, antiemesis for cancer chemotherapy, but none appears to be interested in what is, by pharmaceutical company standards, a small market. In addition to market exclusivity, Unimed secured in June 1998 a "use patent" for dronabinol for the treatment of disturbed patients with dementia; this confers patent protection to Unimed for this use for 20 years from the date of filing of the application,* assuming that this indication eventually gains FDA approval.

The rate-limiting factors in the growth of the market for Marinol, according to Unimed are the lack of physician awareness of the drug's efficacy, its adverse effects, and its restricted availability as a result of placement in Schedule II. Unimed perceives only a small percentage of its market to be lost to "competition" from marijuana itself, but there are, admittedly, no reliable statistics on the number of people who have chosen to treat their symptoms with illegally obtained marijuana, despite their ability to obtain Marinol.

New Routes of Administration

It is well recognized that Marinol's oral route of administration hampers its effectiveness because of slow absorption and patients' desire for

*A use patent—also known as a process patent—accords protection for a method of using a composition or compound. A use patent is not considered as strong as a product patent, which prohibits others from manufacturing, using, or selling the product for all uses, rather than for the specific use defined in a use patent.

more control over dosing. A drug delivered orally is first absorbed from the stomach or small intestine and then passed through the liver, where it undergoes some metabolism before being introduced into the circulation. To overcome the deficiencies of oral administration, Unimed activated an IND in 1998 as a step toward developing new formulations for Marinol. Four new formulations—deep lung aerosol, nasal spray, nasal gel, and sublingual preparation—are under study in Phase I clinical studies being conducted in conjunction with Roxane Laboratories. These formulations seek to deliver Marinol to the circulation more rapidly and directly. The first two fall under inhalation as a route of administration. Inhalation is considered the most promising method, owing to the rapidity of onset of its effects and potential for better titration of the dose by the patient, but it might also carry an increased potential for abuse. The abuse of a drug correlates with its rapidity of onset (G. Koob, IOM workshop). Sublingual route (under the tongue) administration also affords rapid absorption into the circulation, in this case from the oral mucosa. Other researchers are pursuing the delivery of THC through rectal suppositories, but this slower route might not be acceptable to many patients. Transdermal (skin patches) administration, which is best suited to hydrophilic drugs, is precluded by the lipophilicity of THC. Thus, the choice of routes of administration depends heavily on the physicochemical characteristics of the drug and on its safety, abuse liability, and tolerability.

Unimed expects the FDA to require it to conduct studies of the bioavailability, efficacy, and possibly abuse liability of any new formulation it seeks to market. Any formulation that expedites Marinol's onset of action, as suggested above, is thought to carry greater possibility of abuse. The cost of developing each new formulation is estimated by Unimed at \$7–\$10 million.

Unimed and Roxane are developing, or considering development of, five new indications for Marinol: disturbed behavior in Alzheimer's disease, nausea and vomiting in HIV patients who are receiving combination therapy, spasticity in multiple sclerosis, intractable pain, and anorexia in cancer and renal disease.

Costs of Marinol and Marijuana

During the IOM public workshops held during the course of this study, many people commented that an important advantage of using marijuana for medical purposes is that it is much less expensive than Marinol. But this comparison is deceptive. While the direct costs of marijuana are relatively low, the indirect costs can be prohibitive. Individuals who violate federal or state marijuana laws risk a variety of costs associated with engaging in criminal activity, ranging from increased vulner-

ability to theft and personal injury legal fees to long prison terms. In addition, when purchasing illicit drugs there is no guarantee that the product purchased is what the seller claims it is or that it is not contaminated.

The price of Marinol for its most commonly used indication, anorexia in AIDS, is estimated at \$200 per month. The less common indication—nausea and vomiting with cancer chemotherapy—is not as expensive because it is not chronic. Regardless of indication, patients' out-of-pocket expenses tend to be much less—often minimal—because of reimbursement through public or private health insurance. For indigent patients who are uninsured, Roxane sponsors a patient assistance program to defray the cost.

The street value of marijuana, according to the DEA's most recent figures, is about \$5–\$10 per bag of loose plant.^{16*} At the California buyers' clubs, the price is \$2–\$16 per gram, depending on the grade of marijuana. The cost to a patient using marijuana depends on the number of cigarettes smoked each day, their THC content, and the duration of use. Insurance does not cover the cost of marijuana. In addition, it is possible for a person to cultivate marijuana privately with little financial investment.

Thus, Marinol appears to be less expensive than marijuana for patients with health insurance or with financial assistance from Roxane. But if the full cost of Marinol is borne out of pocket by the patient, the cost comparison is not so unambiguous. In this case the daily cost in relation to marijuana varies according to the number of cigarettes smoked: If the patient smokes two or more marijuana cigarettes per day, Marinol might be less expensive than marijuana; if the patient smokes only one marijuana cigarette per day, Marinol might be more expensive than marijuana, according to an analysis submitted to the DEA by Unimed. The cost comparisons will depend on fluctuations in the retail price and street value of Marinol and marijuana, respectively, and will vary if marijuana becomes commercially available.

In summary, Marinol has been on the U.S. market since 1985. Its commercial development depended heavily on research supported by the NIH. Marinol's market has grown to \$20 million in annual sales. Further market growth is expected but is still constrained by lack of awareness, adverse effects, the oral route of administration, and restrictions imposed by drug scheduling. The manufacturer is proceeding with research on new forms of delivery to overcome the problems associated with oral administration. The manufacturer also is proceeding with research on an array of new indications for Marinol.

*The DEA did not provide an estimate of the weight of marijuana per bag.

MARKET OUTLOOK FOR CANNABINOIDS

The potential therapeutic value of cannabinoids is extremely broad. It extends well beyond antiemesis for chemotherapy and appetite stimulation for AIDS, the two indications for which the FDA has approved dronabinol (Marinol). Chapter 4 of this report assesses the possible wider therapeutic potential of marijuana and THC in neurological disorders, glaucoma, and analgesia—all conditions for which clinical research has been under way to fulfill unmet patient needs. New therapeutic uses are being explored in preclinical research. For any of these therapeutic indications, will novel cannabinoids reach the market to satisfy the medical needs of patients?

Economic Factors in Development

The outcomes of preclinical and clinical research determine whether a drug is sufficiently safe and effective to warrant FDA approval for marketing. But the decisions to launch preclinical research and to proceed to clinical trials if early results are promising are dictated largely by economic factors. A pharmaceutical company must decide whether to invest in what is universally regarded as a long and risky research path. For any given drug the question is, Will there be an adequate return on investment? The investment in this case is the high cost of developing a drug. The expectation of high financial returns on investment is what drives drug development.^{44,53}

Market analyses are undertaken to forecast whether a drug will reap a substantial return on investment. The market analysis for a cannabinoid is likely to be shaped by various factors. The average cost of developing a cannabinoid is likely to be higher than that of developing other drugs if its clinical indication is in the therapeutic categories of neuropharmaceutical or nonsteroidal antiinflammatory drug, the two therapeutic categories associated with the highest research and development costs.¹⁹ One reason for higher costs is the need to satisfy the DEA's regulatory requirements related to drug scheduling.

On the "market return" side are multiple factors. A market analysis examines the expected returns from the possible markets for which a cannabinoid could be clinically pursued. The financial size of each market is calculated mostly on the basis of the current and projected patient prevalence (for a given clinical indication), sales data (if available), and competition from other products. The duration of use is also factored in—a drug needed for long-term use in a condition with an early age of onset is desirable from a marketing perspective. Factors that can augment or diminish market return include patentability and other forms of market protection,

reimbursement climate, restrictions in access due to drug scheduling, social attitudes, adverse effect profile, and drug interactions.^{33,53} New cannabinoids generally can receive product patents, giving the patent holder 20 years of protection from others seeking to manufacture or sell the same product. According to U.S. patent law, the product must be novel and "nonobvious" in relation to prior patents.²⁸

Cannabinoids under Development

From publicly available sources, the IOM was able to learn of several cannabinoids being developed for human use (Table 5.2). With the exception of Marinol and marijuana, all are in the preclinical phase of testing in the United States. This list might not be comprehensive, inasmuch as other compounds could be under development, but that information is

proprietary.* The table does not list the full complement of cannabinoids, both agonists and antagonists, being used in research as tools to understand the pharmacology of cannabinoids (for more comprehensive lists of cannabinoids, see Felder and Glass, 1998²⁶; Mechoulam et al., 1998³⁶; Howlett, 1995³⁰; Pertwee 1997⁴⁶). Nor does it list cannabinoids once considered for development but later discontinued. An 18-year survey of analgesics in development in 1980–1998 found that six of the nine cannabinoids under development for analgesia were discontinued or undeveloped,^{49,†} but work on most of these was halted before 1988, when the first endogenous cannabinoid receptor was discovered (chapter 3).

Three points can be made on the basis of Table 5.2. First, virtually all of the listed cannabinoids are being developed by small pharmaceutical companies or by individuals. In general, that implies that their development is considered especially risky from a commercial standpoint in that small companies are often willing to assume greater development risks than larger more established firms (W. Schmidt, personal communication, 1998). Without the benefit of sales revenues, small companies are able to fund their research through financing from venture capital, stock offerings, and relationships with established pharmaceutical companies.⁴³

Second, with the exception of THC, no constituents of the marijuana plant appear to be undergoing development by pharmaceutical companies. A number of plant compounds have been tested in experimental models and humans. For example, the antiemetic properties and negligible side effects of Δ^8 -THC were demonstrated in a clinical trial in children who were undergoing cancer chemotherapy,¹ but no sponsor was interested in developing Δ^8 -THC for commercial purposes (R. Mechoulam, Hebrew University, personal communication, 1998). The absence of plant cannabinoids under development implies that the specter of automatic placement in Schedule I under the CSA is an important deterrent, even though rescheduling would occur before marketing.^{††} The point from the earlier discussion is that automatic, as opposed to *de novo*, scheduling appears to cast a pall over development of a cannabinoid found in the plant. Another impediment is that a cannabinoid extracted

*Information about the existence of an IND is proprietary; it can be confirmed only by the manufacturer, not the FDA.

†Discontinued: levonantradol, nabitan, nantradol, and pravadoline. Undeveloped: CP-47497 and CP-55244.

††As a result of the FDA's approval of an NDA, the drug would be, at a minimum, rescheduled in Schedule II. Depending on abuse liability data supplied by the manufacturer and the FDA's recommendation, the drug could be moved to a less restrictive schedule or be descheduled.

from the plant is not likely to fulfill the criteria for a product patent, although other forms of market protection are possible. Marinol, for example, was accorded orphan drug status and its manufacturer obtained a use patent.

Third, cannabinoids are being developed for therapeutic applications beyond those discussed earlier in this chapter and in chapter 4. One of the most prominent new applications of cannabinoids is for “neuroprotection,” the rescue of neurons from cell death associated with trauma, ischemia, and neurological diseases.^{29,36} Cannabinoids are thought to be neuroprotective—through receptor-dependent⁵¹ as well as receptor-independent pathways; both THC, which binds to CB₁ receptors, and CBD, which does not, are potent antioxidants, effective neuroprotectants because of their ability to reduce the toxic forms of oxygen (free radicals) that are formed during cellular stress.²⁹ The synthetic cannabinoid HU-211 (dexanabinol) is an antioxidant and an antagonist of the NMDA receptor, rather than an agonist at the cannabinoid receptor.⁵² Earlier research demonstrated that HU-211 protects neurons from neurotoxicity induced by excess concentrations of the excitatory neurotransmitter glutamate. Excess release of glutamate, which acts by binding to the NMDA receptor, is associated with trauma and disease.⁵⁴ As an NMDA antagonist, HU-211 blocks the damaging action of glutamate and other endogenous neurotoxic agents.^{52,55} After having been studied in the United Kingdom in Phase I clinical trials, HU-211 progressed to Phase II clinical trials in Israel for treatment of severe closed-head trauma (Knoller et al., 1998).³⁵

Market Prospects

It is difficult to gauge the market prospects for new cannabinoids. There certainly appears to be scientific interest, particularly for the discovery of new cannabinoids, but whether this interest can be sustained commercially through the arduous course of drug development is an open question. Research and development experience is limited; only one cannabinoid, dronabinol, is commercially available, and most of its research and development costs were shouldered by the federal government. Furthermore, the size of dronabinol’s market (at about \$20 million) is modest by pharmaceutical company standards. None of the other cannabinoids in development has reached clinical testing in the United States. Their scientific, regulatory, and commercial fates are likely to be very important in shaping future investment patterns. Experience with the drug scheduling process also is likely to be watched very carefully. If the early products are heavily regulated in the absence of strong abuse liability, future development might be deterred. For the present, what seems to be clear

from the dearth of products in development and the small size of the companies sponsoring them is that cannabinoid development is seen as especially risky.

One scenario is that cannabinoids will be pursued for lucrative markets that reflect large unmet medical needs. Of the therapeutic needs for which cannabinoid receptor agonists have been tested, analgesia is by far the largest. The annual U.S. prescription and over-the-counter analgesic market in 1997 was \$4.4 billion.⁴⁹ Given the long-standing need for less addictive, safer, easier to use, and more effective drugs for acute and chronic pain, it would not be surprising to see cannabinoids developed to treat some segments of the current analgesic market, if their safety and effectiveness were clearly established in clinical trials.

In addition to cannabinoid receptor agonists, two classes of cannabinoid-related drugs might prove therapeutically useful: cannabinoid antagonists and inverse agonists, compounds that bind to receptors but produce effects opposite those of agonists. Neither would be subject to the same scheduling concerns as cannabinoid agonists because they are not found in marijuana and would be highly unlikely to have any abuse potential. Another set of cannabinoid-related drugs, such as those that affect the synthesis, uptake, or inactivation of endogenous cannabinoids might, however, have abuse potential because they would influence the signal strength of endogenous cannabinoids.

The development of specific cannabinoid antagonists, like SR141716A for CB₁ receptors and SR144528 for CB₂ receptors, has provided a substantial impetus to understand cannabinoid actions. Those compounds block many of the effects of THC in animals, and their testing in humans has just begun. Cannabinoid antagonists have physiological effects on their own, in the absence of THC. They might have important therapeutic potential in a variety of clinical situations. For example, THC reduces short-term memory, so it is possible that a CB₁ antagonist like SR141716A could act as a memory-enhancing agent. Similarly, for conditions in which cannabinoids decrease immune function (presumably by binding to CB₂ receptors in immune cells), a CB₂ antagonist might be useful as an immune stimulant.

Cannabinoid inverse agonists would exert effects opposite those of THC and might thus cause appetite loss, short-term memory enhancement, nausea, or anxiety. Those effects could possibly be separated by molecular design, in which case inverse agonists might have some therapeutic value. One report has been published suggesting that the CB₁ receptor antagonist, SR141617A,¹¹ is an inverse agonist, and there will likely be others.

REGULATION OF AND MARKET OUTLOOK FOR MARIJUANA

Marijuana is not legally marketed in the United States.* No sponsor has ever sought marketing approval from the FDA for medical use of marijuana. One sponsor has an IND for a clinical safety study on HIV anorexia (D. Abrams, University of California at San Francisco, personal communication, 1998). Another has an IND pending for the treatment of migraine headaches (E. Russo, Western Montana Clinic, personal communication, 1998). Since 1970, marijuana's manufacture and distribution have been tightly restricted under the CSA, which places marijuana in Schedule I, which is reserved for drugs or other substances with "a high potential for abuse," "no currently accepted medical use," and "lack of accepted safety for use . . . under medical supervision" (21 U.S.C. § 812 (b)(1)).

Marijuana has remained in Schedule I despite persistent efforts at re-scheduling since the 1970s by advocacy groups, such as NORML. Through petitions to the DEA, advocacy groups contend that marijuana does not fit the legal criteria for a Schedule I substance, owing to its purported medical uses and lack of high abuse liability.^{3,4,48} Another rescheduling petition, which was filed in 1995, is being evaluated by the FDA and DEA.

Availability for Research

To use marijuana for research purposes, researchers must register with the DEA, as well as adhere to other relevant requirements of the CSA and other federal statutes, such as the FD&C act. The National Institute on Drug Abuse (NIDA), one of the institutes of NIH, is the only organization in the United States licensed by the DEA to manufacture and distribute marijuana for research purposes. NIDA performs this function under its Drug Supply Program.[†] Through this program, NIDA arranges for marijuana, to be grown and processed through contracts with two organizations: the University of Mississippi and the Research Triangle Institute. The University of Mississippi grows, harvests, and dries marijuana; and the institute processes it into cigarettes. A researcher can obtain marijuana free of charge from NIDA through an NIH-approved research grant to investigate marijuana, or through a separate protocol review.³⁹ Research grant approvals are handled through the conventional NIH peer review

*Under the CSA, its only legal use is in research under strictly defined conditions.

†This is also the program through which several patients receive marijuana under a compassionate use program monitored by the FDA. For history and information on this effort, see Randall (1993).⁴⁸

process for extramural research, a highly competitive process with a success rate in 1997 of 32% of approved NIDA grants.⁴¹ Through the separate protocol review, in which a researcher funds research independently of an NIH grant, NIDA submits the researcher's protocol to several external reviewers who evaluate the protocol on the basis of scientific merit and relevance to the mission of NIDA and NIH.

Through those two avenues marijuana has been supplied to several research groups—most of those that apply. While there has been much discussion of NIDA's alleged failure to supply marijuana for research purposes, we are unaware of recent cases in which they failed to supply marijuana to an investigator with an NIH-approved grant for research on marijuana. Donald Abrams's difficulty in obtaining research funding and marijuana from NIDA has been much discussed,² but the case of a single individual should not be presumed to be representative of the community of marijuana researchers. Failure of investigators who apply to NIH for marijuana research grants to receive funding is hardly exceptional: in 1998 less than 25% of *all* first-time investigator-initiated grant applications (known as RO1s) to the NIH were funded.³⁸

To import marijuana under the CSA for research purposes, the procedures are more complex. Under DEA regulations, marijuana can be imported, provided that the researcher is registered with the DEA, has approval for marijuana research (21 CFR § 1301.11, .13, and .18), and has a DEA-approved permit for importation (21 CFR § 1312.11, .12, and .13), and that the exporter in the foreign country has appropriate authorization by the country of exportation. Importation would enable U.S. researchers to conduct research on marijuana grown by HortaPharm, a company that has developed unique strains of marijuana. However, no U.S. researcher has imported HortaPharm's marijuana because Dutch authorities have refused to issue an export permit, despite the issuance of an import permit by the DEA (D. Pate, HortaPharm, personal communication, 1998).*

HortaPharm, which is in the Netherlands, grows marijuana as a raw material for the manufacture of pharmaceuticals. Through selective breeding and controlled production, HortaPharm has developed marijuana strains that feature single cannabinoids, such as THC or cannabidiol. The plants contain a consistently "clean" phytochemical profile and a higher

*It might eventually be possible to import HortaPharm's marijuana from England, where HortaPharm is growing its marijuana strains for research use in clinical trials for multiple sclerosis (Boseley, 1998).¹⁰ England, as the country of origin, would have to provide appropriate authorization for export of the strains to the United States. Permission to export for research purposes is part of the basis for HortaPharm's participation in this project with GW Pharmaceuticals through a special set of licenses with the British Home Office (David Pate, HortaPharm, personal communication, 1998).

concentration of THC (16%) or other desired cannabinoids than seized marijuana. Marijuana seized in the United States in 1996 had a THC content averaging about 5%.¹⁶ Consistency of THC content is desirable because it overcomes the natural variability due to latitude, weather, and soil conditions. Product consistency is a basic tenet of pharmacology because it enables standardized dosing for regulatory and treatment purposes.

The difficulties of conducting research on marijuana were noted in the 1997 NIH report⁴⁰ that recommended that NIH facilitate clinical research by developing a centralized mechanism to promote design, approval, and conduct of clinical trials.

Regulatory Hurdles to Market

For marijuana to be marketed legally in the United States, a sponsor with sufficient resources would be obliged to satisfy the regulatory requirements of both the FD&C act and the CSA.

Under the FD&C act, a botanical product like marijuana *theoretically* might be marketed in oral form as a dietary supplement;* however, as a practical matter, only a new drug approval is likely to satisfy the provisions of the CSA, which require prescribing and distribution controls on drugs of abuse that also have an “accepted medical use.” (The final paragraphs of this section clarify the criteria for “accepted medical use.”)

Bringing marijuana to market as a new drug is uncharted terrain. The route is fraught with uncertainty for at least three pharmacological reasons: marijuana is a botanical product, it is smoked, and it is a drug with abuse potential. In general, botanical products are inherently more difficult to bring to market than are single chemical entities because they are complex mixtures of active and inactive ingredients. Concerns arise about product consistency, potency of the active ingredients, contamination, and stability of both active and inactive ingredients over time. These are among the concerns that a sponsor would have to overcome to meet the requirements for an NDA, especially those related to safety and to chemistry, manufacturing, and control.

A handful of botanical preparations are on the market, but none received formal approval as a new drug by today’s standards of safety and efficacy (FDA, Center for Drug Evaluation and Research, personal communication, 1998). The three marketed botanical preparations are older drugs that came to market years before safety and efficacy studies were required by legislative amendments in 1938 and 1962, respectively.

*Inhaled products may not lawfully be marketed as dietary supplements.

One of the botanical preparations is the prescription product digitalis. Because it came to market before 1938, it is available today, having been “grandfathered” under the law; but it does not necessarily meet contemporary standards for safety and effectiveness.²⁰ Two other botanical preparations, psyllium and senna, came to market between 1938 and 1962. Drugs entering the market during that period were later required to be evaluated by the FDA in what is known as the over-the-counter drug review process,²⁰ through which psyllium and senna were found to be generally recognized as safe and effective and so were allowed to remain on the market as over-the-counter drugs.* Although no botanical preparations have been approved as new drugs, it is important to point out that a number of individual plant constituents, either extracted or synthesized *de novo*, have been approved (for example, taxol and morphine). But these drug approvals were for single constituents rather than botanical preparations themselves. The FDA is developing guidance for industry to explain how botanicals are reviewed as new drugs, but the final document might not be available before 1999.

That marijuana is smoked might pose an even greater regulatory challenge. The risks associated with smoking marijuana are described in chapter 2. The FDA would have to weigh those risks with marijuana’s therapeutic benefits to arrive at a judgment about whether a sponsor’s NDA for marijuana met the requirements for safety and efficacy under the FD&C act. Marijuana delivered in a novel way that avoids smoking would overcome some, but not all, of the regulatory concerns. Vaporization devices that permit inhalation of plant cannabinoids without the carcinogenic combustion products found in smoke are under development by several groups; such devices would also require regulatory review by the FDA.

The regulatory hurdles to market posed by the CSA are formidable but not insurmountable. If marijuana received market approval as a drug by the FDA, it would most likely be rescheduled under the CSA, as was the case for dronabinol. That is because a new drug approval satisfies the “accepted medical use” requirement under the CSA for manufacture and distribution in commerce.¹³ But a new drug approval is not the *only* means to reschedule marijuana under the CSA.¹⁴ For years advocates for rescheduling have argued that marijuana does enjoy “accepted medical use,” even in the absence of a new drug approval. Although advocates have been unsuccessful in rescheduling efforts, their actions prompted

*Over-the-counter monographs for these products have been issued as tentative final monographs (proposed rules) but have not yet been issued in final form as final rules (FDA, Center for Drug Evaluation and Research, personal communication, 1998).

the DEA to specify the criteria by which it would determine whether a substance had “accepted medical use.” In the DEA’s 1992 denial of a re-scheduling petition, it listed these elements as constituting “accepted medical use”: the drug’s chemistry must be known and reproducible, there must be adequate safety studies, there must be adequate and well-controlled studies proving efficacy, the drug must be accepted by qualified experts, and the scientific evidence must be widely available.¹⁴

Assuming that all of those criteria were satisfied, marijuana could be rescheduled—but into which schedule? The level of scheduling would be dictated primarily by a medical and scientific recommendation to the DEA made by the secretary of DHHS.* As noted earlier, this recommendation is determined by the five scheduling criteria listed in the CSA. However, scheduling in a category less restrictive than Schedule II might be prohibited by international treaty obligations. The Single Convention on Narcotic Drugs, a treaty ratified by the United States in 1967, restricts scheduling of the plant and its resin to at least Schedule II (the more restrictive Schedule I is another option).¹³

Market Outlook

The market outlook for the development of marijuana as a new drug, on the basis of the foregoing analysis, is not favorable, for a host of scientific, regulatory, and commercial reasons. From a scientific point of view, research is difficult because of the rigors of obtaining an adequate supply of legal, standardized marijuana for study. Further scientific hurdles are related to satisfying the exacting requirements for FDA approval of a new drug. The hurdles are even more exacting for a botanical product because of the inherent problems with, for example, purity and consistency. Finally, the health risks associated with smoking pose another barrier to FDA approval unless a new smoke-free route of administration is demonstrated to be safe. Depending on the route of administration, an additional overlay of regulatory requirements might have to be satisfied.

From a commercial point of view, uncertainties abound. The often-cited cost of new drug development, about \$200–\$300 million, might not apply, but there are probably additional costs needed to satisfy the FDA’s requirements for a botanical product. As noted above, no botanical products have ever been approved as new drugs by the FDA under today’s stringent standards for safety and efficacy. Satisfying the legal require-

*At present, there is no practical mechanism for generating such a recommendation outside the new drug approval process, although such a mechanism could, theoretically, be developed.³³

ments of the CSA also will add substantially to the cost of development. On the positive side, so much research already has been done that some development costs will be lower. The cost of bringing dronabinol to market, for example, was reduced dramatically as a result of clinical trials supported with government funding. Nevertheless, it is impossible to estimate the cost of developing marijuana as a new drug. Estimating return on investment is similarly difficult. A full-fledged market analysis would be required for the indication being sought. Such an analysis would take into account the market limitations resulting from drug scheduling restrictions, stigma, and patentability.

The plant does not constitute patentable subject matter under U.S. patent law because it is unaltered from what is found in nature. So-called products of nature are not generally patentable.²⁸ New marijuana strains, however, could be patentable in the United States under a product patent or a plant patent because they *are* altered from what is found in nature. (A product patent prohibits others from manufacturing, using, or selling each strain for 20 years; a plant patent carries somewhat less protection.) HortaPharm has not yet sought any type of patent for its marijuana strains in the United States, but it has received approval for a plant registration in Europe (David Watson, HortaPharm, personal communication, 1998).

In short, development of the marijuana plant is beset by substantial scientific, regulatory, and commercial obstacles and uncertainties. The prospects for its development as a new drug are unfavorable unless return on investment is not a driving force. It is noteworthy that no pharmaceutical firm has sought to bring it to market in the United States. The only interest in its development appears to be in England in a small pharmaceutical firm (see Boseley, 1998¹⁰) and in the United States among physicians without formal ties to pharmaceutical firms (D. Abrams, University of California at San Francisco, and E. Russo, Western Montana Clinic, personal communications, 1998).

CONCLUSIONS

Cannabinoids are an interesting group of compounds with potentially far-reaching therapeutic applications. There is a surge of scientific interest in their development as new drugs, but the road to market for any new drug is expensive, long, risky, and studded with scientific, regulatory, and commercial obstacles. Experience with the only approved cannabinoid, dronabinol, might not illuminate the pathway because of the government's heavy contribution to research and development, dronabinol's scheduling history, and its small market.

There appear to be only two novel cannabinoids actively being developed for human use, but they have yet to be tested in humans in the

United States. Their experience is likely to be more predictive of the marketing prospects for other cannabinoids. It is too early to forecast the prospects for cannabinoids, other than to note that their development at this point is considered to be especially risky, to judge by the paucity of products in development and the small size of the pharmaceutical firms sponsoring them.

The market outlook in the United States is distinctly unfavorable for the marijuana plant and for cannabinoids found in the plant. Commercial interest in bringing them to market appears nonexistent. Cannabinoids in the plant are automatically placed in the most restrictive schedule of the Controlled Substances Act, and this is a substantial deterrent to development. Not only is the plant itself subject to the same scheduling strictures as are individual plant cannabinoids, but development of marijuana also is encumbered by a constellation of scientific, regulatory, and commercial impediments to availability.

Workshop Agendas

Workshop on Perspectives on the Medical Use of Marijuana: Basic and Clinical Science

December 14–16, 1997
Beckman Center, Irvine, California

AGENDA

Sunday, December 14, 1997

- 2:00 p.m. Introduction
Constance Pechura, *IOM Division Director*,
Neuroscience and Behavioral Health
- 2:30 p.m. Public Input Session, *5 minutes per person*
Moderator: Stanley Watson, Jr., *IOM Study Investigator*,
University of Michigan
- 5:30 p.m. ADJOURN

Monday, December 15, 1997

CANNABINOID NEUROSCIENCE

- 8:30 a.m. **Moderator:** Stanley Watson, *IOM Study Investigator*,
University of Michigan
- 8:45 a.m. **Neuropharmacology of Cannabinoids and Their Receptors**
Steven R. Childers, Wake Forest University School of
Medicine
- 9:15 a.m. **Precipitated Cannabinoid Withdrawal and Sensory
Processing of Painful Stimuli**
J. Michael Walker, Brown University
- 9:45 a.m. **Role of Cannabinoids in Movement**
Clara Sanudo, Brown University
- 10:15 a.m. **Tolerance and Cannabinoid-Opioid Interactions**
Sandra P. Welch, Medical College of Virginia
- 10:45 a.m. BREAK
- MEDICAL USES OF MARIJUANA:
CLINICAL DATA AND BASIC BIOLOGY
- 11:10 a.m. **Moderator:** John A. Benson, Jr., *IOM Study Investigator*,
Oregon Health Sciences University
- 11:15 a.m. **Profile of Medical Marijuana Users**
John Mendelson, University of California at San Francisco
- 11:45 a.m. **Immune Modulation by Cannabinoids**
Norbert Kaminski, Michigan State University
- 12:15 p.m. **Psychological Effects of Marijuana Use**
Charles R. Schuster, Wayne State University
- 12:45 p.m. LUNCH

- 1:45 p.m. **Marijuana and Glaucoma**
 Paul Kaufman, University of Wisconsin
- 2:15 p.m. **Effects of Marijuana and Cannabinoids in Neurological Disorders**
 Paul Consroe, University of Arizona Health Sciences Center
- 2:45 p.m. **Neural Mechanisms of Cannabinoid Analgesia**
 Howard Fields, University of California at San Francisco
- 3:15 p.m. **Pain Management**
 Michael Rowbotham, University of California at San Francisco
- 3:45 p.m. **Wasting Syndrome Pathogenesis and Clinical Markers**
 Donald Kotler, St. Luke's-Roosevelt Hospital
- 4:15 p.m. **Clinical Experience with Marijuana**
 Stephen O'Brien, East Bay AIDS Center
- 4:45 p.m. ADJOURN

Tuesday, December 16, 1997

MEDICAL USES OF MARIJUANA:
 CLINICAL DATA AND BASIC BIOLOGY

- 8:30 a.m. **Moderator:** John A. Benson, Jr., *IOM Study Investigator*,
 Oregon Health Sciences University
- 8:45 a.m. **Marijuana in AIDS Wasting: Tribulations and Trials**
 Donald I. Abrams, University of California at San Francisco
- 9:15 a.m. **Nausea and Vomiting: Underlying Mechanisms and Upcoming Treatments**
 Alan D. Miller, The Rockefeller University
- 9:45 a.m. **Postchemotherapy Nausea and Antiemetics**
 Richard J. Gralla, Ochsner Cancer Center

10:15 a.m. BREAK

SUMMARY VIEWS

10:30 a.m. **Marijuana Is Different from THC: A Review of Basic Research and State Studies of Antiemesis**

Richard E. Musty, University of Vermont

11:00 a.m. **Medical Uses of Crude Marijuana: Medical and Social Issues**

Eric A. Voth, The International Drug Strategy Institute

11:30 a.m. **General Questions**

Moderator: John A. Benson, Jr., *IOM Study Investigator*

12:00 noon ADJOURN

**Workshop on
Acute and Chronic Effects of Marijuana Use**

January 22–23, 1998
New Orleans Marriott Hotel
New Orleans, Louisiana

AGENDA

Thursday, January 22, 1998

- 2:00 p.m. Introduction
Constance Pechura, *IOM Division Director*,
Neuroscience and Behavioral Health
- 2:30 p.m. Public Input Session, *5 minutes per person*
Moderator: Stanley Watson, Jr., *IOM Study Investigator*,
University of Michigan
- 4:30 p.m. ADJOURN

Friday, January 23, 1998

- 8:30 a.m. **Moderator:** John A. Benson, Jr., *IOM Study Investigator*,
Oregon Health Sciences University

HEALTH CONSEQUENCES OF MARIJUANA USE

- 9:00 a.m. **Health Consequences of Marijuana Use: Epidemiological
Studies**
Stephen Sidney, Kaiser Permanente, Oakland, CA
- 9:30 a.m. **Immunity, Infections, and Cannabinoids**
Thomas Klein, University of South Florida
- 10:00 a.m. **Pulmonary Effects of Smoked Marijuana**
Donald Tashkin, University of California at Los Angeles
- 10:30 a.m. BREAK

10:45 a.m. **Is Marijuana Carcinogenic?: Epidemiological and Biological Evidence**

Panel Discussion

Stephen Sidney
Donald Tashkin

12:00 noon LUNCH

EFFECTS OF MARIJUANA ON BEHAVIOR

1:30 p.m. **Marijuana: Addictive and Amotivational States, the Scientific Evidence**

John Morgan, City University of New York Medical School

2:00 p.m. **Marijuana's Acute Behavioral Effects in Humans**

Richard Foltin, Columbia University

2:30 p.m. **Tolerance and Dependence Following Chronic Administration of Oral THC or Smoked Marijuana to Humans**

Margaret Haney, Columbia University

3:00 p.m. **Patterns of Continuity and Discontinuity of Marijuana Use in Relationship to Other Drugs**

Robert Pandina, Rutgers University

3:30 p.m. ADJOURN

Workshop on Prospects for Cannabinoid Drug Development

February 23–24, 1998
 National Academy of Sciences Building
 Washington, D.C.

AGENDA

Monday, February 23, 1998

- 1:30 p.m. Introduction
 Constance Pechura, *IOM Division Director*,
 Neuroscience and Behavioral Health
- 2:00 p.m. Public Input Session, *5 minutes per person*
 Moderator: John A. Benson, Jr., *IOM Study Investigator*,
 Oregon Health Sciences University
- 5:30 p.m. ADJOURN

Tuesday, February 24, 1998

- 8:30 a.m. Introduction
 Constance Pechura, *IOM Division Director*
 Neuroscience and Behavioral Health
- Moderator:** Stanley J. Watson, Jr., *IOM Study Investigator*,
 University of Michigan

OVERVIEWS OF PRECEDING WORKSHOPS

- 8:45 a.m. **Acute and Chronic Effects of Marijuana**
 Billy R. Martin, Medical College of Virginia
- 9:25 a.m. **Perspectives on the Medical Use of Marijuana**
 Eric B. Larson, University of Washington Medical School
- 9:55 a.m. **The Neurobiology of Cannabinoid Dependence**
 George F. Koob, Scripps Research Institute
- 10:25 a.m. BREAK

DRUG DEVELOPMENT

10:45 a.m. **Regulatory Requirements Affecting Marijuana**

J. Richard Crout, Crout Consulting

11:15 a.m. **Marinol and the Market**

Robert E. Dudley, Unimed Pharmaceuticals, Inc.

11:45 a.m. **Development of Cannabis-based Therapeutics**

Dave Pate, HortaPharm, B.V.

12:15 p.m. LUNCH

DRUG DELIVERY

1:30 p.m. **Alternative Drug Delivery Technologies for the
Therapeutic Use of Marijuana**

Phyllis I. Gardner, ALZA Corporation, Stanford University

2:00 p.m. **Delivery of Analgesics via the Respiratory Track**

Reid M. Rubsamen, Aradigm Corporation

An Alternative to Oral and Smoked THC**

Mahmoud A. ElSohly, University of Mississippi,
ElSohly Laboratories, Inc.

3:30 p.m. **Concluding Remarks**

John A. Benson, Jr., *IOM Study Investigator*,
Oregon Health Sciences University

3:45 p.m. ADJOURN

APPENDIX C

Scheduling Definitions

SCHEDULING DEFINITIONS ESTABLISHED BY THE CONTROLLED SUBSTANCES ACT OF 1970

Schedule I (includes heroin, LSD, and marijuana)

- (A) The drug or other substance has a high potential for abuse.
- (B) The drug or other substance has no currently accepted medical use in treatment in the United States.
- (C) There is a lack of accepted safety for the use of the drug or other substance under medical supervision.

Schedule II (includes Marinol, methadone, morphine, methamphetamine, and cocaine)

- (A) The drug or other substance has a high potential for abuse.
- (B) The drug or other substance has a currently accepted medical use in treatment in the United States or a currently accepted medical use with severe restrictions.
- (C) Abuse of the drug or other substances may lead to severe psychological or physical dependence.

Schedule III (includes anabolic steroids)

- (A) The drug or other substance has a potential of abuse less than the drugs or other substances in Schedules I and II.

(B) The drug or other substance has a currently accepted medical use in treatment in the United States.

(C) Abuse of the drug or other substance may lead to moderate or low physical dependence or high psychological dependence.

Schedule IV (includes Valium and other tranquilizers)

(A) The drug or other substance has a low potential for abuse relative to the drugs or other substances in Schedule III.

(B) The drug or other substance has a currently accepted medical use in treatment in the United States.

(C) Abuse of the drug or other substance may lead to limited physical dependence or psychological dependence relative to the drugs or other substances in Schedule III.

Schedule V (includes codeine-containing analgesics)

(A) The drug or other substance has a low potential for abuse relative to the drugs or other substances in Schedule IV.

(B) The drug or other substance has a currently accepted medical use in treatment in the United States.

(C) Abuse of the drug or other substance may lead to limited physical dependence or psychological dependence relative to the drugs or other substances in Schedule IV.

SOURCES: LeCraw (1996) and 21 U.S.C. 812.

APPENDIX D

Statement of Task

The study will assess what is currently known and not known about the medical use of marijuana. It will include a review of the science base regarding the mechanism of action of marijuana, an examination of the peer-reviewed scientific literature on the efficacy of therapeutic uses of marijuana, and the costs of using various forms of marijuana versus approved drugs for specific medical conditions (e.g., glaucoma, multiple sclerosis, wasting diseases, nausea, and pain).

The study will also include an evaluation of the acute and chronic effects of marijuana on health and behavior; a consideration of the adverse effects of marijuana use compared with approved drugs; an evaluation of the efficacy of different delivery systems for marijuana (e.g., inhalation vs. oral); an analysis of the data concerning marijuana as a gateway drug; and an examination of the possible differences in the effects of marijuana due to age and type of medical condition.

SPECIFIC ISSUES

Specific issues to be addressed fall under three broad categories: the science base, therapeutic use, and economics.

Science Base

- Review of neuroscience related to marijuana, particularly the relevance of new studies on addiction and craving.
- Review of behavioral and social science base of marijuana use, par-

ticularly assessment of the relative risk of progression to other drugs following marijuana use.

- Review of the literature determining which chemical components of crude marijuana are responsible for possible therapeutic effects and for side effects.

Therapeutic Use

- Evaluation of any conclusions on the medical use of marijuana drawn by other groups.
- Efficacy and side effects of various delivery systems for marijuana compared to existing medications for glaucoma, wasting syndrome, pain, nausea, or other symptoms.
- Differential effects of various forms of marijuana that relate to age or type of disease.

Economics

- Costs of various forms of marijuana compared with costs of existing medications for glaucoma, wasting syndrome, pain, nausea, or other symptoms.
- Assessment of the differences between marijuana and existing medications in terms of access and availability.

These specific areas along with the assessments described above will be integrated into a broad description and assessment of the available literature relevant to the medical use of marijuana.

APPENDIX E

Recommendations Made in Recent Reports on the Medical Use of Marijuana

Recommendations from five recent key reports pertaining to the medical use of marijuana are listed below by subject. Recommendations made on issues outside the scope of this report, such as drug law and scheduling decisions, are not included here. The following reports were reviewed:

- Health Council of the Netherlands, Standing Committee on Medicine. 1996. *Marihuana as Medicine*. Rijswijk, the Netherlands: Health Council of the Netherlands.
- *Report of the Council on Scientific Affairs*. 1997. Report to the American Medical Association House of Delegates. Subject: Medical Marijuana. Chicago: AMA.
- British Medical Association. 1997. *Therapeutic Uses of Cannabis*. United Kingdom: Harwood Academic Publishers.
- National Institutes of Health. 1997. *Workshop on the Medical Utility of Marijuana*. Bethesda, MD: National Institutes of Health.
- World Health Organization. 1997. *Cannabis: A Health Perspective and Research Agenda*. Geneva: WHO.

In November 1998, the British House of Lords Science and Technology Committee published *Medical Use of Cannabis*, in which the committee reported its conviction that “cannabis almost certainly does have genuine medical applications.” The House of Lords report was released too late in the preparation of the present Institute of Medicine report to per-

mit careful analysis and is not summarized here. It is available on the Internet at: *www.parliament.uk*.

GENERAL RECOMMENDATIONS

Health Council of the Netherlands

In order to assess the efficacy of marijuana and cannabinoids, the committee studied literature published during the past 25 years. Based on those findings, the committee concluded that there was insufficient evidence to justify the medical use of marijuana.

AMA House of Delegates

Adequate and well-controlled studies of smoked marijuana should be conducted in patients who have serious conditions for which preclinical, anecdotal, or controlled evidence suggests possible efficacy, including AIDS wasting syndrome, severe acute or delayed emesis induced by chemotherapy, multiple sclerosis, spinal cord injury, dystonia, and neuropathic pain.

British Medical Association

Research on the clinical indications for medical prescription of cannabinoids should be undertaken. For all indications listed below (antiemetics, pain, epilepsy, glaucoma, asthma, immunological effects, multiple sclerosis, spinal cord injury, and other spastic disorders) further research is required to establish suitable methods of administration, optimal dosage regimens, and routes of administration. A central registry should be kept of patients prescribed cannabinoids so that the effects can be followed up over the long term.

National Institutes of Health

For at least some potential indications, marijuana looks promising enough to recommend that new controlled studies be done. The indications in which varying levels of interest were expressed are the following: appetite stimulation and wasting, chemotherapy-induced nausea and vomiting, neurological and movement disorders, analgesia, [and] glaucoma. Until studies are done using scientifically acceptable clinical trial design and subjected to appropriate statistical analysis, the question concerning the therapeutic utility of marijuana will likely remain largely un-

answered. To the extent that the NIH can facilitate the development of a scientifically rigorous and relevant database, the NIH should do so.

World Health Organization

Therapeutic uses of cannabinoids warrant further basic pharmacological and experimental investigation and clinical research into their effectiveness. More research is needed on the basic neuropharmacology of THC and other cannabinoids so that better therapeutic agents can be found.

ANALGESIA

Health Council of the Netherlands

No recommendations made.

AMA House of Delegates

Controlled evidence does not support the view that THC or smoked marijuana offers clinically effective analgesia without causing significant adverse events when used alone. Preclinical evidence suggests that cannabinoids can potentiate opioid analgesia and that cannabinoids may be effective in animal models of neuropathic pain. Further research into the use of cannabinoids in neuropathic pain is warranted.

British Medical Association

The prescription of nabilone, THC, and other cannabinoids should be permitted for patients with intractable pain. Further research is needed into the potential of cannabidiol as an analgesic in chronic, terminal, and postoperative pain.

National Institutes of Health

Evaluation of cannabinoids in the management of neuropathic pain, including HIV-associated neuropathy, should be undertaken.

World Health Organization

No recommendations made, although the report notes that some newly synthesized cannabinoids are extremely potent analgesics; how-

ever, separation of the analgesia and side effects remains to be demonstrated.

NAUSEA AND VOMITING

Health Council of the Netherlands

No recommendations made.

AMA House of Delegates

THC and smoked marijuana are considerably less effective than currently available therapies to treat acute nausea and vomiting caused by chemotherapy, although certain patients still do not respond adequately to conventional therapy. Research involving THC and smoked marijuana should focus on their possible use in treating delayed nausea and vomiting and their adjunctive use in patients who respond inadequately to 5-HT₃ antagonists. The use of an inhaled substance has the potential to benefit ambulatory patients who are experiencing the onset of nausea and are thus unable to take oral medications.

British Medical Association

Further research is needed on the use of Δ^8 -THC as an antiemetic, the use of cannabidiol in combination with THC, and the relative effectiveness of cannabinoids compared with 5-HT₃ antagonists. Further research is needed in other cases, such as postoperative nausea and vomiting.

National Institutes of Health

Inhaled marijuana merits testing in controlled, double-blind, randomized trials for nausea and vomiting.

World Health Organization

More basic research on the central and peripheral mechanisms of the effects of cannabinoids on gastrointestinal function may improve the ability to alleviate nausea and emesis.

WASTING SYNDROME AND APPETITE STIMULATION

Health Council of the Netherlands

No recommendations made.

AMA House of Delegates

THC is moderately effective in the treatment of AIDS wasting, but its long duration of action and intensity of side effects preclude routine use. The ability of patients who smoke marijuana to titrate their dosage according to need and the lack of highly effective, inexpensive options to treat this debilitating disease create the conditions warranting formal clinical trials of smoked marijuana as an appetite stimulant in patients with AIDS wasting syndrome.

British Medical Association

Allowing the prescription of nabilone and THC for cancer chemotherapy and HIV/AIDS seems justified for preventing weight loss and treating anorexia in HIV/AIDS irrespective of whether the patient is experiencing nausea and/or vomiting.

National Institutes of Health

Areas of study for the potential appetite-stimulating properties of marijuana include the cachexia of cancer, HIV/AIDS symptomatology, and other wasting syndromes. Investigations should be designed to assess long-term effects on immunology status, the rate of viral replication, and clinical outcomes in participants as well as weight gain. In therapeutic trials of cachexia, research should attempt to separate out the effect of marijuana on mood versus appetite. Some questions need to be answered in the studies: (1) Does smoking marijuana increase total energy intake in patients with catabolic illness? (2) Does marijuana use alter energy expenditure? (3) Does marijuana use alter body weight and to what extent? (4) Does marijuana use alter body composition and to what extent?

World Health Organization

No specific recommendations are made, although the report notes that dronabinol is an effective appetite stimulant for patients with AIDS wasting syndrome.

MUSCLE SPASTICITY

Health Council of the Netherlands

No recommendations made.

AMA House of Delegates

Considerably more research is required to identify patients who may benefit from THC or smoked marijuana and to establish whether responses are primarily subjective in nature. A therapeutic trial of smoked marijuana or THC may be warranted in patients with spasticity who do not derive adequate benefit from available oral medications, prior to their considering intrathecal baclofen therapy or neuroablative procedures.

British Medical Association

A high priority should be given to carefully controlled trials of cannabinoids in patients with chronic spastic disorders that have not responded to other drugs are indicated. In the meantime, there is a case for the extension of the indications for nabilone and THC for use in chronic spastic disorders unresponsive to standard drugs.

National Institutes of Health

No recommendations are made, although the report notes that marijuana or the use of other cannabinoids as human therapies might be considered for treating spasticity and nocturnal spasms complicating multiple sclerosis and spinal cord injury.

World Health Organization

The report notes that cannabinoids have not yet been proven useful in treating multiple sclerosis, but therapeutic uses of cannabinoids are being demonstrated by controlled studies as an antispasmodic. Research in this area should continue.

MOVEMENT DISORDERS

Health Council of the Netherlands

No recommendations made.

AMA House of Delegates

Considerably more research is required to identify dystonic patients who may benefit from THC or smoked marijuana and to establish whether responses are primarily subjective in nature.

British Medical Association

The potential of (+)-HU-210 for neurodegenerative disorders should be explored through further research.

National Institutes of Health

No recommendations made, although the report notes that marijuana or the use of other cannabinoids as human therapies might be considered for treating for some forms of dystonia.

World Health Organization

No recommendations made, although the report notes that cannabinoids have not yet been proven useful in the treatment of movement disorders.

EPILEPSY**Health Council of the Netherlands**

No recommendations made.

AMA House of Delegates

No recommendations made.

British Medical Association

Trials with cannabidiol (which is nonpsychoactive), used to enhance the activity of other drugs in cases not well controlled by other anti-convulsants, are needed.

National Institutes of Health

No recommendations made, although the report notes that marijuana

or the use of other cannabinoids as human therapies might be considered for treating various active epilepsy states.

World Health Organization

No recommendations made, although the report notes that cannabinoids have not yet been proven useful in the treatment of convulsant disorders, but therapeutic uses of cannabinoids are being demonstrated by controlled studies as an anticonvulsant.

GLAUCOMA

Health Council of the Netherlands

No recommendations made.

AMA House of Delegates

Neither smoked marijuana nor THC is a viable approach in the treatment of glaucoma, but research on their mechanism of action may be important in developing new agents that act in an additive or synergistic manner with currently available therapies.

British Medical Association

Cannabinoids do not at present look promising for this indication, but much further basic and clinical research is needed to develop and investigate cannabinoids that lower intraocular pressure, preferably by topical application (e.g., eye drops, inhalant aerosols), without producing unacceptable systemic and central nervous system effects.

National Institutes of Health

Further studies to define the mechanism of action and to determine the efficacy of Δ^9 -tetrahydrocannabinol and marijuana in the treatment of glaucoma are justified. There does not appear to be any obvious reason to use smoked marijuana as a primary "stand-alone" investigational therapy, as there are many available agents for treatment, and these topical preparations seem to be potentially ideal. An approach that may be useful is to study smoked marijuana in incomplete responders to standard therapies. The suggested design for clinical studies is to add marijuana, oral THC, or placebo to standard therapy under double-blind conditions: (1) Establish dose-response and dose-duration relationships for intraocular pressure

(IOP) and central nervous system effects. (2) Relate IOP and blood pressure measurements longitudinally to evaluate potential tolerance development to cardiovascular effects. (3) Evaluate central nervous system effects longitudinally for tolerance development.

World Health Organization

No recommendations made, although the report notes that, while THC has long been known to reduce the increased intraocular pressure of glaucoma, it has not been fully studied therapeutically. The report also notes that therapeutic uses of cannabinoids are being demonstrated by controlled studies in the treatment of glaucoma.

PHYSIOLOGICAL HARMS

Health Council of the Netherlands

No recommendations made.

AMA House of Delegates

No recommendations made.

British Medical Association

Further research is needed to establish the suitability of cannabinoids for immunocompromised patients, such as those undergoing cancer chemotherapy or those with HIV/AIDS.

National Institutes of Health

Risks associated with smoked marijuana must be considered not only in terms of immediate adverse effects but also long-term effects in patients with chronic diseases. The possibility that frequent and prolonged marijuana use might lead to clinically significant impairments of immune system function is great enough that relevant studies should be part of any marijuana medication development research.

Additional studies of long-term marijuana use are needed to determine if there are or are not important adverse pulmonary, central nervous system, or immune system problems.

World Health Organization

Further studies are needed on the fertility effects in cannabis users in view of the high rate of use during the early reproductive years. Further clinical and experimental research is required on the effects of cannabis on respiratory function and respiratory diseases. More studies are needed to show whether cannabis affects the risk of lung malignancies and at what level of use that may occur. In addition, more studies are needed to clarify the rather different results of pulmonary histopathological studies in animals and man.

More clinical and experimental research is needed on the effects of cannabis on immunological function. More clarity should be sought concerning the molecular mechanisms responsible for immune effects, including both cannabinoid receptor and nonreceptor events.

The possibility that chronic cannabis use has adverse effects on the cardiovascular system should have a priority in epidemiological research.

Research on chronic and residual cannabis effects is also needed. The pharmacokinetics of chronic cannabis use in humans are poorly described, and this lack of knowledge restricts the ability of researchers to relate drug concentrations in blood or other fluids and observed effects.

PSYCHOLOGICAL HARMS

Health Council of the Netherlands

No recommendations made.

AMA House of Delegates

No recommendations made.

British Medical Association

No recommendations made.

National Institutes of Health

No recommendations made.

World Health Organization

There is a need for controlled studies investigating the relationships between cannabis use, schizophrenia, and other serious mental disorders.

There is also a need for case-controlled studies comparing those experiencing cannabis problems with people who have, and do not have, alcohol and other psychoactive substance use problems.

There is a need for better delineation of the clinical features of cannabis dependence and for studies of its responsiveness to interventions aimed at assisting users to stop.

Insufficient research has been undertaken on the “amotivational” syndrome which may or may not result from heavy cannabis use. It is not clear that the syndrome exists, even though heavy cannabis use is sometimes associated with reduced motivation to succeed in school and work. New research is needed to show whether the reduced motivation seen in some cannabis users is due to other psychoactive substance use and whether it precedes cannabis use.

Further development of cognitive and psychomotor tests for controlled studies that are sensitive to the performance effects of cannabis use and that reflect the complexity of specific daily functions (e.g., driving, learning, reasoning) also need additional research.

More research is needed to examine the relationship between THC concentrations in blood and other fluids and the degree of behavioral impairment produced.

SMOKED MARIJUANA AND USE OF PLANTS AS MEDICINE

Health Council of the Netherlands

The committee believes that physicians cannot accept responsibility for a product of unknown composition that has not been subjected to quality control.

AMA House of Delegates

No specific recommendations made, but related issues are discussed in the general recommendation and drug development sections.

British Medical Association

Prescription formulations of cannabinoids or substances acting on the cannabinoid receptors should not include either cigarettes or herbal preparations with unknown concentrations of cannabinoids or other chemicals.

National Institutes of Health

Smoked marijuana should be held to standards equivalent to other

medications for efficacy and safety considerations. There might be some patient populations for whom the inhalation route might offer advantages over the currently available capsule formulation. Smoking plant material poses difficulties in standardizing testing paradigms, and components of the smoke are hazardous, especially in the immunocompromised patient. Therefore, the experts generally favored the development of alternative dosage forms, including an inhaler dosage form into which a controlled unit dose of THC could be placed and volatilized.

World Health Organization

Not discussed in the context of medical use, although many health hazards associated with chronic marijuana smoking are noted.

DRUG DEVELOPMENT

Health Council of the Netherlands

Not discussed.

AMA House of Delegates

The National Institutes of Health should use its resources to support the development of a smoke-free inhaled delivery system for marijuana or THC to reduce the health hazards associated with the combustion and inhalation of marijuana.

British Medical Association

Pharmaceutical companies should undertake basic laboratory investigations and develop novel cannabinoid analogs that may lead to new clinical uses.

National Institutes of Health

NIH should use its resources and influence to rapidly develop a smoke-free inhaled delivery system for marijuana or THC. A recommendation was made for the development of insufflation/inhalation devices or dosage forms capable of delivering purer THC or cannabinoids to the lungs free of dangerous combustion byproducts.

World Health Organization

Not discussed.

APPENDIX F

Rescheduling Criteria

DRUG ENFORCEMENT AGENCY'S FIVE-FACTOR TEST FOR RESCHEDULING*

1. The drug's chemistry must be known and reproducible.

The substance's chemistry must be scientifically established to permit it to be reproduced in dosages which can be standardized. The listing of the substance in a current edition of one of the official compendia, as defined by section 201(j) of the Food, Drug, and Cosmetic Act, 21 USC 321(f), is sufficient generally to meet this requirement.

2. There must be adequate safety studies.

There must be adequate pharmacological and toxicological studies done by all methods reasonably applicable on the basis of which it could be fairly and responsibly concluded, by experts qualified by scientific training and experience to evaluate the safety and effectiveness of drugs, that the substance is safe for treating a specific, recognized disorder.

3. There must be adequate and well-controlled studies proving efficacy.

There must be adequate, well-controlled, well-designed, well-conducted, and well-documented studies, including clinical investigations, by experts qualified by scientific training and experience to evaluate

*Formulated in 1992 in response to a court challenge to scheduling.

the safety and effectiveness of drugs on the basis of which it could fairly and responsibly be concluded by such experts that the substance will have its intended effect in treating a specific, recognized disorder.

4. The drug must be accepted by qualified experts.

The drug must have a New Drug Application (NDA) approved by the Food and Drug Administration . . . or, a consensus of the national community of experts, qualified by scientific training and experience to evaluate the safety and effectiveness of drugs, accepts the safety and effectiveness of the substance for use in treating a specific, recognized disorder. A material conflict of opinion among experts precludes a finding of consensus.

5. The scientific evidence must be widely available.

In the absence of NDA approval, information concerning the chemistry, pharmacology, toxicology, and effectiveness of the substance must be reported, published, or otherwise widely available in sufficient detail to permit experts, qualified by scientific training and experience to evaluate the safety and effectiveness of drugs, to fairly and responsibly conclude the substance is safe and effective for use in treating a specific, recognized disorder.

Executive Summary

In May 2014, Minnesota became the 22nd state to create a medical cannabis program. Distribution of extracted cannabis products in liquid or oil form to qualified, enrolled patients began July 1, 2015. Minnesota's medical cannabis program is distinct from those in nearly all other states as the Minnesota Department of Health's Office of Medical Cannabis is required to study and learn from the experience of participants. This report draws on data from enrollment, purchasing and related health information, and survey results to describe the experience of patients who enrolled during the first year of the program's operation: July 1, 2015 through June 30, 2016.

The Office of Medical Cannabis anticipates performing additional analyses of data for the first year cohort of enrolled patients, as well as initiating analyses of data from patients who enrolled in the program later. Of particular interest are patients who enrolled after intractable pain became a qualifying condition on August 1, 2016. A report is planned for the end of 2017 that will give a preliminary look at the experience of the first several hundred patients certified for intractable pain. It is possible that focused projects will be developed in the future that will draw on medical record information to answer specific questions raised by analyses of the kinds of program data described in this report.

Participation

Between July 1, 2015 and June 30, 2016 a total of 1660 patients enrolled in the program and 577 health care practitioners registered themselves in order to certify that patients have a medical condition that qualifies them for the program. The most common qualifying conditions were severe and persistent muscle spasms (43%), cancer (28%), and seizures (20%). Each of the remaining six qualifying conditions during the first year – Crohn's Disease, Terminal illness, HIV/AIDS, Tourette Syndrome, glaucoma, and ALS – accounted for less than 10% of patients. Ten percent (167 patients) were certified for more than one qualifying condition. Most patients were middle-aged (56% between ages 36-64), 11% were <18, and 11% were ≥65. Distribution by race/ethnicity generally matched the state's demographics, with 90% of patients describing themselves as white.

The legislation that established the program specified there would be one location for purchasing medical cannabis (called Cannabis Patient Centers; CPCs) in each of the state's eight congressional districts. Patients who enrolled in the program during the first year came from throughout the state, with the average distance from the patient's home to the nearest CPC 29 miles (median distance=16 miles). Some patients were a considerable distance from the nearest CPC, however, with 13% over 60 miles from the nearest one. The program allows patients to have one or more parents or non-parent caregivers who register with the program, who are then allowed to transport and administer a patient's medical cannabis. Only 11%

of patients had a registered caregiver, 17% had a registered parent or guardian, and 26% had either a registered parent/legal guardian or a registered caregiver.

Among the 577 health care practitioners who registered with the program 82% were physicians, 13% were advanced practice registered nurses, and 5% were physician assistants.

Medical Cannabis Purchasing Patterns

Most patients make their first medical cannabis purchase within 14 days of program approval. Subsequent purchases typically follow a roughly monthly periodicity. However, intervals between purchases are sometimes less than a month, especially during the first months of program participation as the patient experiments with small amounts of different products. And intervals between purchases are sometimes much longer than a month. Using a cutoff of six months without any medical cannabis purchases as a surrogate for program discontinuation, 51% of patients who enrolled and made a purchase within the first six months of the program discontinued participation in the program as of December 31, 2016.

Medical Cannabis Use Patterns

Each patient's medical cannabis purchasing transactions during their first enrollment year (or through early March if still within their first enrollment year) were analyzed. A total of 16,238 products were purchased during 10,898 transactions, with 38% of all transactions consisting of two or more products. For analytic purposes, products were classified according to the ratio of delta-9-tetrahydrocannabinol (THC) to cannabidiol (CBD) as follows: Very High THC:CBD (100:1 or higher), High THC:CBD (>4:1 up to 99:1), Balanced THC:CBD (1:1 up to 4:1), High CBD:THC (\geq 1:1 up to 99:1), and Very High CBD:THC (100:1 or higher).

Products for enteral administration (swallowed – includes capsules and oral solutions) and products for inhalation (vaporized oil) each accounted for 45% of product purchases. Products for oromucosal administration (absorption through cheek) accounted for 9%. Nearly 50% of all purchases were Very High THC:CBD products, followed by Balanced THC:CBD (30%) and High CBD:THC (15%). Very High THC:CBD products were most commonly oil for vaporization or for oromucosal absorption, while Balanced THC:CBD and High CBD:THC products were most often for enteral administration.

Examining purchasing history across all patients is very complex for reasons that include experimentation with different products over time. As a first approach to assessing routine use of products, most frequently purchased products were examined for each patient. For 28% of patients, two or more products were purchased the same number of times. The product types that emerged as most frequently purchased were Very High THC vaporization oil (25%), High CBD:THC enteral preparations (14%), and Balanced enteral preparations (13%). Most frequently purchased product types varied considerably across medical conditions.

Benefits

Information on patient benefits comes from the Patient Self-Evaluations (PSE) completed by patients prior to each medical cannabis purchase and from patient and health care practitioner surveys. Results of analysis of PSE and survey data indicate perceptions of a high degree of benefit for most patients.

Patients responded to a survey question asking them how much benefit they believe they received from using medical cannabis on a scale from 1 (no benefit) to 7 (great deal of benefit). Across all patients 64% indicated a benefit rating of 6 or 7 and this degree of benefit was indicated by at least half of the patients with each medical condition. A small but important proportion of patients indicated little or no benefit: 9% gave a rating of 1, 2, or 3. Benefit ratings varied somewhat by qualifying medical condition. When patients were asked what the most important benefit was for them, two-thirds indicated a reduction in symptoms directly related to their qualifying medical condition and most of the remainder indicated more general quality of life benefits.

An important part of this report is the verbatim comments written by patients, and the reader is encouraged to review these comments, presented in an Appendix. Examples of these comments include:

- “Almost all muscle spasm and pain associated with spasms are gone. I used to have constant nerve triggered pain that is minimal now. Results were almost immediate. I am sleeping way better now also.”
- “[NAME] has passed away. I am her daughter and was her care giver. She was open to trying medical cannabis and we got the liquid form. It was a saving grace. She was in a lot of pain and when prescribed medications did NOT work – we started this and it kept her calm and relaxed. I am very thankful that we were able to have this option available. It helped to make her last months more bearable and truly it would have been miserable without it.”
- “I am getting enough sleep for the first time since about 2011. My absence seizures have gone from 3-4 a day to almost 0. It also has lessened the severity of grand mal seizures. The recovery time after has gone from around 12 hours to around 4.”
- “At first it helped a lot but my seizures have returned.”
- “Spasms – only a little better.”

Health care practitioners were somewhat more conservative in assessment of benefit to their patients. Across all the benefit ratings by health care practitioners, 38% indicated a rating of 6 or 7 and 23% indicated little or no benefit (rating of 1, 2, or 3). Similarity in benefit assessment between health care practitioners and patients appears to vary by medical condition, with highest discrepancy among seizure patients. Descriptive comments suggest at least part of the difference is driven by perspective of what constitutes benefit. The patients cite quality of life

benefits more often than the health care practitioners, who appear to focus more on objective measures such as seizure counts.

The symptom scores provided in the Patient Self-Evaluation data have the advantage of completeness, since they are required prior to each medical cannabis purchase. In this report a reduction of $\geq 30\%$ was applied to most symptoms to indicate clinically meaningful symptom reduction. Results show patterns similar to those in the survey benefits rating, but usually somewhat smaller in size. For most symptoms between half and two-thirds of patients who achieve clinically meaningful improvement retained that degree of improvement over the next four months.

Examples of proportion of patients achieving and retaining $\geq 30\%$ symptom reduction include:

- Among seizure patients, 68% reported $\geq 30\%$ reduction in seizure frequency and 49% both achieved that level of reduction and retained it, on average, for at least four months
- Among patients with Tourette syndrome, 61% reported $\geq 30\%$ reduction in tic frequency and 46% both achieved that level of reduction and retained it, on average, for at least four months
- Among patients with Crohn's disease, 51% reported $\geq 30\%$ reduction in number of liquid stools per day and 29% both achieved that level of reduction and retained it, on average, for at least four months
- Among patients with severe, persistent muscle spasms, 48% reported $\geq 30\%$ reduction in spasm frequency and 28% both achieved that level of reduction and retained it, on average, for at least four months
- Among cancer patients with at least moderate levels of nausea when they started using medical cannabis, 38% reported $\geq 30\%$ reduction of nausea and 23% both achieved that level of reduction and retained it, on average, for at least four months
- Among cancer patients with at least moderate levels of pain when they started using medical cannabis, 29% reported $\geq 30\%$ reduction of pain and 12% both achieved that level of reduction and retained it, on average, for at least four months

Moderate to severe levels of non-disease-specific symptoms such as fatigue, anxiety, and sleep difficulties were common across all the medical conditions. And the reductions in these symptoms was often quite large. These findings support the understanding that some of the benefit perceived by patients is expressed as improved quality of life.

The type(s) of medical cannabis used at the time patients achieved clinically significant improvement was analyzed for each symptom assessed within each category of medical condition. Full results of these analyses are presented in an Appendix and summaries are in the Benefits chapter.

Adverse Side Effects

At this point, the safety profile of the medical cannabis products available through the Minnesota program seems quite favorable. Approximately 20-25% of enrolled patients report negative physical or mental side effects of some kind, with the majority – around 60% - reporting only one and 90% reporting three or fewer. The vast majority of adverse side effects, around 90%, are mild to moderate in severity. An assessment of the 30 patients reporting severe side effects, meaning “interrupts usual daily activities,” found no apparent pattern of patient age, medical condition, or type of medical cannabis used. The most common adverse side effects are dry mouth, drowsiness, and fatigue. Fortunately, up to the present no serious adverse events (life threatening or requiring hospitalization) have been reported.

Affordability and Suggestions for Improving the Program

Unlike traditional pharmaceuticals whose costs are often covered through insurance reimbursement, medical cannabis purchased through the Minnesota program is currently not covered by insurance and must be purchased out of pocket. The patient survey asked for a rating of product affordability on a scale of 1 (very affordable) to 7 (very prohibitive). More than half (51%) responded with a 6 or a 7 and 86% responded with a score of 4 or higher. “Bring the costs down” was a frequent response when patients and certifying health care practitioners were asked how the program could be improved. Some patients indicated on surveys they used less medical cannabis than they knew was helpful to them because they could not afford it.

1. Introduction

In May 2014, Minnesota became the 22nd state to create a medical cannabis program. Distribution of cannabis products to qualified, enrolled patients began July 1, 2015. Minnesota's medical cannabis program is distinct from those in nearly all other states due to the fact that the Minnesota Department of Health's Office of Medical Cannabis is required to study and learn from the experience of participants. Minnesota's online registry, which integrates information from patients, certifying health care practitioners and manufacturers, continuously captures program data. Data elements from the Registry have been selected to create a de-identified research data set for reporting and research. This report draws on aspects of that research data set to describe the experience of patients who enrolled during the first year of the program's operation: July 1, 2015 through June 30, 2016.

Data in this report come from several aspects of the program's operations:

- Information from registration or enrollment of patients, health care practitioners, and caregivers;
- Information patients provide each time they visit a cannabis patient center for purchase of cannabis products, including information on symptom severity and side effects;
- Details about each cannabis product purchased; and
- Information is derived from responses to periodic surveys of patients and their certifying health care practitioners.

Though there is certainly imprecision in some of the data collected by the program, this report provides important details that can be found in few other states. A notable part of the report is a set of statements regarding benefits, negative effects, and comments about the program made by patients and health care practitioners. These are redacted to protect privacy, but otherwise presented as was written on the surveys. The comments have been coded by type but the verbatim comments have a power of their own, reminding us that each enrollee is a unique individual, not just a number. A few comments are included elsewhere, but the reader is encouraged to spend time reviewing the full listing of responses in the appendices.

The Office of Medical Cannabis anticipates performing additional analyses of data for the first year cohort of enrolled patients, as well as initiating analyses of data from patients who enrolled in the program later. Of particular interest are patients who enrolled after intractable pain became a qualifying condition on August 1, 2016. A report is planned for the end of 2017 that will give a preliminary look at the experience of the first several hundred patients certified for intractable pain. It is possible that focused projects will be developed in the future that will

MINNESOTA MEDICAL CANNABIS PROGRAM: PATIENT EXPERIENCES FROM THE FIRST
PROGRAM YEAR

draw on medical record information to answer specific questions raised by analyses of data derived from the program registry.

2. Patients and Caregivers Registered in the First Program Year

DESCRIPTION OF PATIENTS ENROLLED IN THE FIRST PROGRAM YEAR

Qualifying Condition

During the first year of the Minnesota Medical Cannabis program (July 2015-June 2016), 1,660 patients were certified by registered healthcare practitioners and subsequently enrolled in the program (Figure 2.1). The healthcare practitioners certified the patients as having one or more of the following qualifying conditions: severe and persistent muscle spasms (n=713), cancer (n=468), seizures, including those characteristic of epilepsy (n=328), Crohn's disease (n=108), terminal illness (n=94), HIV/AIDS (n=54), Tourette syndrome (n=30), glaucoma (n=24), and amyotrophic lateral sclerosis (ALS) also known as Lou Gehrig's disease (n=22) (Table 2.1, Figure 2.2). Of the 1660 patients from the first program year, 167 (10.1%) were certified as having more than one qualifying condition; these patients are represented more than once in Table 2.1 and Figure 2.2.

Figure 2.1. Patient enrollment in the first program year.

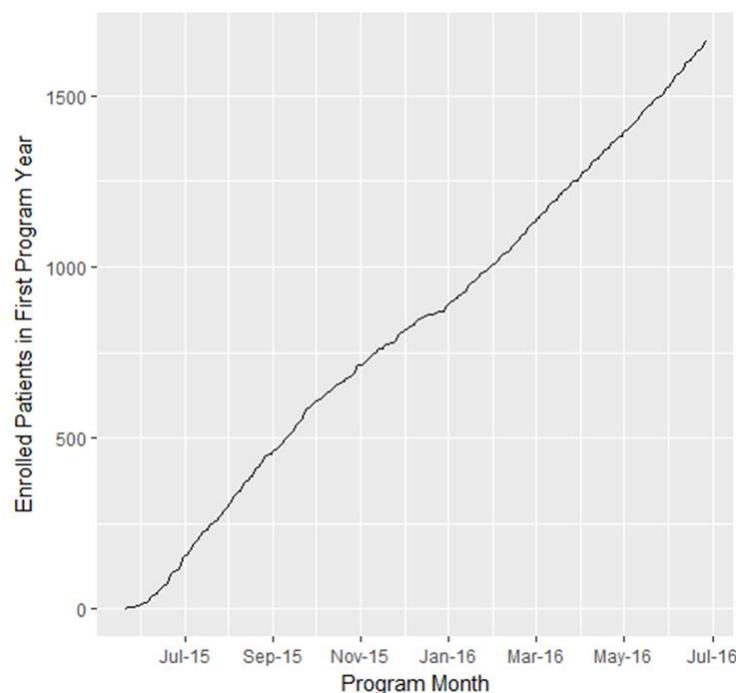

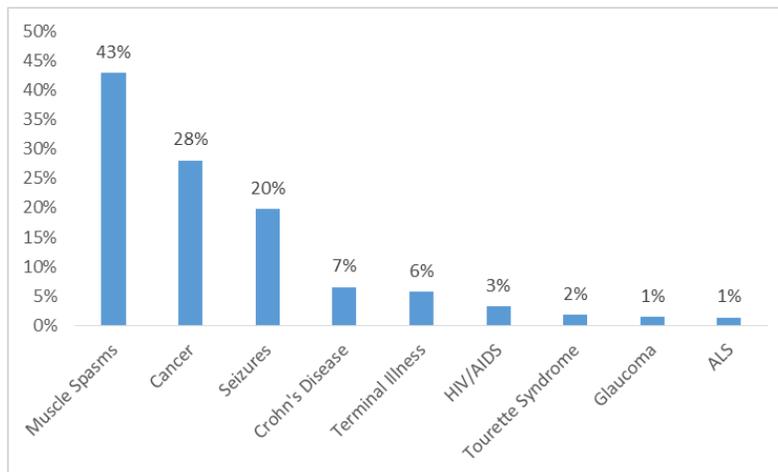

Table 2.1. Patient counts by qualifying condition.

Condition	Count	%
<i>Muscle Spasms</i>	713	43%
<i>Cancer</i>	466	28%
<i>Seizures</i>	328	20%
<i>Crohn's Disease</i>	108	7%
<i>Terminal Illness</i>	94	6%
<i>HIV/AIDS</i>	54	3%
<i>Tourette Syndrome</i>	30	2%
<i>Glaucoma</i>	24	1%
<i>ALS</i>	22	1%

Note: Percentages sum to more than 100 percent because among the 1660 patients enrolled during the first year, 167 (10.1%) were certified for more than one qualifying condition.

Figure 2.2. First year cohort patients by qualifying medical condition.

Note: Percentages sum to more than 100 percent because among the 1660 patients enrolled during the first year, 167 (10.1%) were certified for more than one qualifying condition.

Age and Gender

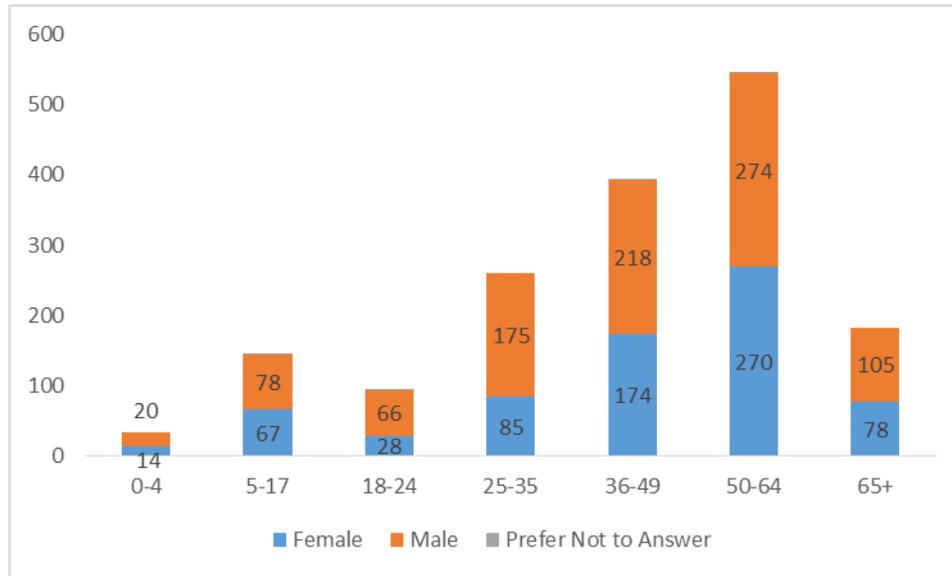

At the time of certifying that a patient has a medical condition qualifying them for the medical cannabis program, the certifying healthcare practitioner enters the patient’s date of birth. Additionally, during registration, patients are asked to report gender and race/ethnicity but are not required to do so. Table 2.2 shows the breakdown of patients by age category and gender at the time of initial program enrollment. The gender breakdown of patients in the first program year was 57% male and 43% female, with <1% of patients declining to report gender. Patients tended to be middle-aged, with 56.3% of the cohort falling between ages 36-64. However, the cohort also included a notable proportion of pediatric patients (10.7%) and patients over 65 years (11.0%).

Table 2.2. Patient counts by age and gender.

	0-4	5-17	18-24	25-35	36-49	50-64	65+
Female	14 (41%)	67 (46%)	28 (29%)	85 (33%)	174 (44%)	270 (49%)	78 (43%)
Male	20 (59%)	78 (53%)	66 (69%)	175 (67%)	218 (55%)	274 (50%)	105 (57%)
Prefer Not to Answer	0 (0%)	1 (1%)	2 (2%)	0 (0%)	2 (1%)	3 (1%)	0 (0%)
Total	34 (2%)	146 (9%)	96 (6%)	260 (16%)	394 (24%)	547 (33%)	183 (11%)

Note: Percentages are calculated based on the total count of patients in each age category.

Figure 2.3. Age and gender breakdown of first year cohort.

Age by Qualifying Condition

Breakdown of age category within each qualifying condition is shown in Table 2.3. Among the first year cohort, average age was 44.3 ± 18.9 years. Age distribution varied substantially across qualifying medical condition groups; patients certified for glaucoma or ALS tended to be older in general (average age of 60.4 ± 14.0 and 61.5 ± 9.6 , respectively); patients certified for seizure disorders or Tourette syndrome generally were younger (23.4 ± 16.0 and 25.3 ± 11.7 , respectively).

Table 2.3. Patient age by qualifying medical condition.

	0-4	5-17	18-24	25-35	36-49	50-64	65+	Mean Age (SD)	Total

Glaucoma	0 (0%)	0 (0%)	1 (4%)	0 (0%)	4 (17%)	11 (46%)	8 (33%)	60.4 (14.0)	24
ALS	0 (0%)	0 (0%)	0 (0%)	0 (0%)	2 (9%)	12 (55%)	8 (36%)	61.5 (9.6)	22

Race and Ethnicity

Table 2.4 shows patient-reported race and ethnicity. Patients were given the option to select multiple race and ethnicity categories, so the counts reflect some patients more than once. Ninety-one patients selected more than one race/ethnicity and 95 patients declined the question. Compared to 2014 Census Bureau estimates of race/ethnicity in Minnesota, the distribution of responding members of the first program year cohort is generally similar, with a slightly higher proportion of American Indians (2.7% versus 1.9%) and lower proportion of Hispanics (2.4% versus 4.9%) and Asians (1.7% versus 5.0%).

Table 2.4. One-year cohort patient race and ethnicity compared to overall state demographics.

Race/Ethnicity	Medical Cannabis Registry	2014 Census Bureau Estimates
American Indian	42 (2.7%)	1.9%
Asian	27 (1.7%)	5.0%
Black	101 (6.5%)	6.5%
Hawaiian	3 (0.2%)	0.1%
White	1410 (90.1%)	87.5%
Hispanic	37 (2.4%)	4.9%
Other	26 (1.7%)	1.7%

Race and ethnicity estimates for Minnesota can be found at the following website:
<http://factfinder.census.gov/faces/nav/jsf/pages/index.xhtml>

Registered Caregivers and Parents/Legal Guardians

If a patient is unable to pick up their medication from a cannabis patient center or is unable to administer the medication, their certifying health care practitioner may also certify the patient's need for a designated caregiver. This allows the enrolled patient to have a caregiver who then undergoes a background check and registers with the program. Registered caregivers can then legally obtain and possess the patient's medical cannabis on their behalf. Additionally, parents or legal guardians of patients can register with the program to act as caregiver and pick up or possess medication on behalf of the patient. Table 2.5 shows the proportion within each

qualifying condition group of patients who have registered caregivers or parents or legal guardians registered to pick up medication on behalf of the patient. Patients certified for ALS, cancer, or terminal illness have the highest proportions of patients with registered caregivers (32%, 15% and 15%, respectively). Patient certified for seizure disorders or Tourette syndrome, who are also generally younger than the cohort at large, have the highest proportion of patients with registered parents or legal guardians in the program (65% and 53%, respectively). Patients with seizures or Tourette syndrome also have the highest proportion of either registered caregivers or registered parents/legal guardians. Table 2.6 shows the absolute number of registered caregivers associated with a patient in the first year cohort, reported by condition. Most patients with registered caregivers have only one caregiver able to pick up medication on their behalf (n=157); 21 patients have two caregivers and one patient has three caregivers.

Table 2.5. Proportion of patients with registered caregivers, parents or legal guardians authorized to pick up medication, or both.

CONDITION	Number of Enrolled Patients	Patients with Registered Caregiver(s)	Patients with Registered Parent(s)/Legal Guardian(s)	Patients with Registered Caregiver(s) or Parent(s)/Legal Guardian(s)
All Conditions	1660	179 (11%)	279 (17%)	430 (26%)
Cancer	466	71 (15%)	23 (5%)	92 (20%)
Terminal Illness	94	14 (15%)	10 (11%)	22 (23%)
Glaucoma	24	3 (13%)	0 (0%)	3 (13%)
HIV/AIDS	54	1 (2%)	0 (0%)	1 (2%)

Geographic Distribution and Distance to Nearest Cannabis Patient Center

At the time of registration, patients provide their home address for verification of Minnesota residency. Home addresses are retained in the patient’s online registry account but are not retained in the research database; in lieu of home address, patient ZIP codes and calculated distances from each address to the nearest cannabis patient center are accessible for research purposes. The general geographic distribution of patients was examined using patient-reported ZIP codes; the first three digits of ZIP codes compose a prefix which corresponds to an approximate geographic region¹. The U.S. Postal Service assigns to each prefix labels that match

¹ <http://pe.usps.com/Archive/HTML/DMMArchive20050106/print/L002.htm>

MINNESOTA MEDICAL CANNABIS PROGRAM: PATIENT EXPERIENCES FROM THE FIRST
PROGRAM YEAR

the major city within the region and approximate surrounding cities; these region labels are shown in Table 2.7, along with the count of patients living in the corresponding ZIP codes.

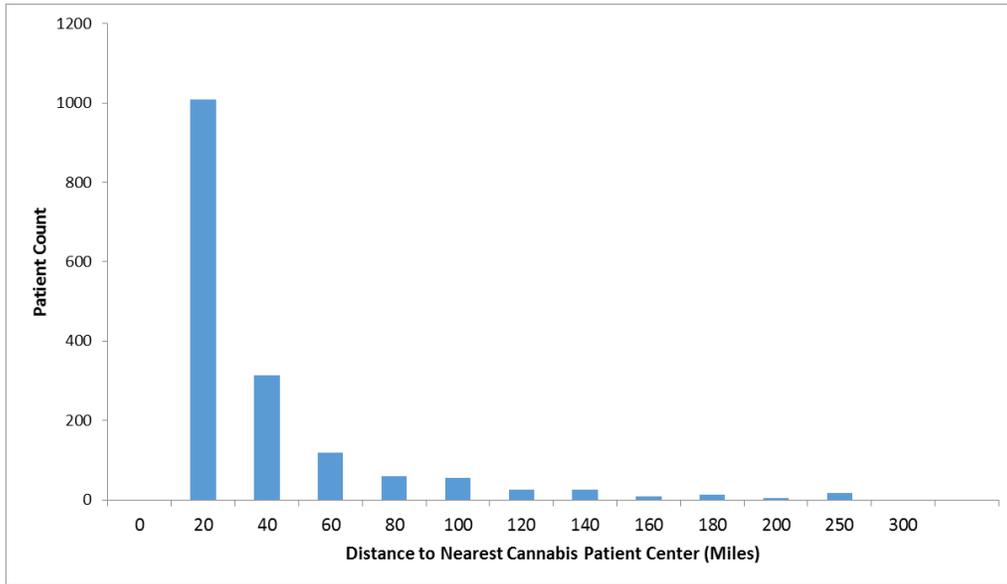

Table 2.7. Geographic distribution of patients by ZIP code prefix.

Region	ZIP Code Range	Patient Count (%)
St Paul	55000-55199	561 (34%)
Minneapolis	55300-55599	671 (40%)
Duluth	55600-55899	59 (4%)
Rochester	55900-55999	104 (6%)
Mankato	56000-56199	63 (4%)
Willmar	56200-56299	49 (3%)
St Cloud	56300-56399	80 (5%)
Brainerd	56400-56499	27 (2%)
Detroit Lakes	56500-56599	28 (2%)
Bemidji	56600-56699	11 (1%)
Grand Forks*	56700-56799	7 (0%)

Note: The Grand Forks region, corresponding to ZIP codes with a 567 prefix, refers to a region including Grand Forks, South Dakota, as well as several ZIP codes located in Minnesota near the western border. Patients living in this region reside in Minnesota.

Two medical cannabis manufacturers each operate four cannabis patient centers where patients can purchase medical cannabis following consultation with pharmacy staff at the center. Minnesota law required that one cannabis patient center be open in each of Minnesota’s eight legislative districts by July 1, 2016 (one year after the program start date). Figure 2.4 shows the distribution of calculated one-way distance from each patient’s home address to the nearest cannabis patient center location as of July 1, 2016, when all eight centers were operational. Average one-way distance is 28.9 ± 36.9 miles; median one-way distance is 15.5 miles. The majority of patients (n=1441; 86.8%) live within 60 miles of the nearest cannabis patient center.

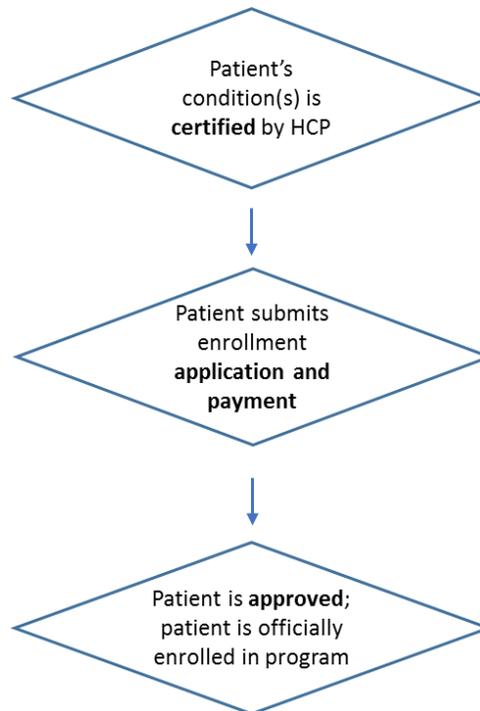

Figure 2.4. Distribution of one-way distance from patient home to nearest cannabis patient center.

From Certification to Program Approval: How Long Does it Take for Patients?

A sequential series of steps are followed in order to move patients from certification by a healthcare practitioner to their enrollment in Minnesota’s Medical Cannabis program. First, patients must have at least one medical condition that qualifies for the program and must have that condition certified by a registered health care practitioner (HCP). After their medical condition is certified, patients have 90 days to submit a complete application to enroll in the program. Patients must also submit payment to cover the annual enrollment fee along with their application materials. Once the application and enrollment fee are submitted, Office of Medical Cannabis (OMC) staff reviews and verifies all submitted materials and can approve the patient for the program. Figure 2.5 depicts the process flow from certification to program approval:

Figure 2.5. Flow chart of enrollment events.

To give current and prospective patients some idea of the time it takes to go from certification to program approval, records from patients in the first program year cohort (n = 1660) were analyzed at different time points: 1) time between certification to program approval, 2) time between certification to enrollment payment, and 3) time between enrollment payment and program approval.

Time from Certification to Program Approval

Just over half of all patients (54.7%) in the cohort (n = 1660) were approved/enrolled in the program within 3 days of having their condition(s) certified. Close to 90% (1484 out of 1660 patients) were enrolled in the program within a month of being certified.

Time from Certification to Annual Enrollment Fee Payment

Records of enrollment fee payments were unavailable for patients who did not make an electronic payment; therefore, calculations of time between certification and enrollment fee payment was restricted to 1579 patients (95.1% of patients in the cohort represented) who paid the enrollment fee electronically. Of these patients, 57.2% of them (n = 903) submitted payment within 1 day of getting their qualifying condition(s) certified by their HCP. More than 90% of patients (n = 1452) submitted payment within one month of certification.

Time from Annual Enrollment Fee Payment and Program Approval

Records of enrollment fee payments were not available for all patients in the cohort; therefore, calculations of time between enrollment fee payment and program approval was restricted to 1579 patients (95.1% of patients in the cohort represented). Of these patients, 72.7% of them (n = 1148) were approved for the program (officially enrolled in the program) within a day of submitting their annual enrollment fees. Close to all patients (99.3%) were enrolled in the program within a month of submitting their annual enrollment fees. The small proportion of patients who do not get approved within a month of their fee submission generally reflects patients who submitted inadequate or incomplete information during the enrollment submission process (meaning that the Office of Medical Cannabis is waiting for additional information to approve them for the program).

From Certification to Program Approval: Conclusions

Just over half of all patients in the cohort were officially enrolled in the program within three days of being certified. Within a week of certification, 70% of patients were enrolled in the program. This suggests that the majority of patients move relatively quickly from certification to enrollment in the program.

When breaking down the process flow between certification and program approval, it typically took longer for patients to move from certification to paying the enrollment fee than it did from their paying the enrollment fee to getting approved. This generally reflects the nature of the process flow going from certification to paying the enrollment fee: after patients are certified, the patient must self-initiate and complete the submission of all application materials along with payment (involves variable amounts of time to gather all materials and to ensure sufficient funds to make fee payment). This is in contrast to the step between enrollment fee payment and getting approved for the program: patient has submitted all materials and payment by this

point and – unless they are directed otherwise by OMC staff – will get approved for the program in the order their materials were received in the queue.

Re-Enrollment

The Minnesota medical cannabis program requires by statute that once a patient becomes certified as having a qualifying condition and enrolled in the program, the patient's enrollment lasts for one year; therefore each year a patient must be re-certified as having at least one qualifying condition and must re-enroll in the program and pay an annual enrollment fee. If a patient is not re-certified as having a qualifying condition and does not re-enroll in the program by the anniversary date of the most recent enrollment, their account is deactivated and they are no longer able to purchase medical cannabis from a cannabis patient center or retain the protections of the program. To investigate the rate at which enrolled patients who approach their expiration dates re-enroll in the program, patients who enrolled in the program during the first program month (including those who were approved early, prior to the program start in July 2015) were examined. A total of 253 patients were enrolled in the first program month; these patients' enrollments expired in July 2016. Re-enrollment activity for these patients was examined six months following expiration of the first enrollment year. Within six months following the expiration of the first year of enrollment, 115 (45%) among these patients re-enrolled in the program. Of the remaining 138 patients who did not re-enroll during this period, 24 patients (17%) died within 18 months of initial enrollment. Additionally, patients can re-enroll at any time following expiration, and some patients who did not re-enroll immediately may do so at a later time.

Most patients who re-enrolled within six months of expiration did so prior to expiration (44%) or within the first month after enrollment expiration (40%). Only 3% of these patients re-enrolled beyond three months post expiration. Timing of re-enrollment for patients who initially enrolled during the first program month are shown in Table 2.8.

Table 2.8. Timing of program re-enrollment for patients enrolled in the first program month.

Time Re-Enrollment Occurred	Patient Count (%)
Prior to Expiration	51 (44%)
1st Month After Expiration	46 (40%)
2nd Month After Expiration	0 (0%)
3rd Month After Expiration	15 (13%)
4th Month After Expiration	1 (1%)
5th Month After Expiration	2 (2%)
6th Month After Expiration	0 (0%)
<i>Total Count of Patients Re-enrolled Within 6 Months of Annual Expiration Date</i>	<i>115</i>

Note: Among the 253 patients who enrolled in the program in July 2015, 115 (45%) re-enrolled within six months of expiration. Percentages are based on a total number of re-enrollments within this period (n=115).

At the time of enrollment expiration, a patient can allow their enrollment to lapse without any action or communication with the Office of Medical Cannabis. Currently OMC does not collect information systematically on why patients chose to either re-enroll or let their current enrollment expire. However, some insight into program discontinuation is available from a Continued Use survey, which asks patients who have not purchased medical cannabis for 60 days whether they have decided to stop the treatment, whether they received any benefits from the treatment, and what their reasons are for either stopping or pausing the treatment. Early results looking at patients who purchased medical cannabis within the first three program months but discontinued purchasing for 60 days showed that 62% (n=10) of patients who indicated they planned to stop using medical cannabis (n=16) found little or no benefit from the treatment. Among 59 patients who indicated they were unsure of whether they would continue or that they intended to continue the treatment, 35 (73%) cited cost as a barrier to continuing. These results do not directly answer the question of why some patients do not re-enroll but give some indication of potential reasons for doing so. (For methodology and preliminary results from the Continued Use survey, see [“Early Results of Office of Medical Cannabis Surveys: May 2016”](#) on the [Office of Medical Cannabis](#) website).

3. Health Care Practitioners Registered in the First Program Year

The Minnesota Medical Cannabis program outlines a set of qualifying medical conditions which make a patient eligible for enrollment in the program. By Minnesota statute, a patient must be certified by a Minnesota-licensed physician, physician assistant (PA), or advanced practice registered nurse (APRN) as having one or more of the qualifying conditions. A Minnesota practitioner with appropriate credentials must first register with the Minnesota Medical Cannabis program before they can certify patients for the program: practitioners complete a short online form with their name and clinic information to register. Office of Medical Cannabis staff verify the provider's entered information and their Drug Enforcement Agency (DEA) license prior to approving the practitioner to certify patients. This chapter will describe the certifying healthcare practitioners who registered in the first program year.

Healthcare Practitioner Count, Age and Gender

From July 2015- June 2016, 577 healthcare practitioners licensed in Minnesota registered in the medical cannabis program, including 473 physicians (82%), 77 APRNs (13%) and 27 PAs (5%). Table 3.1 shows the breakdown of healthcare practitioner (HCP) type, gender and average age, based on publicly available data from the Boards of Medical Practice and Nursing. Physicians registered in the program were predominantly male (72%) and were generally older than registered APRNs and PAs, who were predominantly female (88% and 78%, respectively).

Figure 3.1. Count of registered healthcare practitioners during the first program year.

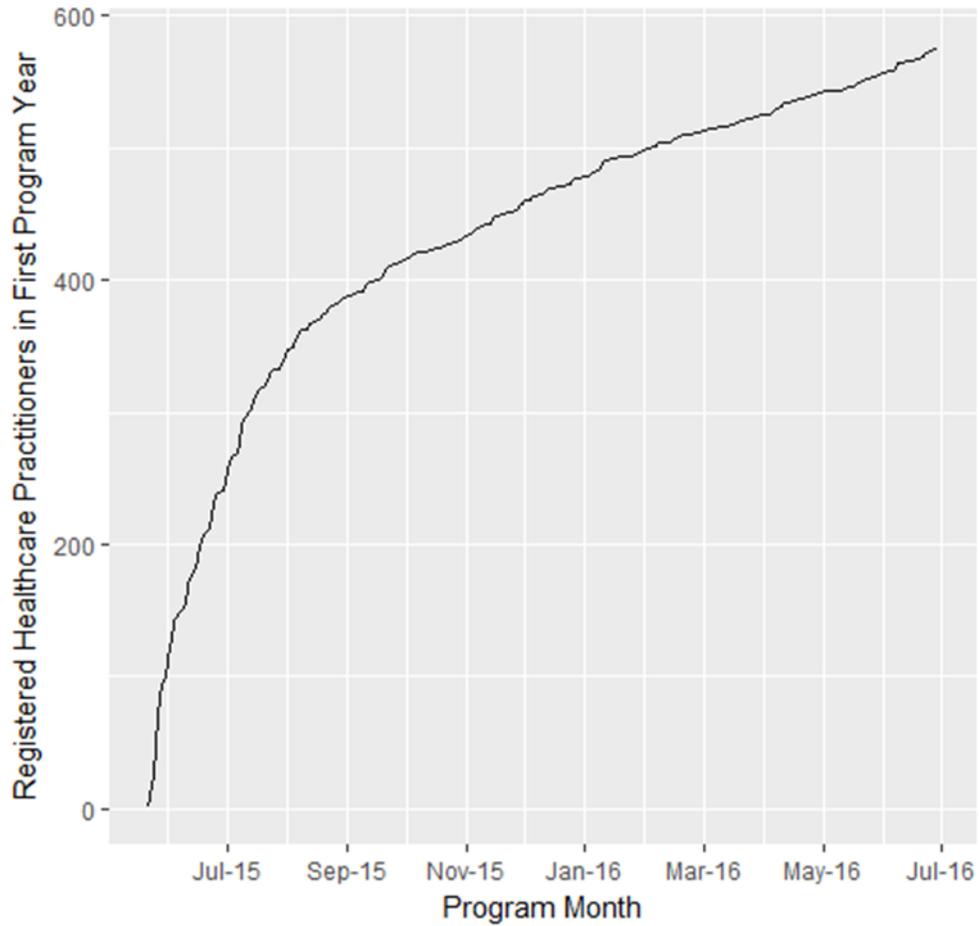

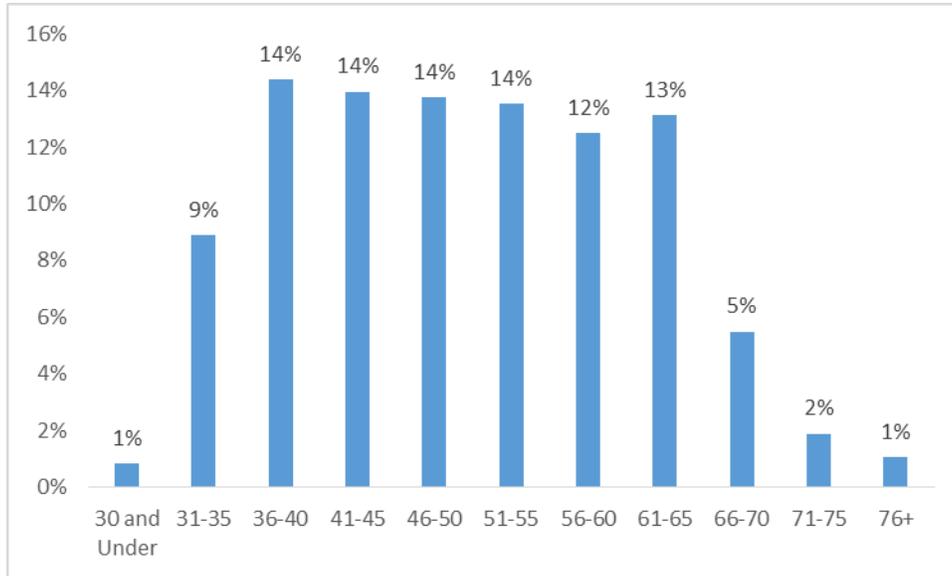

Table 3.1. Healthcare practitioner by type, with gender and average age.

HCP TYPE	N	%	MALE: N (%)	MEAN AGE (SD)
Physician	473	82%	341 (72%)	50.3 (11.3)
APRN	77	13%	9 (12%)	47.0 (9.4)
PA	27	5%	6 (22%)	39.9 (9.5)
Total	577	100%	356 (62%)	49.4 (11.2)

Note: Age data was unavailable for 17 APRNs and three physicians.

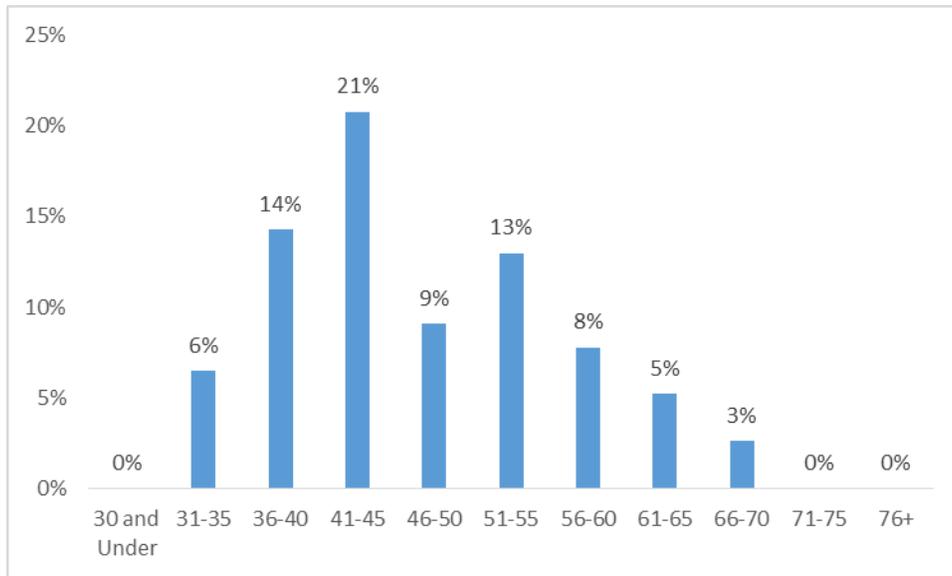

More detailed representations of age distribution among registered physicians, PAs and APRNs are available in Figures 3.2-3.4. Figure 3.2 shows the age distribution in 5 year increments of physicians enrolled in the first program year; most physicians fall between ages 36-65 years (81%) with relatively even distribution of numbers across this range. Figure 3.3 shows the age distribution for APRNs; 51% of APRNs are 50 years or under. Figure 3.4 shows the age distribution for PAs registered in the program; most PAs fall between ages 31-45 (78%).

Figure 3.2. Age distribution of physicians registered in the medical cannabis program (n=473).

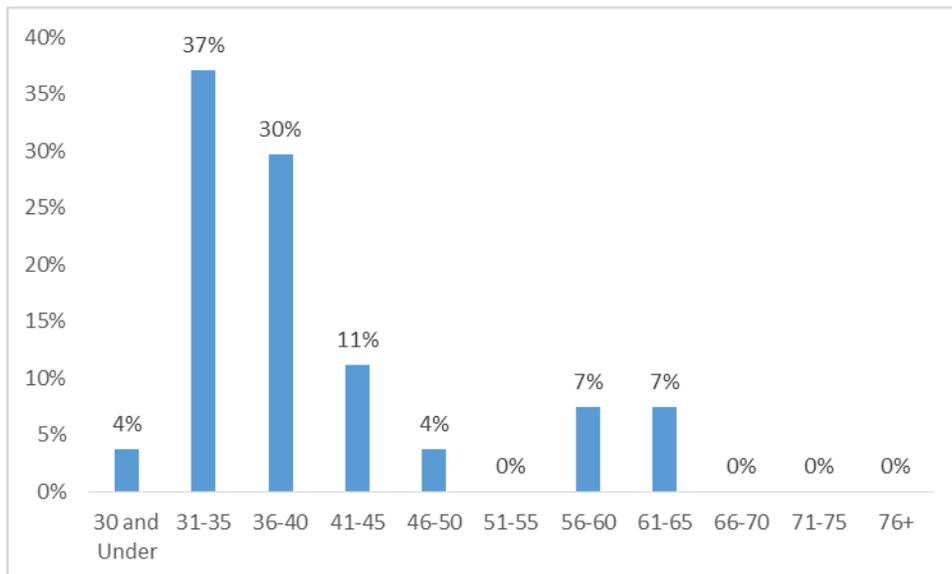

Note: Age data was not publicly available for three physicians registered in the first program year.

Figure 3.3. Age distribution of advanced practice registered nurses registered in the medical cannabis program (n=77).

Note: Age data was not publicly available for 17 APRNs registered in the first program year.

Figure 3.4. Age distribution of physician assistants registered in the medical cannabis program (n=27).

Registered Physician Specialties and Licensures

The Minnesota Board of Medical Practice lists information on Minnesota-licensed physicians and physician assistants. Included is self-reported “Area of Specialty” information indicating a physician’s (or physician assistant’s) certifications from the American Board of Medical Specialties or American Osteopathic Specialty Boards. While physician assistant specialty information is infrequently provided, physicians often list certifications in more than one area of specialty. For example, physicians practicing as oncologists may list certifications in the areas of Internal Medicine, Hematology, and Medical Oncology. A variety of specialties were represented among physicians registered in the first program year, including subspecialties of neurology (neurology with special qualifications in child neurology, clinical neurophysiology, and epilepsy), pediatrics (pediatric hematology-oncology) and internal medicine or family medicine (gastroenterology, geriatric medicine, hospice and palliative medicine, sports medicine, nephrology, and infectious disease). Specialties including ophthalmology, dermatology, radiology and surgery were also represented. In cases where a physician listed an area of specialty and subspecialty, such as Internal Medicine and Gastroenterology, the subspecialty was chosen to represent the physician’s practice (in this case, Gastroenterology). Table 3.2 shows the distribution of physician specialties; each physician is represented only once. Two physicians who are licensed in Minnesota and registered in the program do not have any listed specialties with the Board of Medical Practice; they are therefore excluded from Table 3.2. The most common specialty category for physicians registered in the first program year was primary care (38%), which included internal medicine (13%), family medicine (23%) and pediatrics (2%). Physicians with specialization in oncology (17%) and neurology (14%) were also common.

Table 3.2. Registered physician specialty categories.

Registered Physician Specialties	N (%)
Primary Care	179 (38%)
<i>Internal Medicine</i>	<i>61 (13%)</i>
<i>Family Medicine</i>	<i>109 (23%)</i>
<i>Pediatrics</i>	<i>8 (2%)</i>
Oncology	81 (17%)
Neurology	65 (14%)
Pediatric Specialty	29 (6%)
Hospice/Palliative Medicine	25 (5%)
Physical Medicine and Rehabilitation	21 (4%)
Gastroenterology	11 (2%)
Psychiatry	10 (2%)
Ophthalmology	9 (2%)
Surgery	8 (2%)
Infectious Disease	6 (1%)
Radiology/Radiation Oncology	5 (1%)
Pain Medicine	5 (1%)
Nephrology	3 (1%)
Geriatric Medicine	3 (1%)
Emergency Medicine	2 (0%)
Rheumatology	2 (0%)

Obstetrics and Gynecology	2 (0%)
Sports Medicine	2 (0%)
Anesthesiology	2 (0%)
Dermatology	1 (0%)
Public Health and Preventive Medicine	1 (0%)
Pulmonary Disease	1 (0%)
Sleep Medicine	1 (0%)

Advanced Practice Registered Nurse Licensures

Advanced practice RNs include licensed Clinical Nurse Specialists (CNS), Certified Registered Nurse Anesthetists (CRNA), Certified Nurse-Midwives (CNM) or Certified Nurse Practitioners (CNP). Among the 77 APRNs who registered in the first program year, 75 held CNP certification, 1 held CNS certification, and 1 held both CNP and CNS certifications.

Summary

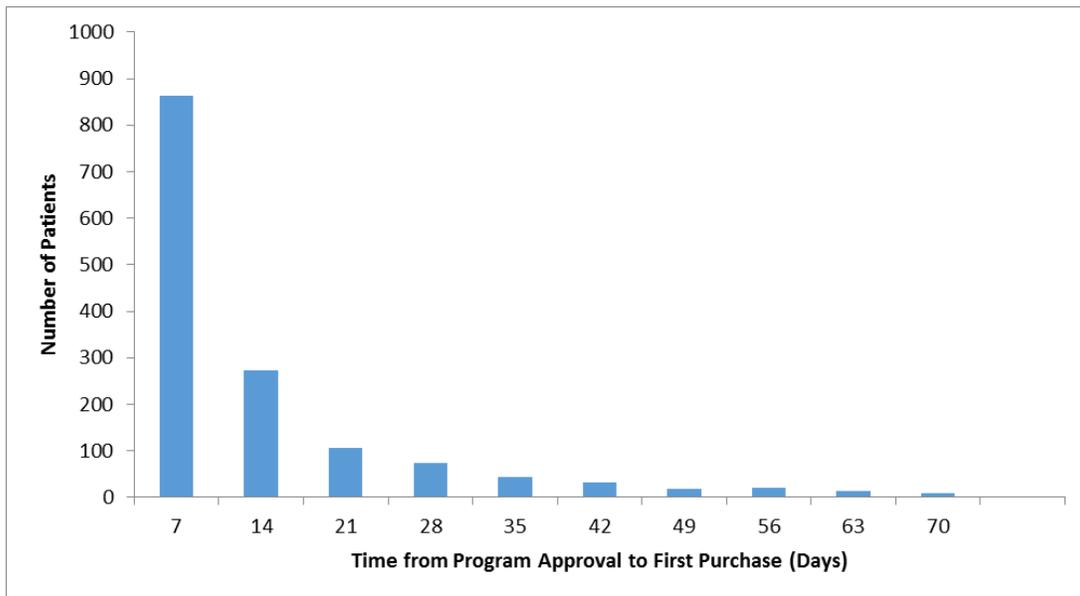

In the first year of the Minnesota Medical Cannabis program, 577 licensed healthcare practitioners registered as certifying providers with the program, predominantly physicians (82%). There were age and gender differences across the HCP types; physicians tended to be older and male; PAs and APRNs tended to be younger and female. Physician licensure information showed that physicians from a diversity of clinical practices are involved in certifying patients for the medical cannabis program, but the majority of these providers are primary care providers or specialties that typically manage patients with the Minnesota program’s qualifying conditions (i.e. severe muscle spasms, seizure disorders, Tourette syndrome and ALS are typically managed by neurologists; cancer is often managed by oncologists).

4. Frequency and Duration of Medical Cannabis Purchases

Time from Program Approval to First Medical Cannabis Purchase

Once a patient is approved for the medical cannabis program, the patient and/or their registered caregiver(s) or parent(s)/legal guardian(s) can visit any of the eight cannabis patient centers and purchase medical cannabis. Figure 4.1 shows the distribution of time from program approval to first medical cannabis purchase for patients enrolled during the first program year who purchased medical cannabis before December 31, 2016 (n=1528). Many patients (n=196; 13%) made a first purchase within one day of program approval; over half (n=864; 57%) made a first purchase within seven days and most patients (n=1137; 74%) made a first purchase within 14 days of program approval.

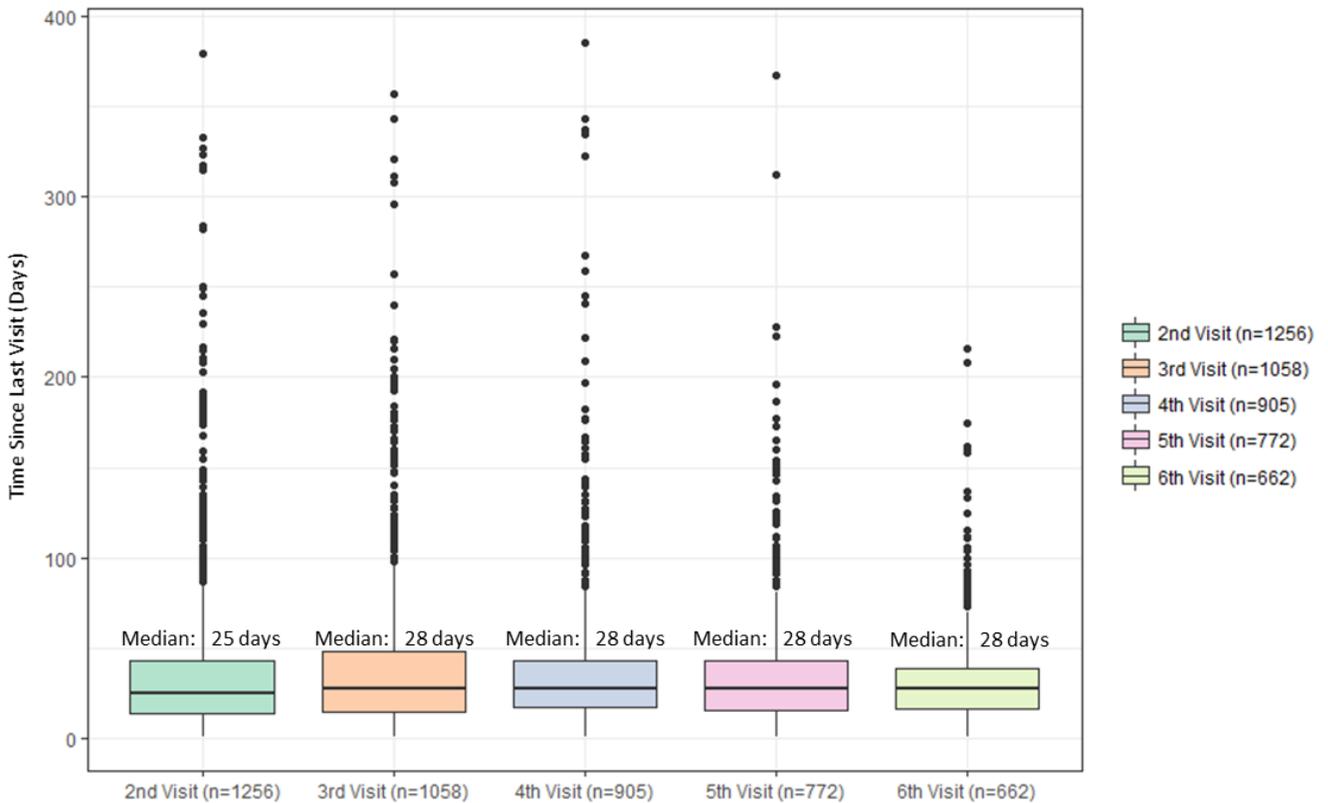

Figure 4.1. Time from patient approval to first medical cannabis purchase.

Time Between Purchases

According to Minnesota statute, patients can purchase up to a 30-day supply of medicine at a cannabis patient center. However, visits to a cannabis patient center vary from 30-day intervals for several reasons. Figure 4.2 shows the intervals between purchases for patients from the one-year cohort with at least two purchases (n=1256). Patients must purchase medical cannabis with cash and many patients report that the medicine's cost is prohibitive; for these reasons, patients may purchase smaller quantities than a month's supply and visit cannabis patient centers more frequently than once a month. On the other hand, many patient responses to the Continued Use Survey (see ["Early Results of Office of Medical Cannabis Surveys: May 2016"](#) on the [Office of Medical Cannabis](#) website) indicated a quantity of medicine intended to be a 30-day supply lasted longer than 30 days, or the patient chose to use the medicine sparingly as a cost-saving measure and therefore the supply lasted longer than anticipated. However, the median times between visits for the first consecutive six visits were close to the expected interval of one month (median time since last visit: 25, 28, 28, 28, and 28 days for the second, third, fourth, fifth and sixth visits, respectively).

Figure 4.2. Time between visits for patients with two or more visits from July 2015-December 2016.

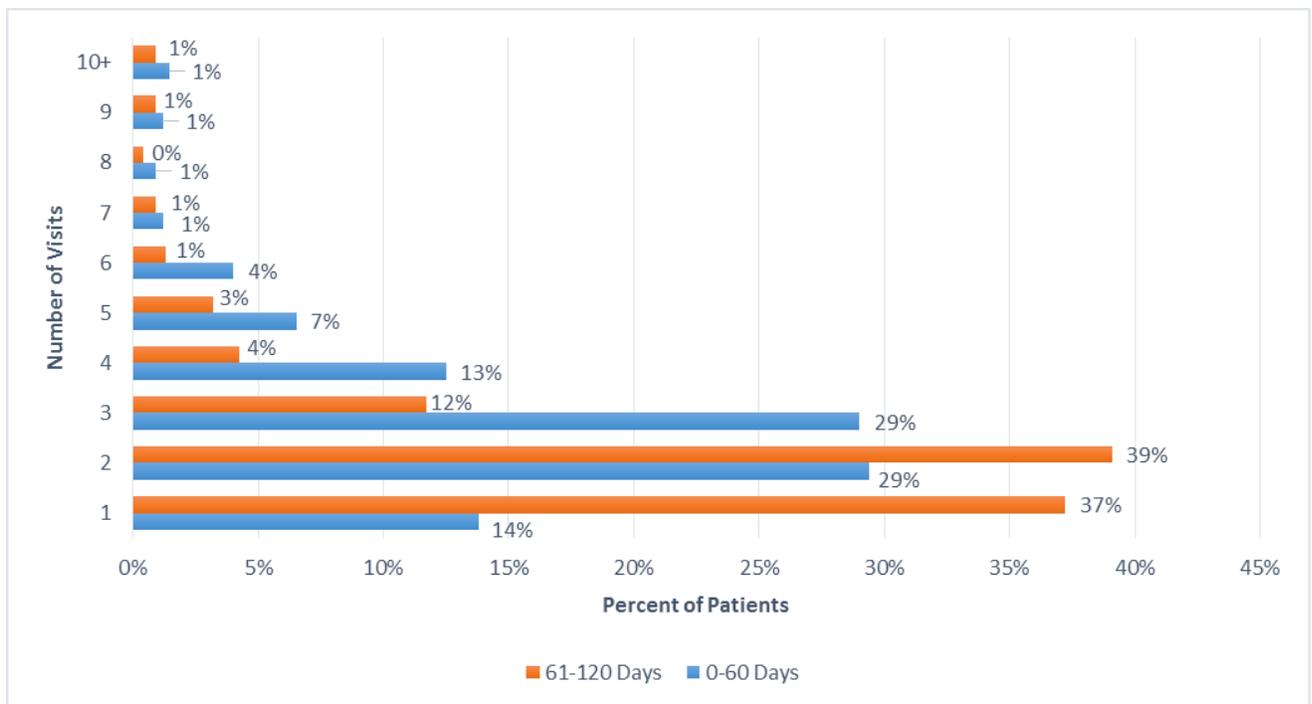

Note on boxplots: upper and lower hinges for each boxplot correspond to the 75th and 25th percentiles of each distribution, respectively. The upper and lower whiskers extend to the highest and lowest values that are within 1.5 x the interquartile range from the upper and lower hinges, respectively. Data beyond the whiskers, plotted as individual points, are outliers.

Purchasing Activity in First Four Months of Program Participation

Patients beginning medical cannabis treatment often try different types of products with varying ratios of THC:CBD and routes of administration to achieve optimal symptom management; therefore patients may be more likely to make more visits to cannabis patient centers at the beginning of treatment and fewer visits in later times once the patient’s regimen had been established. As seen in Figure 4.2, frequency of visits (represented as time between consecutive visits) varies widely across patients. To compare purchasing activity in the first two months versus the second two months of program activity, the number of visits for each patient with continuous enrollment was examined in the first and second 60 days of program activity (day 0 defined as the date of first medical cannabis purchase). Patients who made no

purchases between days 61 and 120 or beyond day 120 were excluded to eliminate patients who had atypical purchasing activity or quit the program during this time window. Figure 4.3 shows the distribution of number of visits per patient which occurred in the first and second 60 days of program activity (n=752). During the first 60 days of program activity, median number of visits was 3 and 543 of 752 patients in this group (72%) made three or fewer purchases. During days 61-120 of program activity, median number of visits was 2 and 662 of 752 patients (88%) made three purchases or less. While the distributions of purchasing activity in the first 60 days and second 60 days is roughly similar, they indicate that purchasing activity is slightly greater during the first 60 days of program activity.

Figure 4.3. Number of visits in first 60 days and second 60 days of program activity, for patients with one or more purchases in both 60 day intervals.

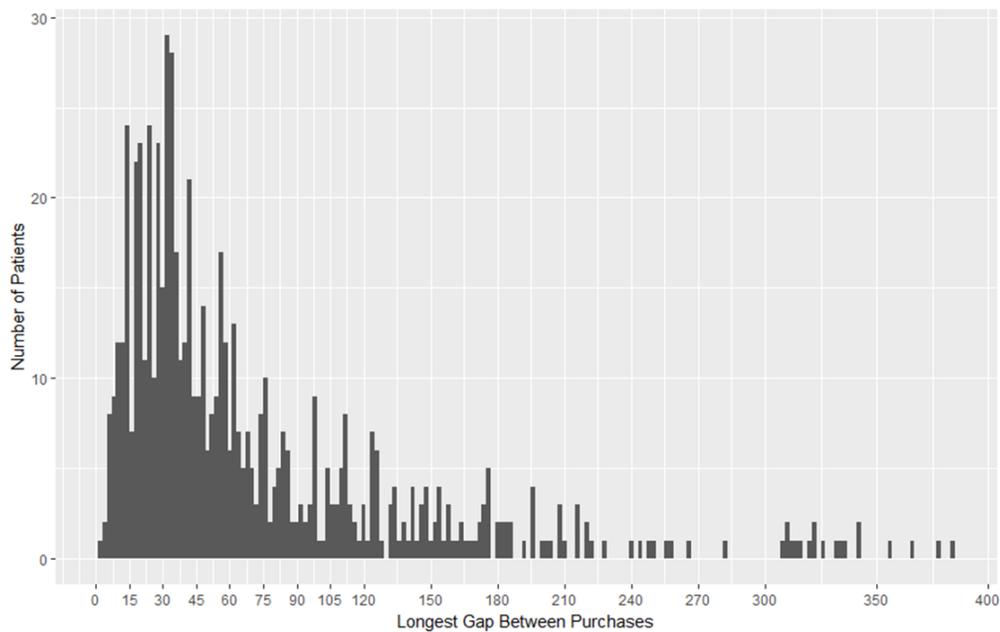

Patients Who Stopped Purchasing Medical Cannabis

Since patients make an annual payment to be enrolled in the medical cannabis program, if they decide at some point during the following year to discontinue medical cannabis treatment, it is unlikely they will request to be withdrawn from the program, as there is no financial incentive to do so. Therefore, to understand discontinuation in the program, a functional definition was created based on purchasing patterns. For each patient in the one year cohort enrolled with a first purchase prior to December 31, 2015 and making at least two purchases before December 31, 2016 (n=669), the longest gap between consecutive purchases from July 2015-December 2016 is shown in Figure 4.4; median longest gap in this group was 47 days. Among these

patients, 546 (82%) had a longest gap between purchases of 120 days or less; 616 (92%) had a longest gap between purchases of 180 days or less. Median longest gap for each patient is significantly longer than median time between visits for patient's first six visits; this suggests that there may be a great deal of variability within a patient's inter-visit times. Early patient responses to the Continued Use survey point to factors which may impact purchasing frequency: unexpectedly low rate of product usage, cost-motivated reduction or temporary cessation of product usage, unrelated medical treatment changes which interfered with cannabis usage, or out-of-state travel.

Figure 4.4. Distribution of longest gap between visits per patient, July 2015-December 2016.

Since most patients (92%) enrolled and purchasing within the first six program months who made two or more purchases by December 31, 2016 had no inter-visit gaps longer than 180 days, program discontinuation was defined for this analysis as ceasing purchasing activity for six months or longer during the period included in this analysis (July 2015-December 2016). This definition was applied to all patients enrolled in the first six program months who made at least one purchase (n=774) to find the proportion of patients (regardless of duration enrolled in the program) who did not make any purchases for at least six months, through the end of 2016. Of these 774 patients making at least one medical cannabis purchase, 398 patients (51%) made no purchases for at least six months, as of December 2016. Based on the distribution of longest gaps between purchases in this subset of the one-year cohort, it is likely that this proportion is

a rough estimate of the proportion of patients who quit the program within 18 months after trying medical cannabis.

Using a six month window with no purchases as a surrogate for program discontinuation has limitations. For example, our analysis did not account for duration of enrollment and any effect it may have on purchasing patterns. However, it gives an approximation of patients who abandon medical cannabis treatment and roughly aligns with the re-enrollment rate of 45% in patients enrolled in the first program month (see “Re-Enrollment” in Chapter 2: Description of Patients and Designated Caregivers).

Frequency and Duration of Medical Cannabis Purchases: Conclusions

Most patients make their first medical cannabis purchase within 14 days of program approval. Subsequent purchases often follow a roughly monthly periodicity, with median inter-visit gap at 25 days for the gap between the first and second visit and 28 days for the next four inter-visit gaps. Additionally, patients tend to make purchases slightly more frequently in the first 60 days of program activity compared to the second 60 days of program activity (median number of visits is 3 from 0-60 days and 2 from 61-120 days). Finally, most patients (92%) do not have an inter-visit gap longer than 180 days; using 6 months or more of no purchasing activity as a surrogate for program discontinuation, 51% of patients who enrolled and made a purchase within the first six months of the program ceased purchasing medical cannabis as of December 31, 2016.

5. Medical Cannabis Use Patterns

Medical cannabis purchasing records were extracted from the registry in early March 2017 for patients enrolled in the 1st program year. From this data, all transactions that occurred within a patient's first enrollment year were retained. For those patients whose first enrollment year had not yet ended at the time of data extraction, all purchasing transactions were retained. This resulted in a dataset with the following:

- 10,898 purchasing transactions consisting of:
- 16,238 products within these transactions (37.9% of all purchasing transactions consisted of two or more products), which
- Represented 1529 patients (92.1% of the first program year cohort).

For analytical purposes, all 16,238 product transactions were classified according to the ratio of delta-9-tetrahydrocannabinol (THC) to cannabidiol (CBD) found in the medical cannabis products. Products ranged from containing very high THC to CBD content to those with very high CBD to THC, as well as everything in between (products with relatively balanced amounts of THC and CBD). For definitions on THC:CBD ratio classifications, see Box 5.1.

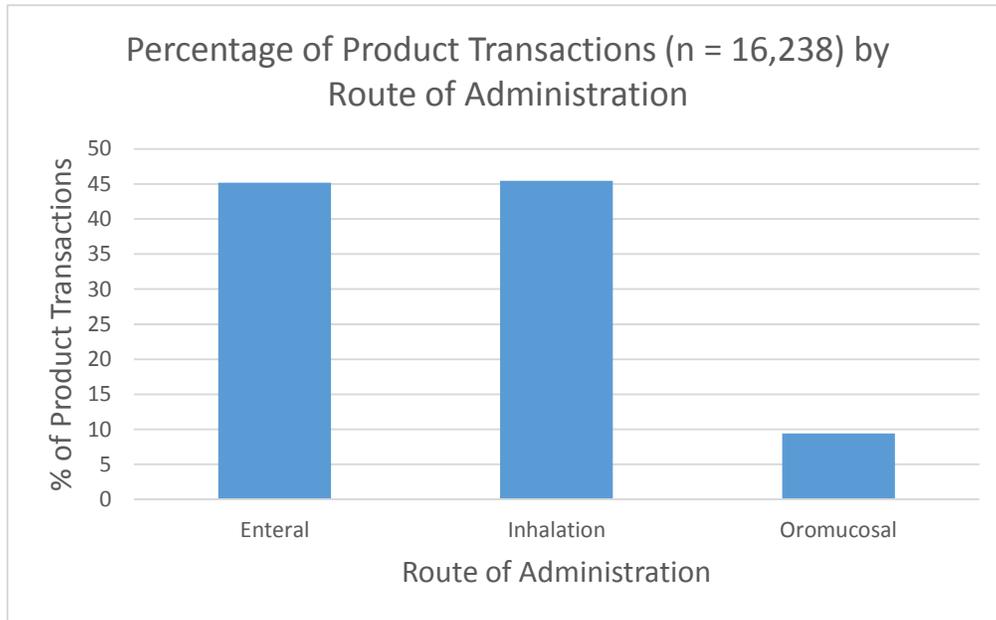

Box 5.1. Definitions to classify medical cannabis products by THC:CBD ratios.

Product Classifications Based on THC to CBD content:

- **Very High THC to CBD** = 100:1 or higher
- **High THC to CBD** = >4:1 up to 99:1
- **Balanced** = 1:1 up to 4:1
- **High CBD to THC** = \geq 1:1 up to 99:1
- **Very High CBD to THC** = 100:1 or higher

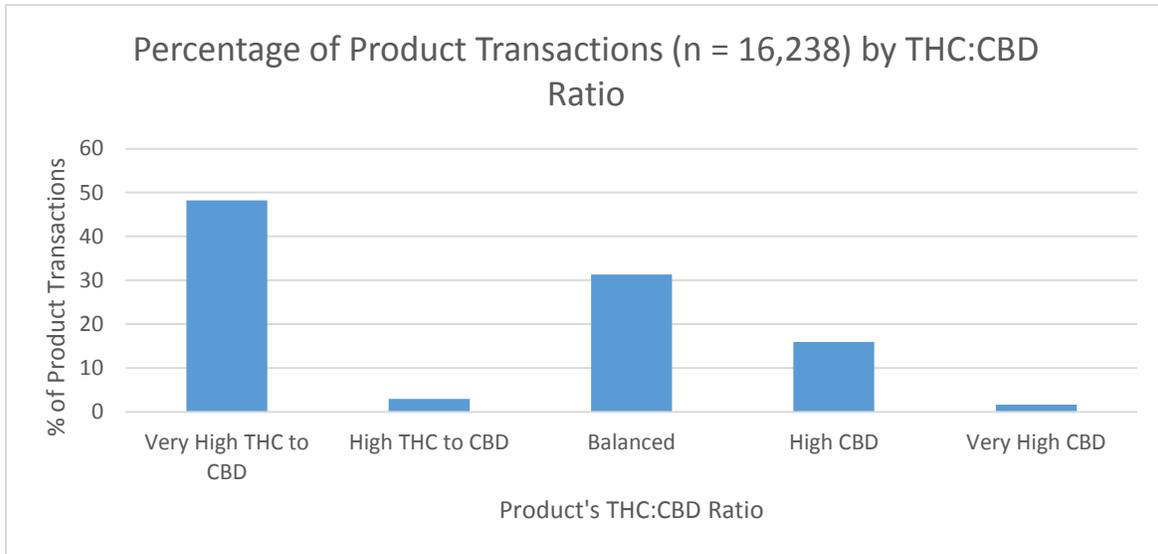

Products purchased for enteral administration (swallowed – includes capsules and oral solutions) and inhalation (vaporized oil) represented the majority of the products purchased (90.6% of all product transactions) with significantly fewer products purchased for oromucosal absorption (oil absorbed through cheek; 9.4% of all product transactions). In fact, products for enteral administration and inhalation were roughly equally purchased by patients, respectively representing 45.2% (n = 7333) and 45.4% (n = 7376) of all products dispensed. See Figure 5.1.

Figure 5.1. Purchasing transactions categorized by the product’s intended route of administration (out of 16,238 products dispensed).

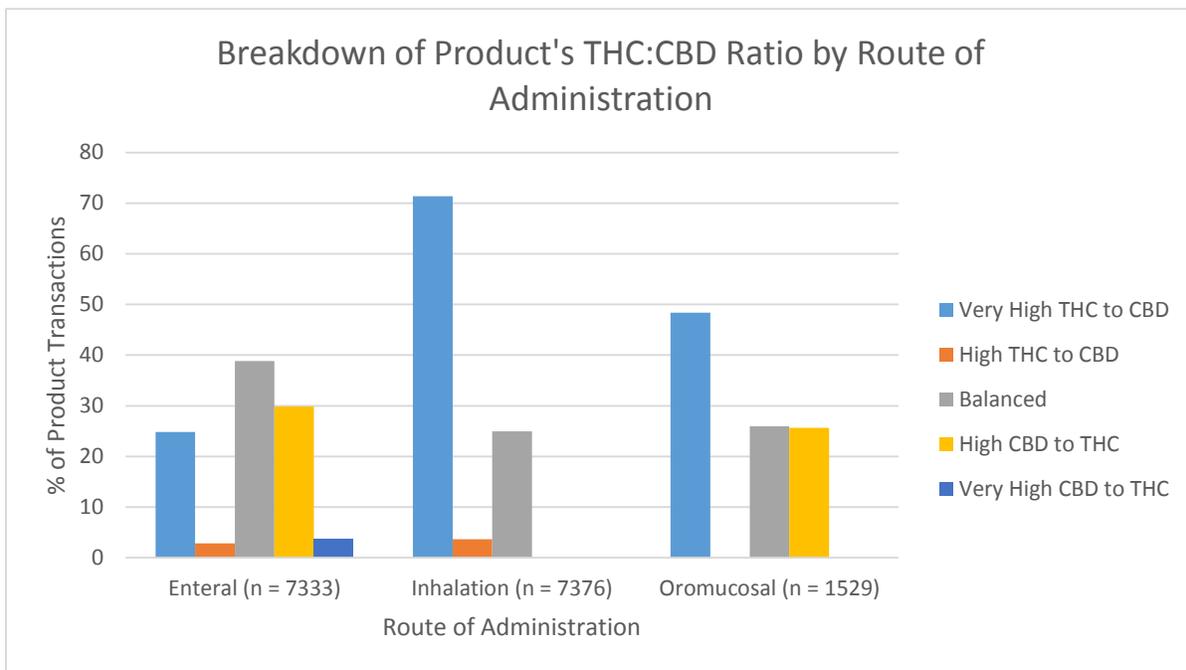

When products were classified by the ratio of THC to CBD present in the product, the following patterns emerged. Firstly, 48.2% of all product transactions were for products with very high THC amounts compared to CBD (hundreds to one). Balanced products (roughly equal amounts of THC to CBD) represented the next biggest group of products purchased, representing 31.3% of products dispensed. This was followed by high CBD to THC products which represented 15.9% of all product transactions. See Figure 5.2.

Figure 5.2. Product transactions represented by the THC to CBD ratio available in the product.

Product transactions were also examined by the products' THC:CBD ratios as a function of their routes of administration (see Figure 5.3). Of all product transactions intended for enteral administration, close to 39% of them were for products with relatively balanced THC:CBD ratios followed by products with high CBD:THC (29.9%) and very high THC:CBD products (24.8%). Product transactions for inhalation predominately had very high THC to CBD (71.4%). Lastly, close to half (48.4%) of all oromucosal product transactions were for very high THC:CBD products, with roughly a quarter each constituting balanced and high CBD to THC products (respectively 26.0% and 25.6%).

Figure 5.3. A percentage breakdown of product transactions by the THC:CBD product ratio types as a function of route of administration.

Most Frequently Purchased Product(s)

Examining purchasing history across all patients is very complex. For example, patients may experiment with different products as they explore what works best for them, and some may establish a pattern of using more than one product. Additionally, those using more than one product do not always purchase all of those products at each purchasing transaction. As a first approach to assessing routine use of products, we report here the product(s) most frequently purchased by each patient. Table 5.1 shows the product(s) that were identified as the most frequently purchased by patients (indicated by “X”), as well as the percentage of patients it represents from the 1529 patients included in this analysis. Additionally, the table displays the average daily THC and CBD dose across patients for the product(s) purchased most frequently based on THC/CBD content information (provided by the medical cannabis manufacturers) as well as pharmacist-entered information regarding the length of time the product supply should last. Omitted from display in Table 5.1 are cases where two or less people had the same combination of most frequently purchased product(s)—this was done for ease of interpretation, as some of those cases seemed to be indicative of a wider range of experimentation across multiple products and/or indicative of patients with a shorter purchasing history.

Table 5.1 shows that roughly 72% of all patients most frequently purchased a single product that falls under 1) a specific THC:CBD ratio and 2) is intended for a particular route of administration (note the rows that have a single “X” in Table 5.1). Roughly a quarter of all patients most frequently purchased a very high THC to CBD product intended for vaporization followed by relatively similar numbers of patients most frequently purchasing a single, balanced-enteral product or a single, high CBD:THC-enteral product (respectively 12.6% and 13.7%). For patients most frequently purchasing two or more products an equal number of times, the most common combination was for an enteral-balanced product and an inhaled-very high THC:CBD product, accounting for 3% of all patients.

While the subsequent portions of this section will be devoted to stratifying routine product use by qualifying condition, the following statement should be made: the method for determining routine product use in this report (most frequently purchased) is relatively simple and, therefore, poses limitations for understanding the complexities in medication usage. Future endeavors will include a further discussion and potential refinement in methodology to better capture medical cannabis use in program participants

Table 5.1. Product(s) most frequently purchased by each patient (out of 1529 patients), along with average daily THC/CBD dose (mg).

Severe and Persistent Muscle Spasm Patients

Of the 1529 patients represented in this analysis, 44.3% (677) of them were certified as having Severe and Persistent Muscle Spasms, including those Characteristic of Multiple Sclerosis. Table 5.2 shows the product(s) that were identified as the most frequently purchased by muscle spasm patients (indicated by “X”), as well as the percentage of patients it represents from the 677 patients included in this analysis.

The most frequently purchased product for the majority of patients (70.2%) was a single product with a specific THC:CBD ratio and route of administration. The most common product purchased was a very high THC:CBD-inhaled product (32.3% of all patients) followed by a balanced-enteral and balanced-inhaled product (16.7% and 7.2%, respectively). For patients who purchased multiple products most frequently an equal number of times, the most common combination purchased was for a very high THC:CBD-inhaled product and a balanced-enteral product, accounting for 4.3% of all patients.

Table 5.2. Product(s) most frequently purchased by each muscle spasm patient (out of 677 patients), along with average daily THC/CBD dose (mg).

Cancer Patients

Of the 1529 patients represented in this analysis, 26.6% (406) of them were certified for Cancer. Table 5.3 shows the product(s) that were identified as the most frequently purchased by cancer patients (indicated by “X”), as well as the percentage of patients it represents from the 406 patients included in this analysis.

The majority of patients (61.6%) most frequently purchased a single product with a specific THC:CBD ratio and route of administration. Most commonly purchased products were a very high THC:CBD-inhaled product (23.9% of all patients) followed by a balanced-enteral and very high THC:CBD-oral mucosal product (10.3% and 9.6%, respectively). For patients who purchased multiple products most frequently an equal number of times, the most common combination purchased was for a very high THC:CBD product – one for enteral administration and one for inhalation (accounted for 5.4% of all patients).

Table 5.3. Product(s) most frequently purchased by each cancer patient (out of 406 patients), along with average daily THC/CBD dose (mg).

Seizure Patients

Of the 1529 patients represented in this analysis, 19.8% (303) of them were certified for Seizures, including those Characteristic of Epilepsy. Table 5.4 shows the product(s) that were identified as the most frequently purchased by seizure patients (indicated by “X”), as well as the percentage of patients it represents from the 303 patients included in this analysis.

89.1% of all patients most frequently purchased a single product with a specific THC:CBD ratio and route of administration. Most commonly used products were a high CBD:THC-enteral product (59.7% of all patients) followed by a very high THC:CBD-inhaled product and high CBD:THC-oral mucosal product (7.9% and 5.0%, respectively).

Table 5.4. Product(s) most frequently purchased by each seizure patient (out of 303), along with average daily THC/CBD dose (mg).

Crohn's Disease Patients

Of the 1529 patients represented in this analysis, 6.7% (103) of them were certified for Crohn's Disease. Table 5.5 shows the product(s) that were identified as the most frequently purchased by Crohn's patients (indicated by "X"), as well as the percentage of patients it represents from the 103 patients included in this analysis.

71.8% of all patients most frequently purchased a single product with a specific THC:CBD ratio and route of administration. Most commonly used products were a very high THC:CBD-inhaled product (28.2% of all patients) followed by a balanced-enteral and balanced-inhaled product (16.5% and 8.7%, respectively). For patients who purchased multiple products most frequently an equal number of times, the most common combination identified was for a balanced-enteral product and a very high THC:CBD-inhaled product, accounting for 4.9% of all patients.

Table 5.5. Product(s) most frequently purchased by each Crohn’s Disease patient (out of 103 patients), along with average daily THC/CBD dose (mg).

Terminal Illness Patients

Of the 1529 patients represented in this analysis, 5.4% (82) of them were certified for Terminal Illness. Table 5.6 shows the product(s) that were identified as the most frequently purchased by terminal illness patients (indicated by “X”), as well as the percentage of patients it represents from the 82 patients included in this analysis.

68.3% of all patients most frequently purchased a single product with a specific THC:CBD ratio and route of administration. Most commonly used products were a very high THC:CBD-inhaled product (26.8% of all patients) followed by a balanced-enteral and balanced-orumucosal product (both respectively accounting for 8.5% of all patients). For patients who purchased multiple products most frequently an equal number of times, the most common combination identified was for a very high THC:CBD product – one for enteral administration and the other for oromucosal absorption (accounted for 3.7% of all patients).

Table 5.6. Product(s) most frequently purchased by each terminal illness patient (out of 82 patients), along with average daily THC/CBD dose (mg).

HIV/AIDS Patients

Of the 1529 patients represented in this analysis, 3.2% (49) of them were certified for Human Immunodeficiency Virus and/or Acquired Immune Deficiency Syndrome (HIV/AIDS). Table 5.7 shows the product(s) that were identified as the most frequently purchased by HIV/AIDS patients (indicated by “X”), as well as the percentage of patients it represents from the 49 patients included in this analysis.

75.5% of all patients most frequently purchased a single product with a specific THC:CBD ratio and route of administration. Most commonly used products were a very high THC:CBD-inhaled product (51.0% of all patients) followed by a balanced-enteral product (12.2% of patients). For patients who purchased multiple products most frequently an equal number of times, the most common combination identified was for two inhaled products – one of a very high THC:CBD ratio and the other a balanced THC:CBD ratio (accounted for 10.2% of all patients).

Table 5.7. Product(s) most frequently purchased by each HIV/AIDS patient (out of 49 patients), along with average daily THC/CBD dose (mg).

Enteral			Inhalation			Oromucosal

Tourette Syndrome Patients

Of the 1529 patients represented in this analysis, 1.9% (29) of them were certified for Tourette Syndrome. Table 5.8 shows the product(s) that were identified as the most frequently purchased by Tourette Syndrome patients (indicated by “X”), as well as the percentage of patients it represents from the 29 patients included in this analysis.

93.1% of all patients most frequently purchased a single product with a specific THC:CBD ratio and route of administration. Most commonly used products were a balanced-enteral product (20.7% of all patients) followed by a very high THC:CBD-inhaled product and a very high THC:CBD-oral mucosal product (respectively at 20.7% and 13.8% of all patients).

Table 5.8. Product(s) most frequently purchased by each Tourette Syndrome patient (out of 29 patients), along with average daily THC/CBD dose (mg).

Glaucoma Patients

Of the 1529 patients represented in this analysis, 1.5% (23) of them were certified for Glaucoma. Table 5.9 shows the product(s) that were identified as the most frequently purchased by glaucoma patients (indicated by “X”), as well as the percentage of patients it represents from the 23 patients included in this analysis.

56.5% of all patients most frequently purchased a single product with a specific THC:CBD ratio and route of administration. Most commonly used products were a very high THC:CBD-inhaled product (21.7% of all patients) followed by a very high THC:CBD-enteral product and a balanced-enteral product (respectively at 17.4% and 13.0% of all patients).

Table 5.9. Product(s) most frequently purchased by each glaucoma patient (out of 23 patients), along with average daily THC/CBD dose (mg).

Medical Cannabis Use Patterns: Conclusions

To establish medication use patterns in program participants, a total of 16,238 product transactions were analyzed from 1529 patients in the 1st program year cohort. When product transactions were examined by each product's intended route of administration and THC:CBD content, the following patterns emerged. Firstly, roughly 90% of all products were purchased for enteral administration (through mouth via capsules or oral solutions) and inhalation (vaporized oil). Secondly, approximately 50% of all product transactions were for products very high in THC relative to CBD followed by balanced THC:CBD products (~30%) and high CBD:THC products (~15%). Very high THC:CBD products were most commonly purchased for inhalation or oromucosal absorption, while balanced and high CBD:THC products were most commonly used for enteral administration.

For this report, the most frequently purchased product(s) were identified for each patient as one method for understanding routine purchasing patterns. 72.5% of all patients most frequently purchased one type of product, with the most frequently purchased single product being a very high THC:CBD-inhaled product followed by a high CBD:THC-enteral and balanced-enteral product. For specific differences in the most frequently purchased products among qualifying conditions, the reader is encouraged to refer back to those specific sections.

6. Benefits

Summary

Information on patient benefits comes from the Patient Self-Evaluation (PSE) completed by patients prior to each medical cannabis purchase and from patient and health care practitioner surveys. Results of analysis of PSE and survey data indicate perceptions of a high degree of benefit for most patients.

Patients responded to a survey question asking them how much benefit they believe they received from using medical cannabis on a scale from 1 (no benefit) to 7 (great deal of benefit). Across all patients 64% indicated a benefit rating of 6 or 7 and this degree of benefit was indicated by at least half of the patients with each medical condition (see Table 6.1). A small but important proportion of patients indicated little or no benefit: 9% gave a rating of 1, 2, or 3. When patients were asked what the most important benefit was for them, two-thirds indicated a reduction in symptoms directly related to their qualifying medical condition and most of the remainder indicated more general quality of life benefits.

An important part of this report is the verbatim comments written by patients, and the reader is encouraged to review these comments in *Appendix A: Patient-Reported Benefits from Surveys*. Examples of these comments include:

- “Almost all muscle spasm and pain associated with spasms are gone. I used to have constant nerve triggered pain that is minimal now. Results were almost immediate. I am sleeping way better now also.”
- “[NAME] has passed away. I am her daughter and was her care giver. She was open to trying medical cannabis and we got the liquid form. It was a saving grace. She was in a lot of pain and when prescribed medications did NOT work – we started this and it kept her calm and relaxed. I am very thankful that we were able to have this option available. It helped to make her last months more bearable and truly it would have been miserable without it.”
- “I am getting enough sleep for the first time since about 2011. My absence seizures have gone from 3-4 a day to almost 0. It also has lessened the severity of grand mal seizures. The recovery time after has gone from around 12 hours to around 4.”
- “At first it helped a lot but my seizures have returned.”
- “Spasms – only a little better.”

Table 6.1. Patient-perceived benefit (n=792).

	No Response	1	2 or 3	4 or 5	6 or 7
All Patients	4%	4%	5%	23%	64%
Muscle Spasms	2%	3%	3%	22%	69%
Cancer	5%	5%	6%	21%	64%
Seizures	5%	5%	9%	29%	51%
Crohn's Disease	0%	2%	5%	22%	71%
Terminal Illness	11%	3%	3%	13%	71%
HIV/AIDS	4%	0%	8%	8%	79%
Tourette Syndrome	6%	0%	0%	25%	69%
Glaucoma	23%	8%	0%	0%	69%
ALS	9%	9%	0%	18%	64%

Patient responses about degree of benefit experienced: 1=no benefit; 7=great deal of benefit.

Health care practitioners were somewhat more conservative in assessment of benefit to their patients. Across all the benefit ratings by health care practitioners, 38% indicated a rating of 6 or 7 and 23% indicated little or no benefit (rating of 1, 2, or 3). Similarity in benefit assessment between health care practitioners and patients appears to vary by medical condition, with highest discrepancy among seizure patients. Descriptive comments suggest at least part of the difference is driven by perspective of what constitutes benefit. The patients cite quality of life benefits more often than the health care practitioners, who appear to focus more on objective measures such as seizure counts.

The symptom scores provided in the Patient Self-Evaluation data have the advantage of completeness, since they are required prior to each medical cannabis purchase. In this report a reduction of $\geq 30\%$ was applied to most symptoms to indicate clinically meaningful symptom reduction. In the text of the report, we present results for the more conservative of the two methods used to calculate $\geq 30\%$ symptom reduction. However, *Appendix D: Symptom Results*

from the Patient Self-Evaluation shows results for both methods (details can be found in this chapter). Results show patterns similar to those in the survey benefits rating, but usually somewhat smaller in size. For example, among patients with muscle spasms, weekly muscle spasm frequency was reduced $\geq 30\%$ within the first four months of medical cannabis use in 48% of patients (see Table 6.2). Importantly, in the four months after first achieving this degree of spasm reduction, more than half the patients retained this degree of improvement. That is, of all patients with muscle spasms, 48% achieved $\geq 30\%$ reduction in spasm frequency and 28% both achieved that degree of improvement and retained it over the next four months. Full results for symptom improvement analyses and for persistence of improvements are in *Appendix D: Symptom Results from the Patient Self-Evaluation*. Results for selected symptoms are presented in Table 6.2. For most symptoms, between half and two-thirds of patients who achieve clinically meaningful improvement retained that degree of improvement over the next four months.

Examples of proportion of patients achieving and retaining $\geq 30\%$ symptom reduction include:

- Among seizure patients, 68% reported $\geq 30\%$ reduction in seizure frequency and 49% both achieved that level of reduction and retained it, on average, for at least four months
- Among patients with Tourette syndrome, 61% reported $\geq 30\%$ reduction in tic frequency and 46% both achieved that level of reduction and retained it, on average, for at least four months
- Among patients with Crohn's disease, 51% reported $\geq 30\%$ reduction in number of liquid stools per day and 29% both achieved that level of reduction and retained it, on average, for at least four months
- Among patients with severe, persistent muscle spasms, 48% reported $\geq 30\%$ reduction in spasm frequency and 28% both achieved that level of reduction and retained it, on average, for at least four months
- Among cancer patients with at least moderate levels of nausea when they started using medical cannabis, 38% reported $\geq 30\%$ reduction of nausea and 23% both achieved that level of reduction and retained it, on average, for at least four months
- Among cancer patients with at least moderate levels of pain when they started using medical cannabis, 29% reported $\geq 30\%$ reduction of pain and 12% both achieved that level of reduction and retained it, on average, for at least four months

Moderate to severe levels of non-disease-specific symptoms such as fatigue, anxiety, and sleep difficulties were common across all the medical conditions. And the reductions in these symptoms was often quite large. These findings support the understanding that some of the benefit perceived by patients is expressed as improved quality of life.

The type(s) of medical cannabis used at the time patients achieved clinically meaningful improvement was analyzed for each symptom assessed within each category of medical condition. Full results of those analyses are in *Appendix D: Symptom Results from the Patient Self-Evaluation* and summaries are presented in this chapter. In most cases, a few combinations

of product types were purchased more frequently than others when analyzing data by patient condition

Table 6.2 Symptom improvement for selected symptoms. Note: for spasticity, pain, appetite, nausea, and vomiting the analysis was conducted on patients with moderate to severe symptoms at baseline.

	% of Patients who Achieved Threshold Symptom Improvement (≥30% Improvement Unless Otherwise Noted)	% of All Patients that Both Achieved Threshold Symptom Improvement and Retained that Degree of Improvement for at Least 4 Months
MUSCLE SPASMS		
Weekly spasm frequency (n = 629)	48%	28%
Spasticity (n = 618)	36%	17%
Pain (n = 640)	34%	17%
CANCER		
Pain (n = 356)	29%	12%
Appetite (n = 321)	39%	22%
Nausea (n = 283)	38%	23%
Vomiting (n = 168)	48%	27%
SEIZURES		
Weekly seizure frequency (n = 262)	68%	49%
CROHN'S DISEASE		
# Liquid stools/day (n = 41)	51%	29%
Abdominal pain (details in text; n = 73)	53%	19%
General well-being (details in text; n = 15)	47%	13%
Measures Combined (details in text; n = 102)	51%	22%
Weight (≥ 3 pound gain; n = 102)	21%	12%
TERMINAL ILLNESS		
Pain (n = 72)	19%	10%

HIV/AIDS		
Pain (n = 45)	40%	20%
Appetite (n = 39)	49%	31%
Weight (≥ 3 pound gain; n = 48)	15%	6%
TOURETTE SYNDROME		
Weekly tic frequency (n = 28)	61%	46%
GLAUCOMA (see text)		
ALS		
Weekly spasm frequency (n = 18)	33%	22%
Spasticity (n = 15)	20%	20%
Pain (n = 17)	47%	12%

Benefits Reported on Surveys

In addition to collecting data on severity of symptoms related to each patient's qualifying condition or conditions before each medical cannabis purchase, the Office of Medical Cannabis sought to gain a qualitative understanding of patient-reported benefits and harms of program participation. Utilizing expertise within the Minnesota Department of Health, the Office of Medical Cannabis developed a Patient Experience survey, which captures information on benefits and harms of program participation. A parallel survey was developed for each patient's certifying health care practitioner, which captures similar information from the clinician's perspective. The surveys include scaled response and open-response questions; health care practitioners were also asked to provide any clinical observations they noted about the patient's experience with medical cannabis. Healthcare providers familiar with the program provided feedback as part of the development process.

Survey Methodology and Data Preparation

The surveys are provided through an online platform with a hard copy alternative. The Patient Experience survey is sent three months after the patient's first medical cannabis purchase, six months after the first purchase and every six months thereafter. Healthcare practitioner surveys are sent six months after the patient's first purchase and every six months thereafter. Surveys are accessible through the patient or healthcare practitioner's registry page and through introductory emails containing unique links. To maximize survey submission rates, the survey can be submitted with incomplete responses to any of the questions. Each of the surveys is available online to the recipient for 45 days. Patient recipients receive reminder emails after one week; after two weeks with no response, paper copies of surveys are mailed to the recipient. For patients without online access the full process is accomplished by mail.

Initially, patient and healthcare practitioners (HCPs) were sent one survey three months after the patient's first purchase, without recurrence. This schedule was revised to include recurring surveys roughly every six months to provide patients and their HCPs an opportunity to report ongoing progress or changes to the patient's condition; however the HCP survey sent three months after the first purchase was eliminated based on feedback that three months may not allow enough time for the provider to see their patient following initial certification. These changes were implemented in April 2016; as a result, HCP survey data collected three months after the first purchase is only available for the first six months of the program (this includes patients who enrolled and made a first purchase between July 1, 2015 and December 31, 2015). All survey data presented in this chapter are from the patient and health care practitioner surveys sent three months after the patient's first medical cannabis purchase.

Patients and their certifying HCPs were asked to report the "most important benefit" and "most important negative effect" related to medical cannabis treatment. Survey responses from patients and health care practitioners on perceived benefits and perceived negative effects

were reported in free-text format; each response was individually reviewed and classified into a category of benefit or negative effects. Reported benefits typically included either direct improvement of symptoms related to the patient’s qualifying condition or more general improvements in health or quality of life, referred to in this report as global health benefits. Additionally, many responses included more than one type of benefit; in these cases, the first reported benefit was presumed to be the most important benefit. In this report, we examine both overall perceptions of benefit, as well as type of reported benefit.

Patient Experience Survey Results

Patient Experience Survey Response Rate

Of 1491 patients who were approved and made their first medical cannabis purchase in the first year of the program (July 1, 2015- June 30, 2016), 792 patients (53%) submitted a survey three months after making the first purchase. As of December 31, 2016, 90 patients (5%) were known to be deceased since enrolling in the program. These patients were included in this report, as in some cases caregivers or relatives and HCPs completed surveys, reflecting on the patient’s experience for the period of time the patient did use medical cannabis.

Table 6.3. Patient survey response rates by age group.

	Total	Patient Responses
0-4	62	17 (53%)
5-17	129	76 (59%)
18-24	89	51 (57%)
25-35	234	132 (56%)
36-49	355	192 (54%)
50-64	462	258 (56%)
65+	160	66 (41%)
Total	1491	792 (53%)

Table 6.4. Patient total counts and patient response rates by qualifying medical condition.

	Total	Patient Responses
Muscle Spasms	653	373 (57%)
Cancer	386	157 (41%)
Seizures	287	182 (63%)
Crohn's Disease	99	55 (56%)
Terminal Illness	79	38 (48%)
HIV/AIDS	46	24 (52%)
Tourette Syndrome	28	16 (57%)
Glaucoma	21	13 (62%)
ALS	21	11 (52%)

Table 6.5. Patient survey response rates by race and ethnicity.

	Total	Patient Responses
American Indian	37	14 (38%)
Asian	24	8 (33%)
Black	86	35 (41%)
Hawaiian	3	0 (0%)
White	1249	712 (57%)
Other	24	9 (38%)
Hispanic	35	14 (40%)

Patient response rates varied across age group, qualifying condition and race and ethnicity (Tables 6.3-6.5). Elderly patients (ages 65 and over) had the lowest response rate (41%); patients certified for cancer and terminal illness also had low response rates relative to other certified condition groups (41% and 48%, respectively). In general, racial and ethnic minorities were under-represented in survey responses.

Patient Perceptions of Benefits from Medical Cannabis

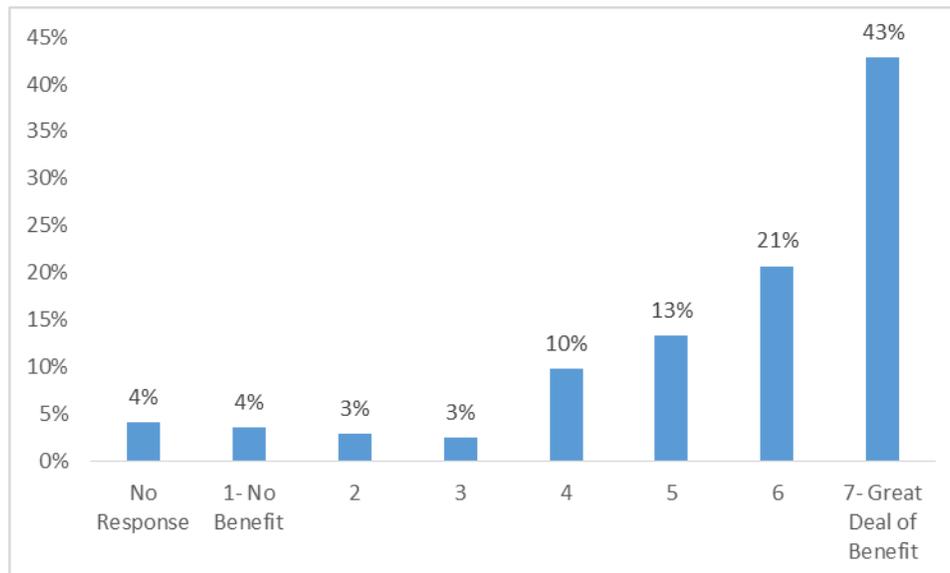

The Patient Experience and HCP surveys both ask respondents to report how much benefit they believe the patient received from using medical cannabis, on a scale from 1 (no benefit) to 7 (a great deal of benefit). Figures 6.1-6.10 show the distribution of benefit scores on this scale, as reported by patients, for all patients and by patients with each qualifying condition.

The percentages in Figures 6.1-6.10 are based on the total number of patient responses in each condition group and not the number of complete benefit scores for each group (33 patients submitted surveys without completing the benefit score question, but were included in the denominators).

ALL QUALIFYING CONDITIONS

Figure 6.1 below shows all patient responses about degree of benefit experienced. Among patient respondents, 43% report the highest degree of benefit from medical cannabis: “a great deal of benefit” or a score of 7 on a scale from 1-7.

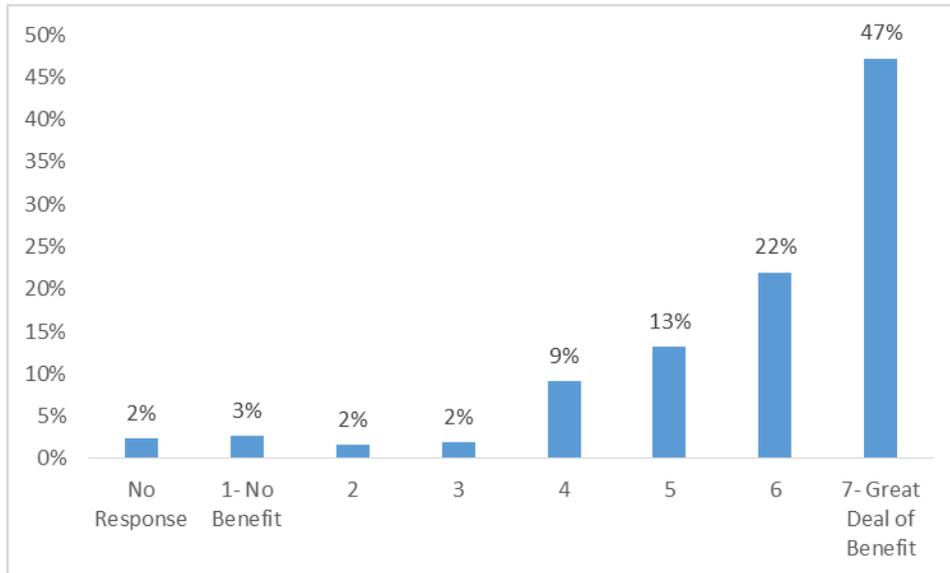

Figure 6.1. Patient-Perceived Benefit: All Conditions (N=792).

SEVERE AND PERSISTENT MUSCLE SPASMS

Figure 6.2 shows responses from patients certified for severe and persistent muscle spasms regarding degree of benefit experienced. Among respondents, 47% report a score of 7 on a scale from 1-7.

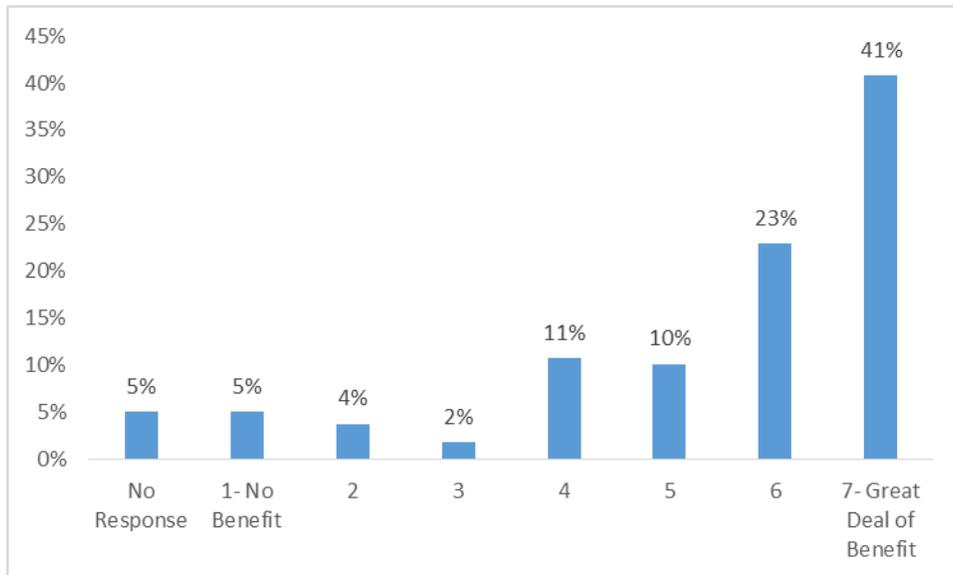

Figure 6.2. Patient-Perceived Benefit: Muscle Spasms (N=373)

CANCER

Figure 6.3 shows responses from patients certified for cancer regarding degree of benefit experienced. Among respondents, 41% report a score of 7 on a scale from 1-7.

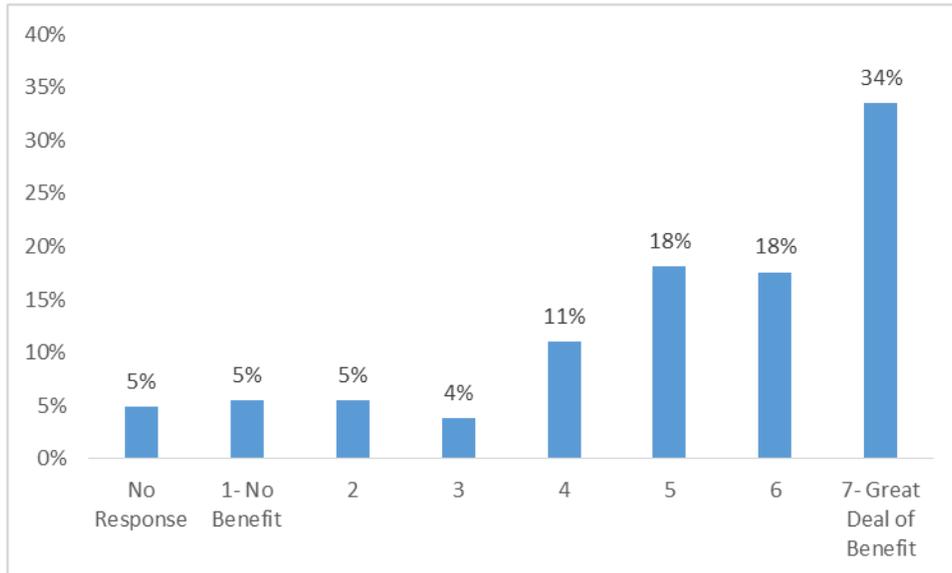

Figure 6.3. Patient-Perceived Benefit: Cancer (N=157)

SEIZURES

Figure 6.4 shows responses from patients certified for seizure disorders regarding degree of benefit experienced. Among respondents, 34% report a score of 7 on a scale from 1-7.

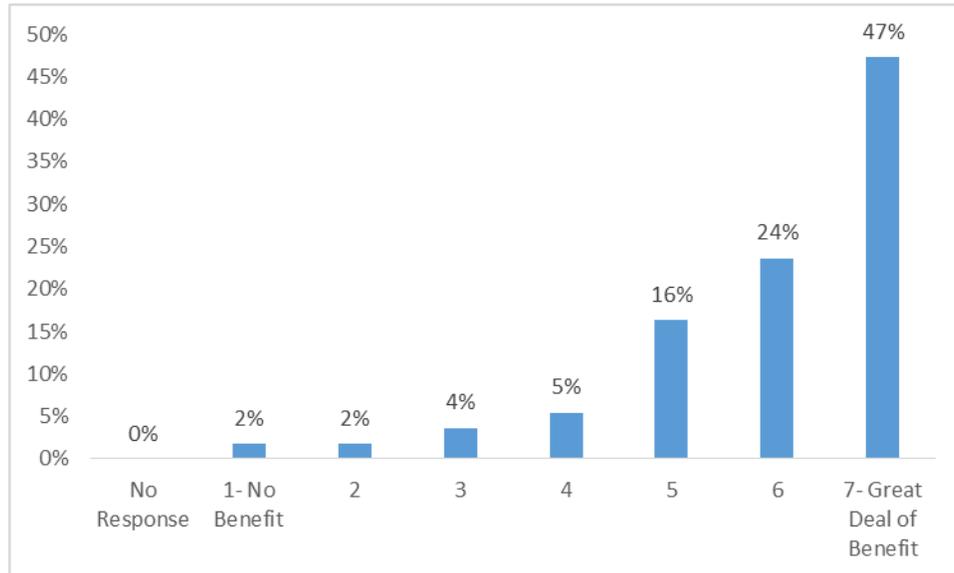

Figure 6.4. Patient-Perceived Benefit: Seizures (N=182)

CROHN'S DISEASE

Figure 6.5 shows responses from patients certified for Crohn's disease regarding degree of benefit experienced. Among respondents, 47% report a score of 7 on a scale from 1-7.

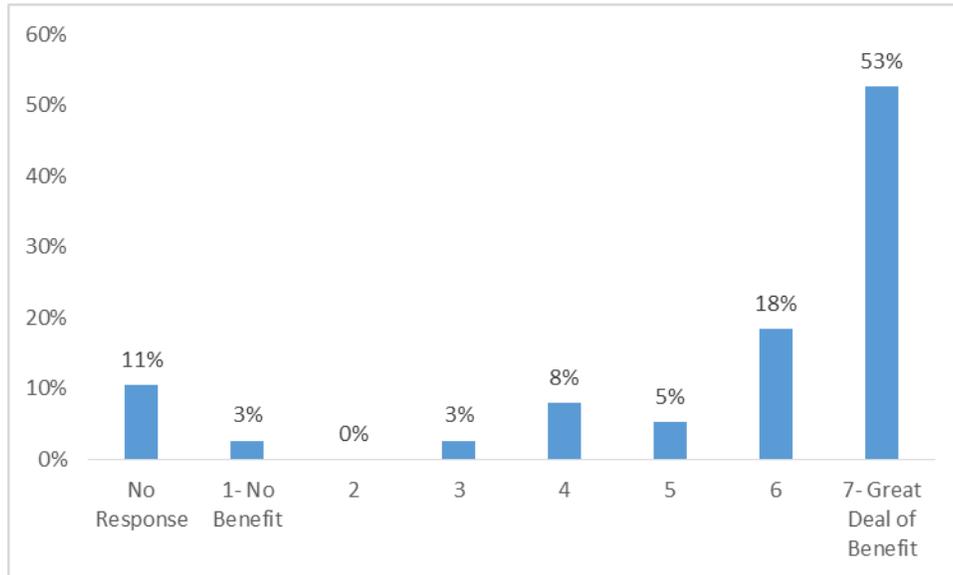

Figure 6.5. Patient-Perceived Benefit: Crohn's Disease (N=55)

TERMINAL ILLNESS

Figure 6.6 shows responses from patients certified for terminal illness regarding degree of benefit experienced. Among respondents, 53% report a score of 7 on a scale from 1-7.

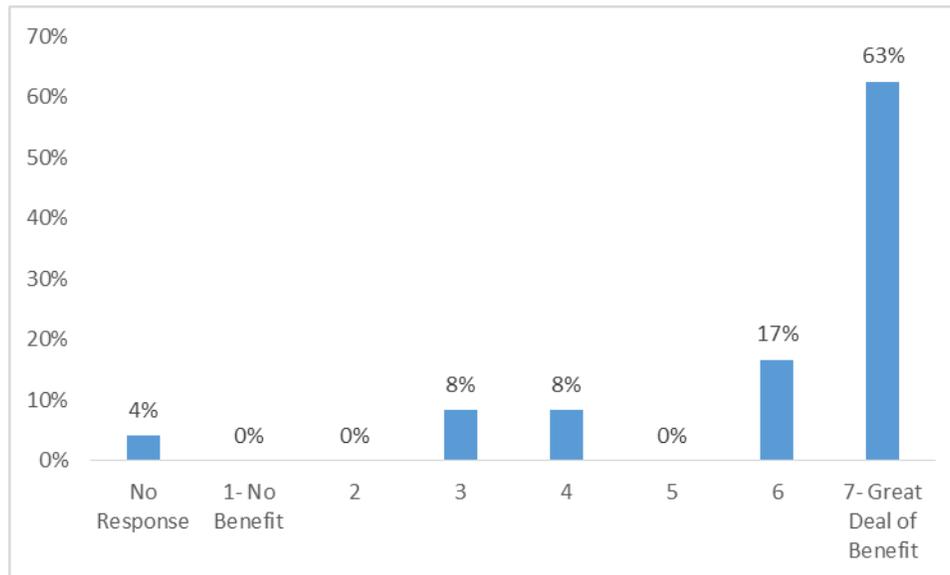

Figure 6.6. Patient-Perceived Benefit: Terminal Illness (N=38)

HIV/AIDS

Figure 6.7 shows responses from patients certified for HIV/AIDS regarding degree of benefit experienced. Among respondents, 63% report a score of 7 on a scale from 1-7.

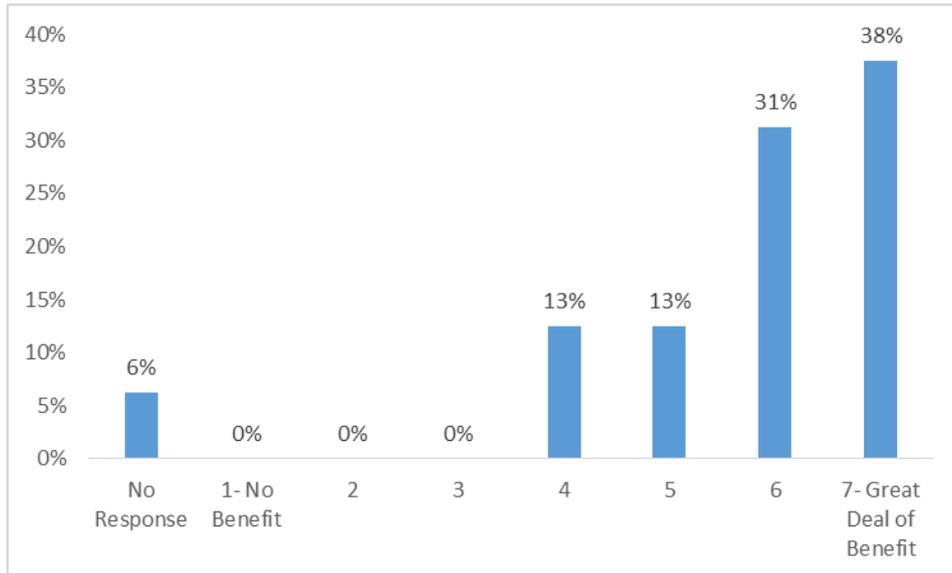

Figure 6.7. Patient-Perceived Benefit: HIV/AIDS (N=24)

TOURETTE SYNDROME

Figure 6.8 shows responses from patients certified for Tourette syndrome regarding degree of benefit experienced. Among respondents, 38% report a score of 7 on a scale from 1-7.

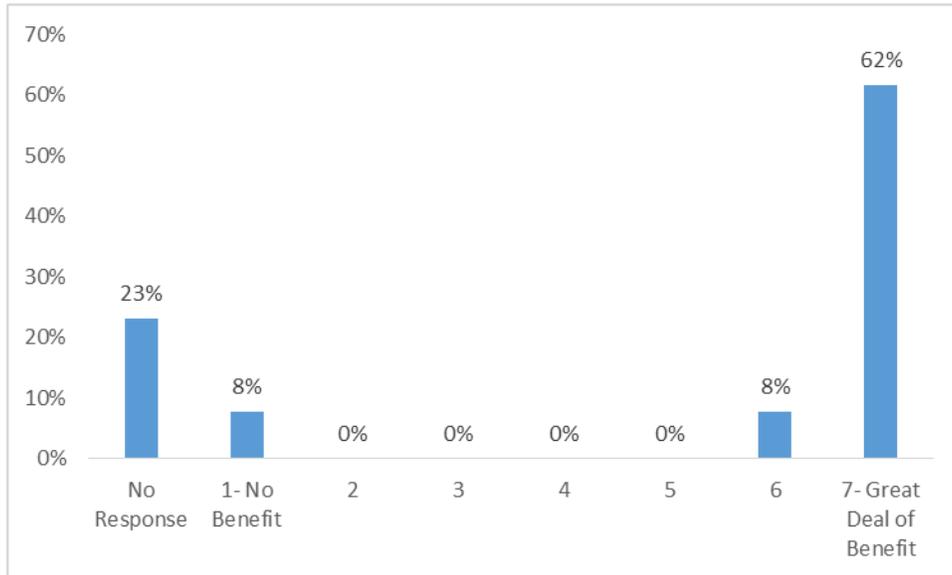

Figure 6.8. Patient-Perceived Benefit: Tourette Syndrome (N=16)

GLAUCOMA

Figure 6.9 shows responses from patients certified for glaucoma regarding degree of benefit experienced. Among respondents, 62% report a score of 7 on a scale from 1-7.

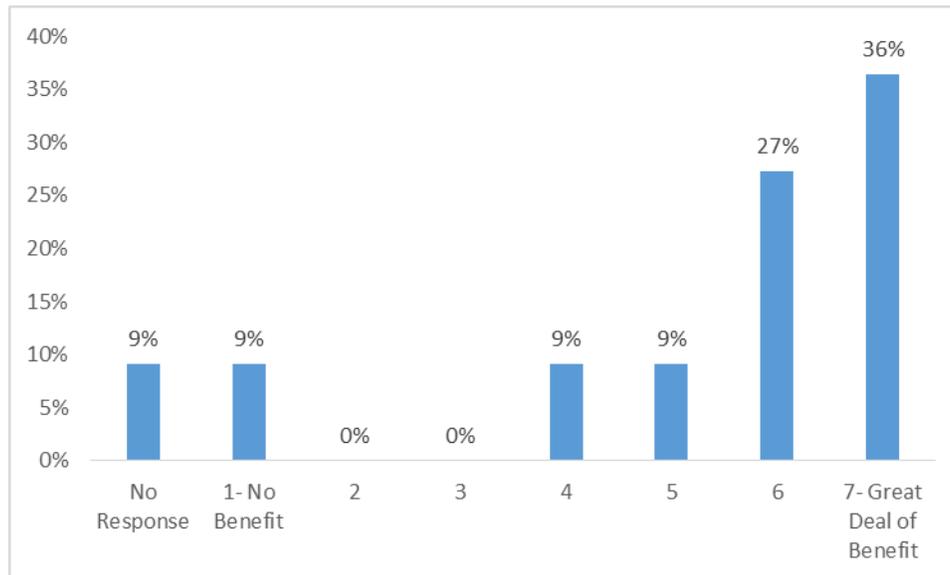

Figure 6.9. Patient-Perceived Benefit: Glaucoma (N=13)

ALS

Figure 6.10 shows responses from patients certified for ALS regarding degree of benefit experienced. Among respondents, 36% report a score of 7 on a scale from 1-7.

Figure 6.10. Patient-Perceived Benefit: ALS (N=11)

Patient Perceptions of Types of Benefits from Medical Cannabis Treatment

In both the Patient Experience and HCP surveys, patients and their certifying HCPs had an opportunity to describe the most significant benefit to the patient that was associated with medical cannabis treatment. Each response was reviewed and classified as symptom improvement (based on qualifying condition), or global health benefit, which included all health benefits not specifically related to the relief of symptoms directly associated with the patient's qualifying medical condition(s). Note that not all completed surveys had a response for this question; 86% of the Patient Experience surveys did and 66% of the HCP surveys did. Among the 681 completed Patient Experience survey responses that indicated a most significant benefit, 64% classified the benefit as symptom improvement and 25% classified it as a global health benefit; the remaining comments regarding benefit were improvement of symptoms other than those related to the qualifying condition or global health benefits. Tabulation of those responses is reported below, but the reader is also encouraged to read the verbatim responses in *Appendix A: Patient-Reported Benefits from Surveys*. Reading the words written by the patient gives a more nuanced understanding of the benefits and provides a reminder that each of the respondents is an individual person. The following is a selection of the comments, chosen to reflect the full range of benefits perceived:

- “Almost all muscle spasms and pain associated with spasms are gone. I used to have constant nerve triggered pain that is minimal now. Results were almost immediate. I am sleeping way better now also.”
- “A large reduction in symptoms, allowing me to participate in my daily life without a large number of limits my symptoms would place on me – stools decreased from over 8 a day to about 2 with much less blood and mucous in stools. Pain has reduced to a tolerable amount”
- “[NAME] has passed away. I am her daughter and was her care giver. She was open to trying medical cannabis and we got the liquid form. It was a saving grace. She was in a lot of pain and when prescribed medications did NOT work – we started this and it kept her calm and relaxed. I am very thankful that we were able to have this option available. It helped to make her last months more bearable and truly it would have been miserable without it.”
- “Has eased my muscle spasms and cramping. Has helped my visual issues. Has helped me to maintain healthy weight. Have been able to sleep much better and have cut other pain prescriptions way back. Seems to take pain away enough that I have been more active and am able to function on household tasks to a somewhat normal level. My brain seems to be working better as well ie. concentration/focusing and remembering.”
- “I am getting enough sleep for the first time since about 2011. My absence seizures have gone from 3-4 a day to almost 0. It also has lessened the severity of grand mal seizures. The recovery time after has gone from around 12 hours to around 4.”
- “Within 1 week of use, my tics disappeared and have stayed gone even with occasional use. This has never happened previously in my life, so it is very effective.”
- “At first it helped a lot but my seizures have returned.”
- “Spasms – only a little better.”

Symptom Improvement from Medical Cannabis Treatment

Table 6.6 summarizes the reported “most important benefits” which could be considered improvement of a symptom related to the patient’s qualifying condition from reports of patients, categorized by the benefit score reported by the patient. For patients with severe muscle spasms, reports of spasm reduction or pain reduction were considered symptom improvement. For patients with cancer (regardless of whether their condition was associated with severe/chronic pain, nausea or severe vomiting, cachexia or severe wasting, or a combination), pain reduction, nausea and/or vomiting reduction, and weight gain and/or appetite improvement were considered symptom improvement. For patients with seizures, reports of fewer seizures, less severe seizures, or both, were considered symptom improvement. For patients with Crohn’s disease, pain reduction, weight gain and/or appetite improvement, and reduction in related symptoms including stool frequency were considered symptom improvement. For patients with terminal illnesses (regardless of whether their condition was associated with severe/chronic pain, nausea or severe vomiting, cachexia or

severe wasting, or a combination), reduction in pain, nausea and/or vomiting and weight gain and/or appetite improvement were considered symptom improvement. For patients certified for HIV/AIDS, reduction in pain, nausea and/or vomiting, and weight gain and/or appetite improvement were considered symptom improvement. In patients with Tourette syndrome, reduced tics or specific mention of reduced Tourette symptoms were considered symptom improvement. In patients certified for glaucoma, reduction in intraocular pressure or reference to treatment of glaucoma “symptoms” was considered symptom improvement. Finally, for patients with ALS, reduction in pain or spasms were considered symptom improvement.

Among patients with severe and persistent muscle spasms, 26% reported pain reduction and another 25% reported spasm reduction as the most important benefit. Among seizure patients, 51% reported seizure reduction (either in frequency or severity). Among cancer patients, 26% reported pain reduction as the primary benefit; 25% reported weight gain, appetite improvement, or reduced nausea or vomiting. Among Crohn’s disease respondents, 25% reported reduced pain, 16% reported reduced severity or frequency of gastrointestinal symptoms and 4% reported weight gain or appetite improvement as the primary benefit. Among patients with terminal illness, 21% reported reduced nausea or vomiting, 18% reported pain reduction and 8% reported weight gain or appetite improvement as the most important benefit. Thirty-one percent of glaucoma patient respondents reported reduction of glaucoma-related symptoms. Among ALS patients, 27% reported pain reduction and 9% reported spasm reduction as the most important benefit. Among HIV/AIDS patients, 25% reported reduced pain, 17% reported reduced nausea and/or vomiting and 12% reported weight gain or appetite improvement as the most important benefit. Finally, among patients with Tourette syndrome, 63% reported a reduction in tics or other symptoms of Tourette syndrome.

Table 6.6. Distribution of Symptom Improvement by Condition: Patient Surveys

Patient Perceptions of Global Health Benefits from Medical Cannabis

Many patients responded to the question regarding “most important benefit” by describing benefits not specifically related to the symptoms of their qualifying conditions. These responses were reviewed and classified into categories of “global health benefits”- broader benefits which impact the patient’s overall health. Global health benefits reported by patients included improvement in quality of life, improvement in sleep (whether or not explicitly tied to reduction in symptoms related to qualifying condition), improved mobility and/or ability to function or perform regular tasks, reduced anxiety or increased calmness, improved alertness and/or cognitive functioning, and reduced usage of other medications (often reported as reduction in dosage and/or side effects related to use of other medications). Clearly, global health benefits may be due to improvements in symptoms specifically related to the qualifying condition, so the dividing line between these categories is a bit blurry.

Table 6.7 shows the number of responses by type of global health benefit, along with the associated benefit score reported by the patient. Overall, 6% of patient respondents reported

improved sleep as the most important benefit from medical cannabis; 4% reported improved quality of life, 4% reported reduced usage of other medication, 3% reported reduced anxiety, and 2% reported improved alertness or cognitive function.

Table 6.7. Distribution of Global Health Benefits Condition: Patient Surveys

	1 (No Benefit)	2	3	4	5	6	7 (Great Deal of Benefit)	Total

Health Care Practitioner Survey Results

HCP Survey Response Rate

As a result of changing the survey schedule during the first program year, the healthcare providers of 774 patients who were enrolled and made a first medical cannabis purchase in the first six months of the program (July 1 – December 31, 2015) received a survey three months after the patient’s first purchase; the remaining 717 could therefore not be included in the reporting below. The subset of Patient Experience survey responses that corresponds to this group of HCP responses is included below for comparison. Of 774 patients in this group, 437 patients (57%) submitted a survey three months after making the first purchase. Of the 262 health care practitioners (HCP) who certified these patients, 114 (43.5%) completed surveys for 251 (32%) patients.

Table 6.8. Healthcare Practitioner and Patient Experience survey response rates by age group.

	Total	HCP Responses	Patient Responses
0-4	15	7 (47%)	9 (60%)
5-17	90	36 (40%)	49 (54%)
18-24	48	18 (38%)	28 (58%)
25-35	110	32 (29%)	59 (54%)
36-49	194	66 (34%)	114 (59%)
50-64	225	65 (29%)	131 (58%)
65+	92	27 (29%)	47 (51%)
Total	774	251 (32%)	437 (58%)

Table 6.9. Patient total counts and HCP/patient response rates by qualifying medical condition.

	Total	HCP Responses	Patient Responses
Muscle Spasms	305	98 (32%)	182 (60%)
Cancer	192	51 (27%)	84 (44%)
Seizures	189	64 (34%)	120 (63%)
Crohn's Disease	58	25 (43%)	34 (59%)
Terminal Illness	43	12 (28%)	21 (49%)
HIV/AIDS	26	12 (46%)	15 (58%)
Tourette Syndrome	11	4 (36%)	6 (55%)
Glaucoma	11	3 (27%)	5 (45%)
ALS	15	5 (33%)	7 (47%)

Table 6.10. Patient total counts and HCP/patient response rates by race and ethnicity.

	Total	HCP Responses	Patient Responses
American Indian	16	6 (38%)	7 (44%)
Asian	17	8 (47%)	7 (41%)
Black	41	14 (35%)	15 (37%)
Hawaiian	1	0 (0%)	0 (0%)
White	665	218 (33%)	395 (59%)
Other	14	5 (36%)	6 (43%)
Hispanic	18	4 (22%)	6 (33%)

Response rates for the Patient Experience and HCP surveys varied widely across age group, qualifying condition and race and ethnicity (Tables 6.8-6.10). Patient response rate was lowest among the oldest age group (65+; 51%) and HCP response rate was generally lower for older age groups. Among HCP responses, certifiers of patients with HIV/AIDS and Crohn’s disease had the highest response rates (46% and 43%, respectively). Among patient responses, patients certified for severe and persistent muscle spasms, seizures and Crohn’s disease had the highest response rates (60%, 63%, and 59%, respectively). Finally, racial and ethnic minorities were generally under-represented among patient responses.

Healthcare Practitioner Perceptions of Benefit

The Patient Experience and HCP surveys both ask respondents to report how much benefit they believe the patient received from using medical cannabis, on a scale from 1 (no benefit) to 7 (a great deal of benefit). Figures 6.11-6.20 show the distribution of benefit scores on this scale, as reported by HCPs, for all patients and by patients with each qualifying condition.

A note on how proportions were calculated: the total number of HCP responses is reflected in Figures 6.11-6.20; this includes 45 HCP responses with either no response or a “0” option selected for the benefit scale, which indicates that the HCP did not have enough information about the patient to answer the question of benefit.)

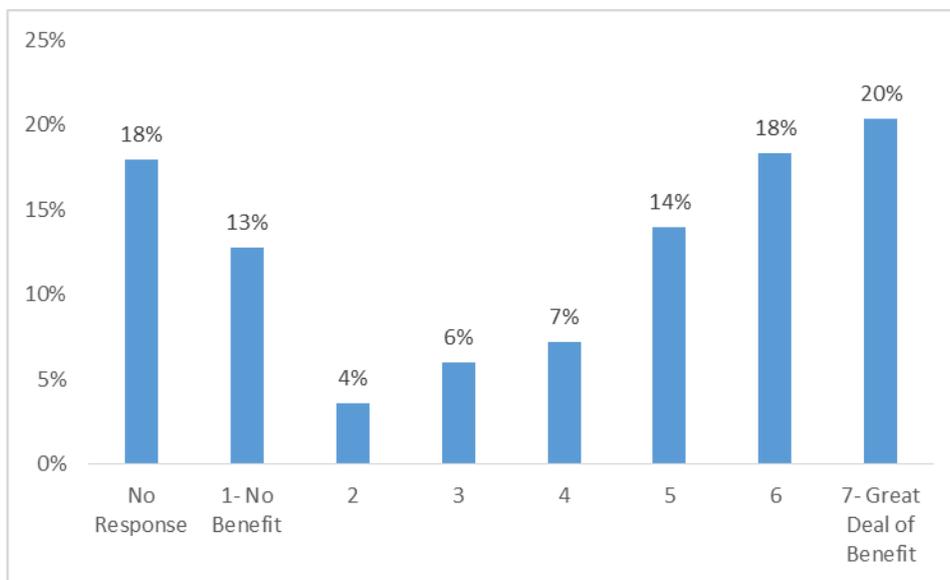

Note that results from patient surveys (Figures 6.1-6.10) and health care practitioner surveys (Figures 6.11-6.20) do not pertain to identical groups of patients. That is, some patients have

only a patient survey completed, some have only a HCP survey completed, some have neither completed, and some (n=126) have a completed survey from both the patient and their certifying HCP. For this reason, comparison of results from patient and HCP surveys must be approached with caution, except for the last group, where there is a completed survey from both the patient and the HCP. Further on in this section (Table 6.13 and Figures 6.21-6.28) comparisons for that last group are presented. In general, responses from HCPs report a lower degree of benefit than the patient responses.

ALL QUALIFYING CONDITIONS

Figure 6.11 shows all HCP responses about degree of benefit experienced. Benefit ratings were provided on 206 of the 251 submitted surveys. Among the 251 surveys, 32 (13%) reported no benefit and 51 (20%) reported the highest degree of benefit (score of 7); 150 (60%) reported a benefit score ≥ 4 on the seven-point scale.

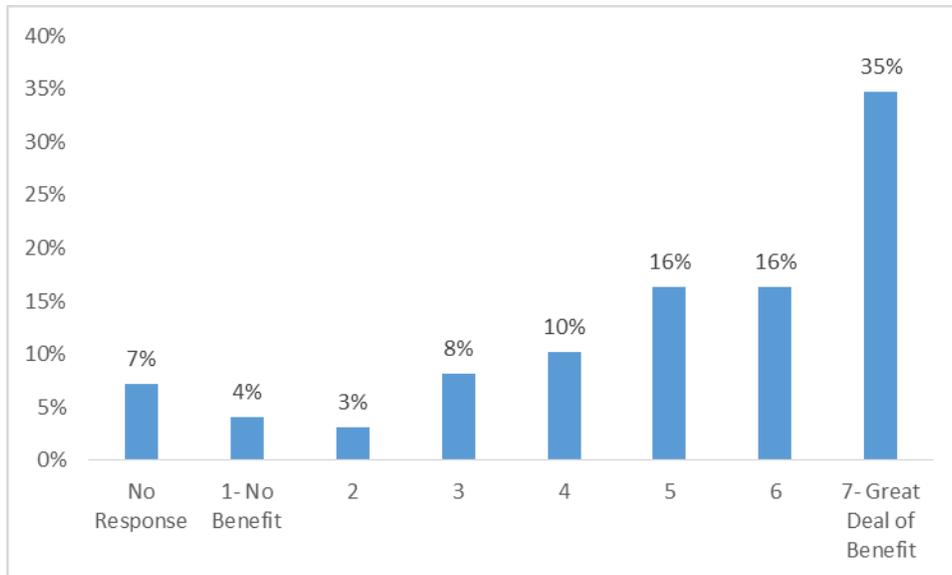

Figure 6.11. HCP-Perceived Benefit: All Conditions (N=251)

SEVERE AND PERSISTENT MUSCLE SPASMS

Figure 6.12 shows HCP benefit score responses for patients certified for severe and persistent muscle spasms. Benefit ratings were provided on 91 of the submitted surveys. Among the 91 responses, 4 reported no benefit and 34 reported the highest degree of benefit (score of 7); 76 (84%) reported a benefit score ≥ 4 on the seven-point scale.

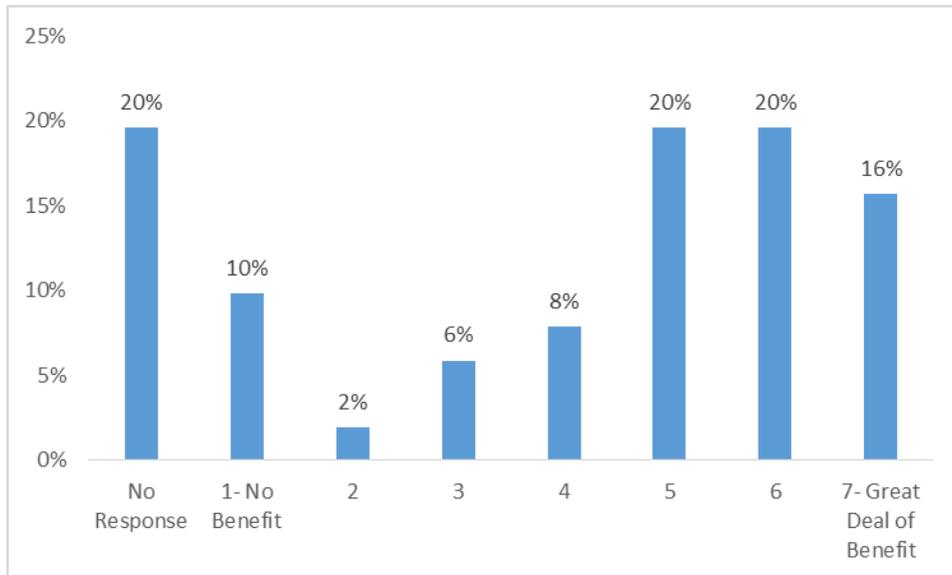

Figure 6.12. HCP-Perceived Benefit: Severe and Persistent Muscle Spasms (N=98)

CANCER

Figure 6.13 shows HCP benefit score responses for patients certified for cancer. Benefit ratings were provided on 41 of the submitted surveys. Among the 41 responses, 5 reported no benefit and 8 reported the highest degree of benefit (score of 7); 32 (78%) reported a benefit score ≥ 4 on the seven-point scale.

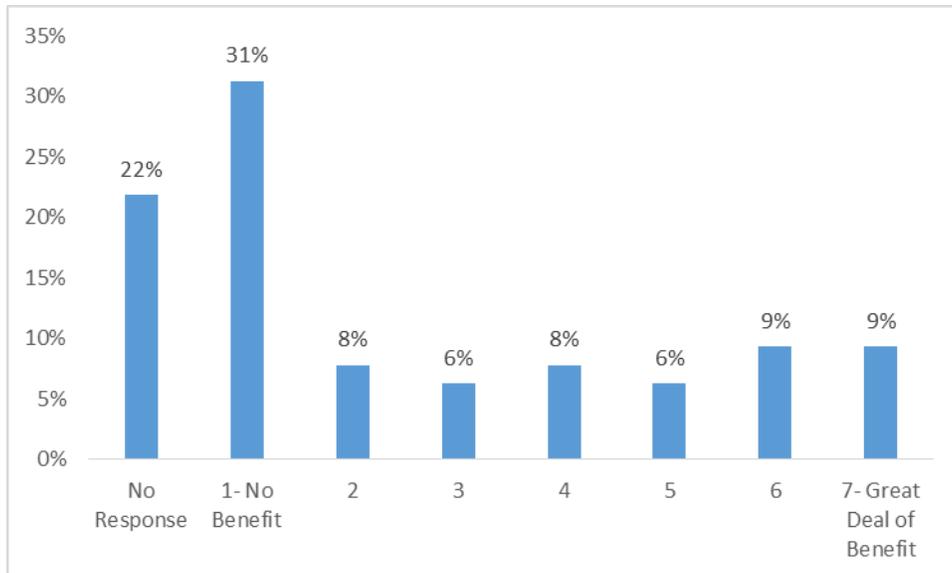

Figure 6.13. HCP-Perceived Benefit: Cancer (N=51)

SEIZURES

Figure 6.14 shows HCP benefit score responses for patients certified for seizures. Benefit ratings were provided on 50 of submitted surveys. Among the 50 responses, 20 reported no benefit and 6 reported the highest degree of benefit (score of 7); 21 (42%) reported a benefit score ≥ 4 on the seven-point scale.

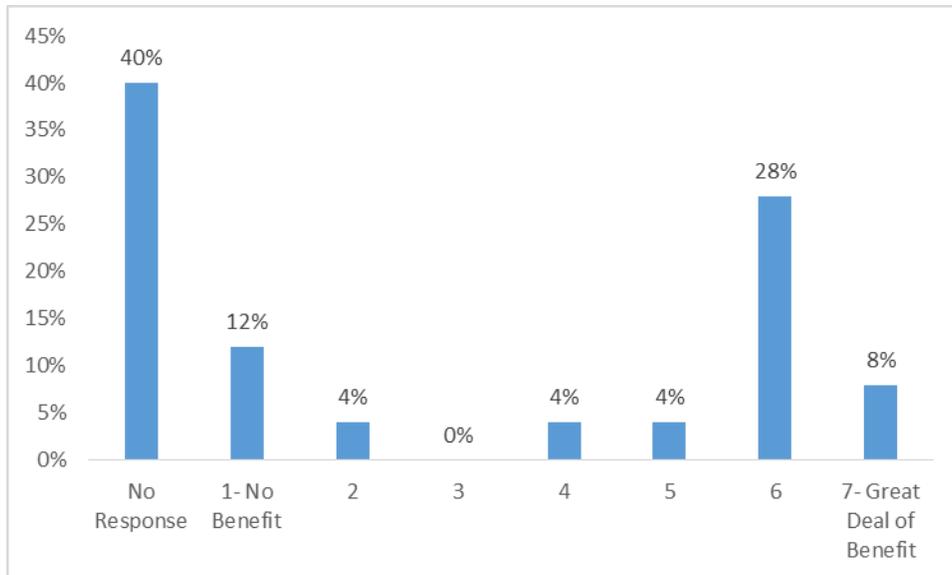

Figure 6.14. HCP-Perceived Benefit: Seizures (N=64)

CROHN'S DISEASE

Figure 6.15 shows HCP benefit score responses for patients certified for Crohn's disease. Benefit ratings were provided on 15 of the completed surveys. Among the 15 responses, 3 reported no benefit and 2 reported the highest degree of benefit (score of 7); 11 (73%) reported a benefit score ≥ 4 on the seven-point scale.

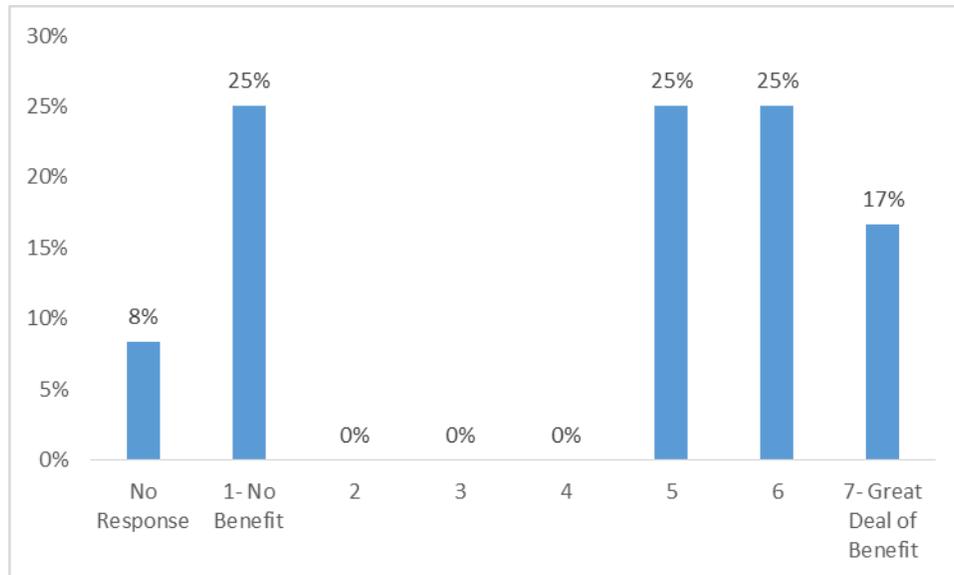

Figure 6.15. HCP-Perceived Benefit: Crohn's Disease (N=25)

TERMINAL ILLNESS

Figure 6.16 shows HCP benefit score responses for patients certified for terminal illness. Benefit ratings were provided on 11 of the completed surveys. Among the 11 responses, 3 reported no benefit and 2 reported the highest degree of benefit (score of 7); 8 (73%) reported a benefit score ≥ 4 on the seven-point scale.

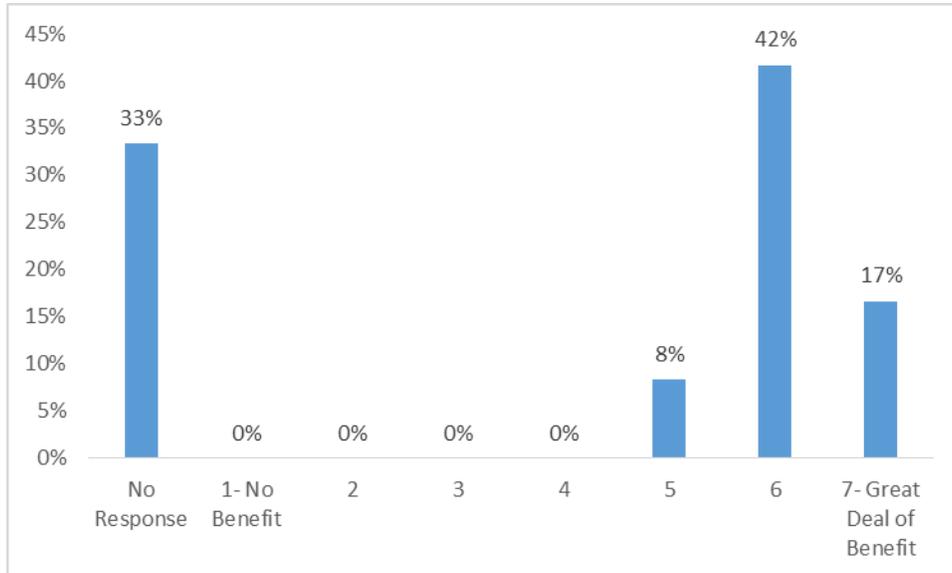

Figure 6.16. HCP-Perceived Benefit: Terminal Illness (N=12)

HIV/AIDS

Figure 6.17 shows HCP benefit score responses for patients certified for HIV/AIDS. Benefit ratings were provided on 8 of the 12 completed surveys. Among the 8 responses, none reported no benefit and two reported the highest degree of benefit (score of 7); all eight reported a benefit score ≥ 4 on the seven-point scale.

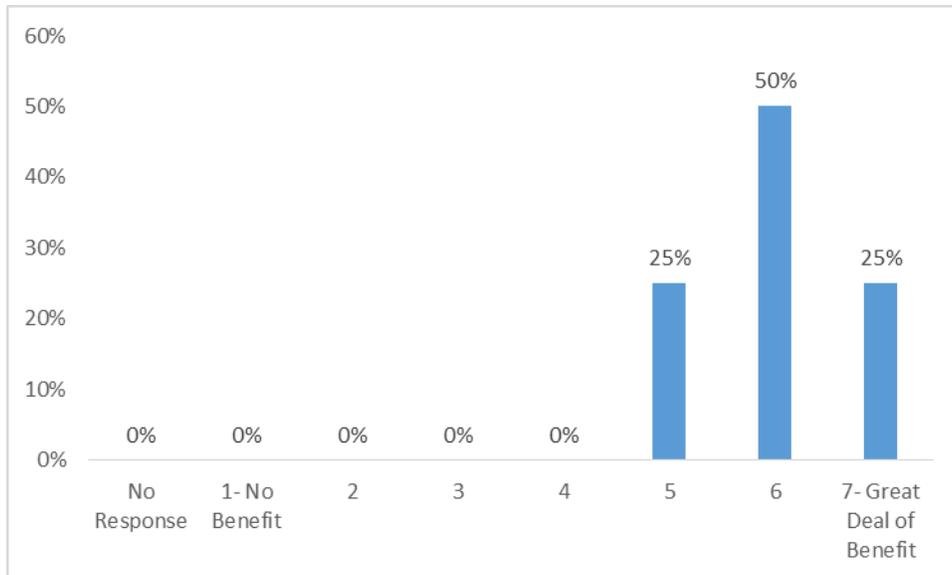

Figure 6.17. HCP-Perceived Benefit: HIV/AIDS (N=12)

TOURETTE SYNDROME

Figure 6.18 shows HCP benefit score responses for patients certified for Tourette syndrome. Benefit ratings were provided on all four of the completed surveys. Among the 4 responses, none reported no benefit and one reported the highest degree of benefit (score of 7); all four reported a benefit score ≥ 4 on the seven-point scale.

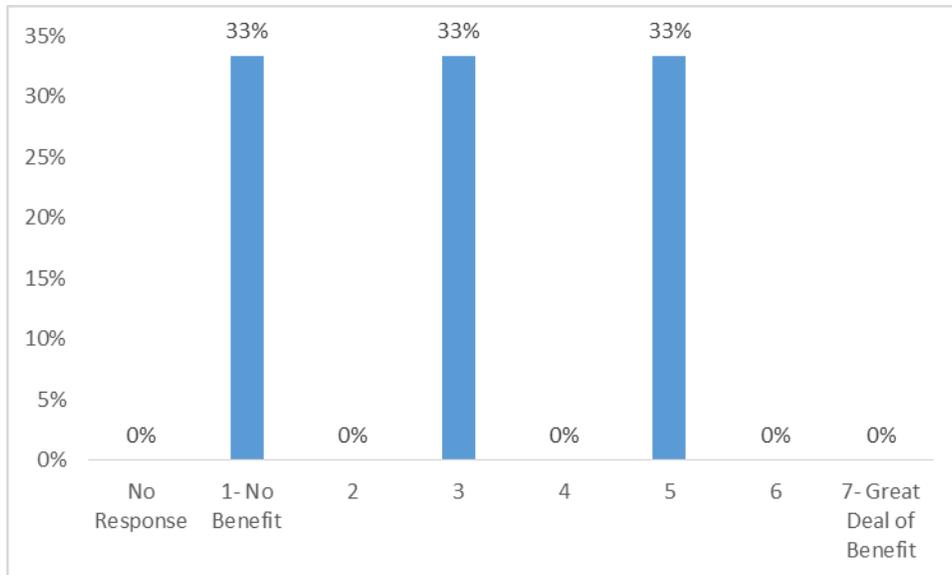

Figure 6.18. HCP-Perceived Benefit: Tourette Syndrome (N=4)

GLAUCOMA

Figure 6.19 shows HCP benefit score responses for patients certified for glaucoma. Benefit ratings were provided on all three of the completed surveys. Among the 3 responses, one reported no benefit and none reported the highest degree of benefit (score of 7); only one reported a benefit score ≥ 4 on the seven-point scale.

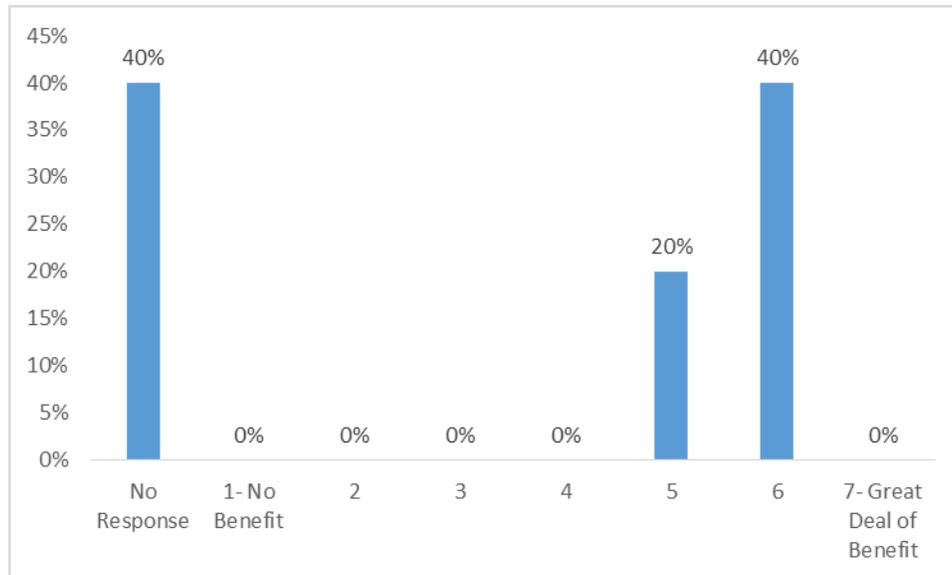

Figure 6.19. HCP-Perceived Benefit: Glaucoma (N=3)

ALS

Figure 6.20 shows HCP benefit score responses for patients certified for ALS. Benefit ratings were provided on 3 of the 5 completed surveys. Among the 3 responses, none reported no benefit and none reported the highest degree of benefit (score of 7); all three reported a benefit score ≥ 4 on the seven-point scale.

Figure 6.20. HCP-Perceived Benefit: ALS (N=5)

HCP Perceptions of Symptom Improvement from Medical Cannabis Treatment

Similar to the format in the Patient Experience survey, the HCP surveys asks certifying HCPs to describe the most significant benefit to the patient that is associated with medical cannabis treatment. Each response was reviewed and classified into broad categories of symptom improvement or global health benefits, as described in an earlier section. A full report of all benefit comments from HCPs can be found in *Appendix B: Healthcare Practitioner-Reported Benefits from Surveys*. Table 6 summarizes the reported “most important benefits” which could be considered improvement of a symptom related to the patient’s qualifying condition from reports of both patients and HCPs, again using a subset of patient responses from the same time window as HCP responses (surveys for patients making a first purchase between July 2015 and December 2015).

Table 6.11 Distribution of Symptom Improvement by Condition

Symptom Improvement by Score		1	2	3	4	5	6	7	Total
		(No Benefit)						(Great Deal of Benefit)	
Muscle Spasms									
Spasm Reduction	Patient (n=182)	-	-	-	6 (3%)	5 (3%)	14 (8%)	25 (14%)	50 (28%)
	HCP (n= 98)	-	-	1 (1%)	2 (2%)	6 (6%)	9 (9%)	9 (9%)	28 (29%)

	HCP (n= 5)	-	-	-	-	-	2 (40%)	1 (20%)	3 (60%)

Symptom Improvement by Score		1 (No Benefit)	2	3	4	5	6	7 (Great Deal of Benefit)	Total
Glaucoma									
<i>Reduced Glaucoma Symptoms</i>	Patient (n=5)	-	-	-	-	-	-	2 (40%)	2 (40%)
	HCP (n= 3)	-	-	1 (33%)	-	-	-	-	1 (33%)
ALS									
<i>Spasm Reduction</i>	Patient (n=7)	-	-	-	-	-	1 (14%)	-	1 (14%)
	HCP (n= 5)	-	-	-	-	1 (20%)	1 (20%)	-	2 (40%)
<i>Pain Reduction</i>	Patient (n=7)	-	-	-	-	-	1 (14%)	2 (29%)	3 (43%)
	HCP (n= 5)	-	-	-	-	-	1 (20%)	-	1 (20%)

Patients represented in Patient Experience survey responses and in HCP responses were different; thus a direct comparison cannot be made between the proportions of patients and HCPs reporting any given benefit. However, it is worth noting that relatively high levels of symptom improvement benefit (most scores are above 4) are seen in both patient and HCP survey results. Among patient respondents certified for muscle spasms, 22% report spasm reduction at a high degree of benefit (scores of 6 or 7) and 18% of HCP responses for patients with muscle spasms report spasm reduction at a high degree of benefit. Among responses of patients certified for seizures, 40% reported reduction in seizure number or severity at a high degree of benefit; among HCP responses for patients with seizures, 14% reported seizure reduction (severity or frequency) at a high degree of benefit. Among patient responders certified for cancer, 15% reported pain reduction at a high degree of benefit; 13% reported reduced nausea or vomiting at a high degree of benefit and 12% reported weight gain or appetite improvement at a high degree of benefit. Among HCP responses for patients certified for cancer, 8% reported pain reduction at a high degree of benefit, 14% reported reduced nausea or vomiting and 2% reported weight gain or appetite improvement at a high degree of benefit.

HCP Perceptions of Global Health Benefits from Medical Cannabis Treatment

Table 6.12 summarizes responses to the Patient Experience and HCP surveys about the most significant benefit to the patient that were not classified as improvement of symptoms related to the qualifying medical condition.

As with Table 6.11, the proportion of patients reporting a type of global health benefit cannot be directly compared to the proportion of HCPs reporting a type of global health benefit to the patient because each group of responders is different. However, in general a higher proportion of the patient responses report a global health benefit as the primary benefit from medical cannabis than HCP responses and generally global health benefits are reported at a relatively high degree of perceived benefit (scores of 4 or greater).

Overall, 1% of HCP respondents and 6% of patient respondents reported improved sleep as the most important benefit from medical cannabis; 3% of HCP respondents and 4% of patients reported improved quality of life; 2% of HCP reports and 3% of patient reports cited reduced usage of other medications or related side effects as the most important benefit.

A full report of all benefit comments from HCPs can be found in *Appendix B: Healthcare Practitioner-Reported Benefits from Surveys*.

Table 6.12 Distribution of Global Health Benefits by Condition

Global Health Benefits by Score		1 (No Benefit)	2	3	4	5	6	7 (Great Deal of Benefit)	Total
Muscle Spasms									
<i>Improved Quality of Life</i>	Patient (n=182)	-	-	-	-	-	2 (1%)	3 (2%)	5 (3%)

Additional Clinical Observations

Healthcare practitioners were asked to provide any additional clinical observations or insights on the impact of medical cannabis treatment on the patient’s condition, and were specifically prompted to report any observations on drug interactions. A third of the 114 observations describe a decrease in the patients’ other medications- mainly opioids and benzodiazepines. The survey healthcare practitioners will complete for patients certified for intractable pain will ask specifically about this issue. There were a few comments about drug interactions with anti-epileptic drugs, including in some cases the anticipated ability to decrease dose of Clobazam. A full report of these observations can be found in *Appendix C: Healthcare Practitioner-Reported Clinical Observations from Surveys*.

Patient Versus HCP Perceptions of Benefit from Medical Cannabis

Among survey respondents, there were 126 patients who submitted a survey for whom their certifying health care practitioner also completed a survey. Comparison of benefit scores reported by the patient to benefit scores reported by the healthcare practitioner are shown in Table 6.13, grouping scores of 1 or 2 in a category representing no or little benefit; scores of 3, 4, or 5 were grouped into a category representing mild or moderate benefit and scores of 6 or 7 were placed in a category representing strong benefit. Among these 126 patients and their HCPs, 81 (64%) of patient-HCP pairs were in general agreement regarding degree of benefits experienced: 46% reported strong benefit from medical cannabis; 15% reported mild or moderate benefit and 3% reported no or little benefit (Table 6.13). When interpreting the meaning of these comparisons, it must be kept in mind that the 126 patients for whom both Patient Experience and HCP survey results are available are not necessarily representative of all patients who enrolled in the program during its first year of operation.

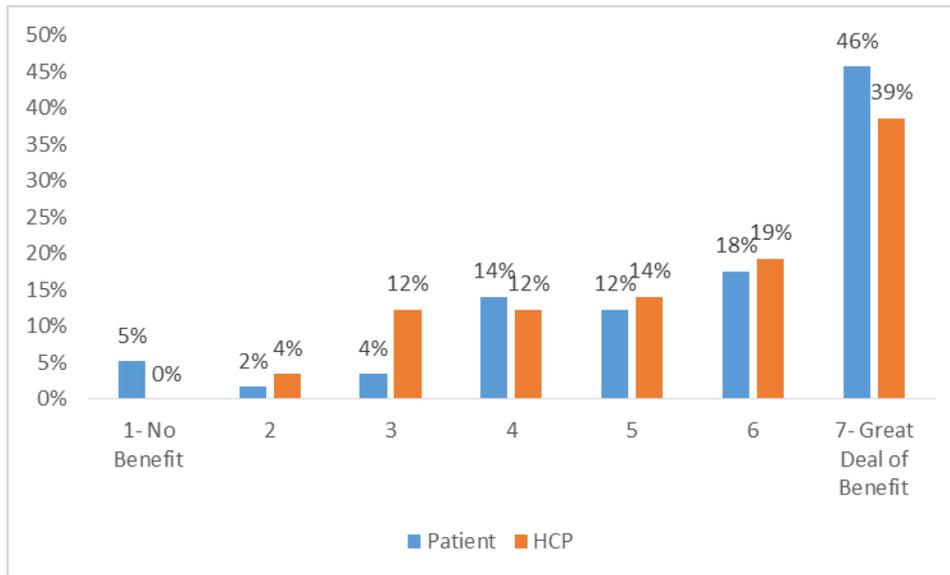

Table 6.13. Distribution of patient-reported benefits and HCP-reported benefits for patients with both patient and HCP surveys completed (n=126).

	HCP-Perceived Benefit		
Patient-Perceived Benefit	No/Little Benefit (1-2)	Mild/Moderate Benefit (3-5)	Strong Benefit (6-7)
No/Little Benefit (1-2)	4 (3%)	1 (1%)	2 (2%)
Mild/Moderate Benefit (3-5)	7 (6%)	19 (15%)	10 (8%)
Strong Benefit (6-7)	2 (2%)	23 (18%)	58 (46%)

Severe and Persistent Muscle Spasms

Figure 6.21 shows benefit scores reported by patients and their certifying HCPs for muscle spasms patients for whom both scores were available (n=57). Comparison of proportions of patients and HCPs reporting each benefit score shows fairly good agreement: 46% of patients and 39% of HCPs report scores of 6 or 7; 5% of patients and 0% HCPs report no benefit.

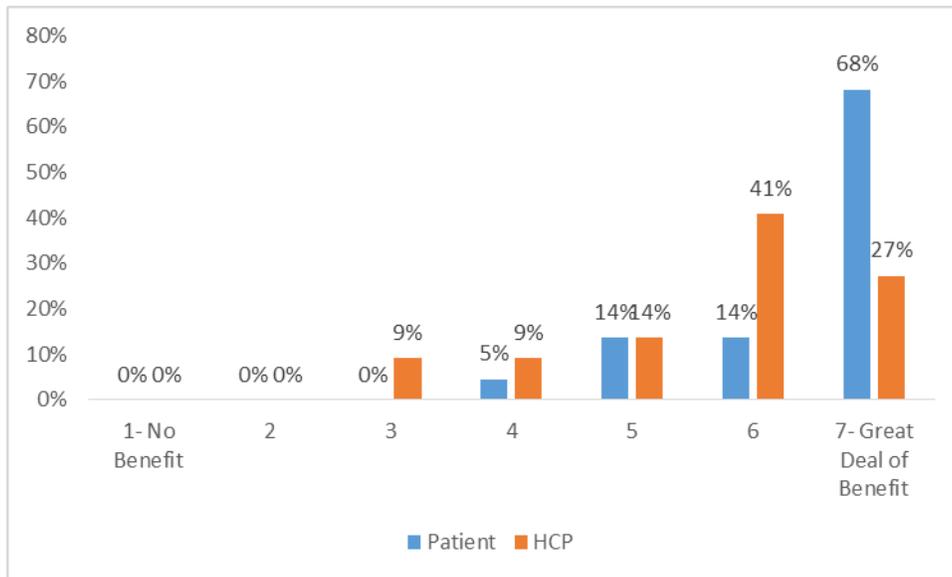

Figure 6.21. Muscle Spasms (N=57): Perceived Benefit

Cancer

Figure 6.22 shows benefit scores reported by patients and their certifying HCPs for cancer patients for whom both scores were available (n=22). Comparison of proportions of patients and HCPs reporting each benefit score shows differences in effect size but general agreement that patients experienced some benefit. Among this group, 68% of patients and 27% of HCPs report scores of 6 or 7; 0% patients and 0% HCPs report scores of 1 or 2.

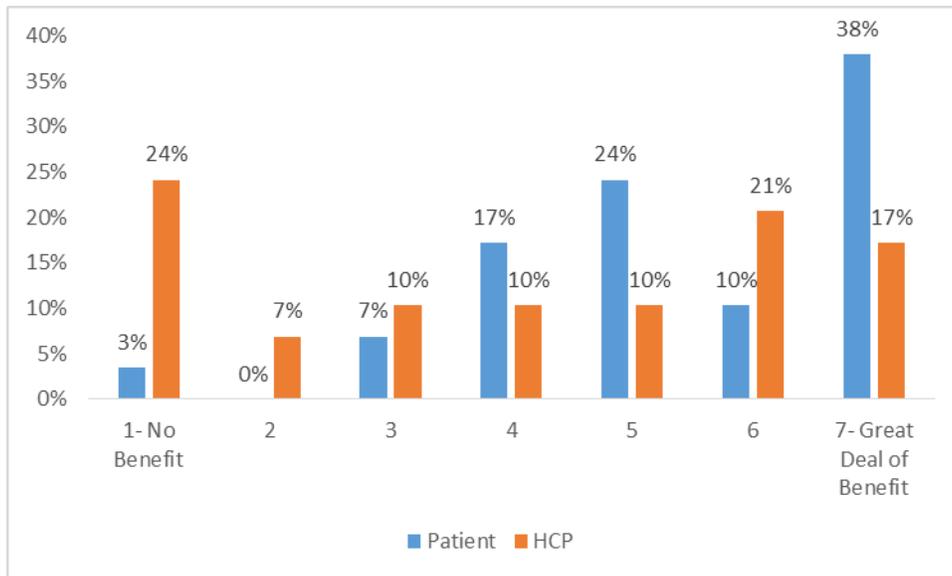

Figure 6.22. Cancer (N=22): Perceived Benefit

Seizures

Figure 6.23 shows benefit scores reported by patients and their certifying HCPs for seizure patients for whom both scores were available (n=29). Comparison of proportions of patients and HCPs reporting each benefit score shows that generally patients report higher degrees of benefit than HCPs: 38% of patients versus 17% of HCPs report scores of 6 or 7; 3% of patients versus 24% HCPs report no benefit.

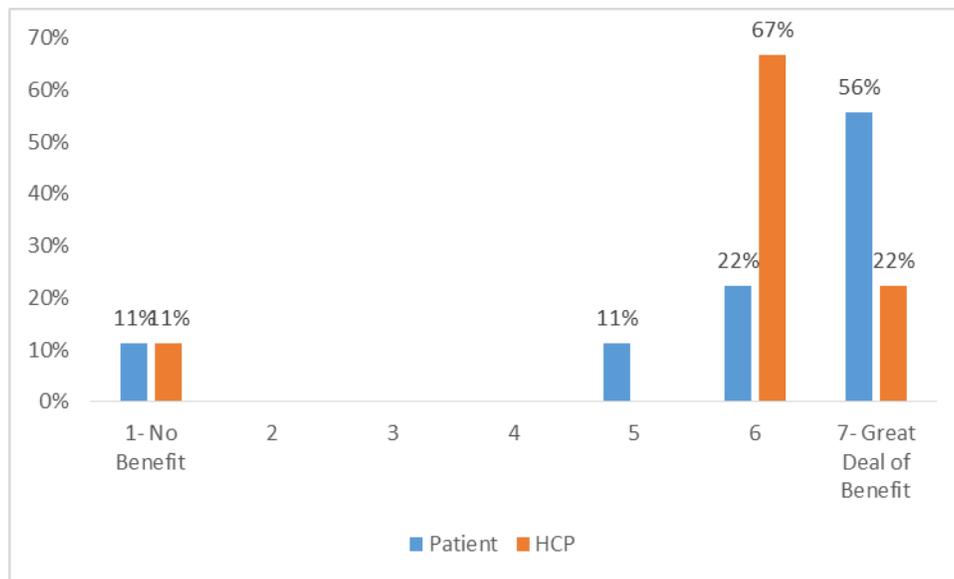

Figure 6.23. Seizures (N=29): Perceived Benefit

Crohn's Disease

Figure 6.24 shows benefit scores reported by patients and their certifying HCPs for Crohn's disease patients for whom both scores were available (n=9). Comparison of proportions of patients and HCPs reporting each benefit score shows general agreement about degree of benefit experienced: 89% of patients and 78% of HCPs report scores of 6 or 7; 11% of both patients and HCPs report scores of 1.

Figure 6.24. Crohn's Disease (N=9): Perceived Benefit

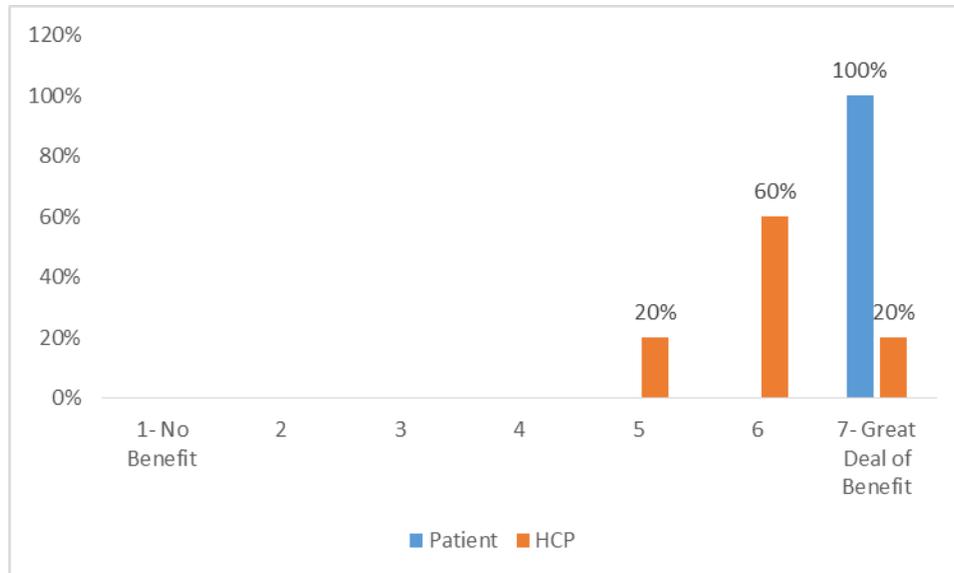

Terminal Illness

No patients with terminal illness had both an HCP-submitted survey and patient-submitted survey.

HIV/AIDS

Figure 6.25 shows benefit scores reported by patients and their certifying HCPs for HIV/AIDS patients for whom both scores were available (n=5). Comparison of proportions of patients and HCPs reporting each benefit score shows general agreement about degree of benefit experienced: 100% of patients and 80% of HCPs report scores of 6 or 7.

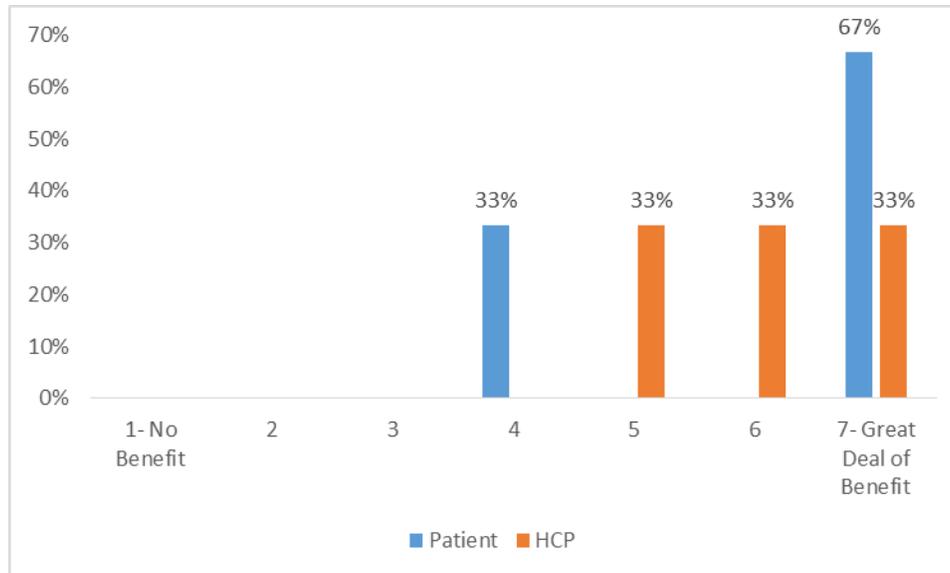

Figure 6.25. HIV/AIDS (N=5): Perceived Benefit

Tourette Syndrome

Figure 6.26 shows benefit scores reported by patients and their certifying HCPs for Tourette syndrome patients for whom both scores were available (n=3). Comparison of proportions of patients and HCPs reporting each benefit score shows general agreement about degree of benefit experienced: 67% of patients and 67% of HCPs report scores of 6 or 7.

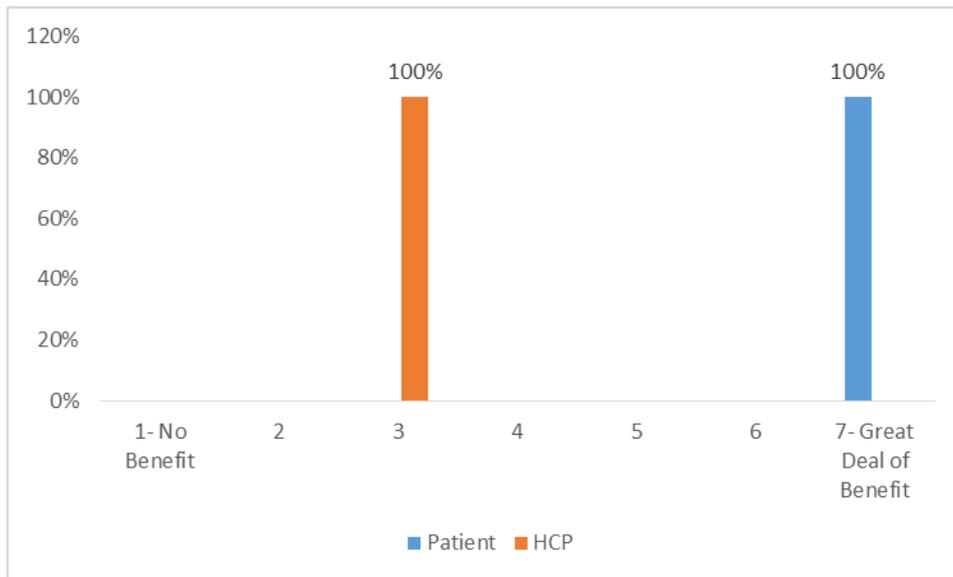

Figure 6.26. Tourette Syndrome (N=3): Perceived Benefit

Glaucoma

Figure 6.27 shows the benefit scores reported for one glaucoma patient who completed a survey (reported benefit score of 7) and whose HCP also completed a survey (reported benefit score of 3).

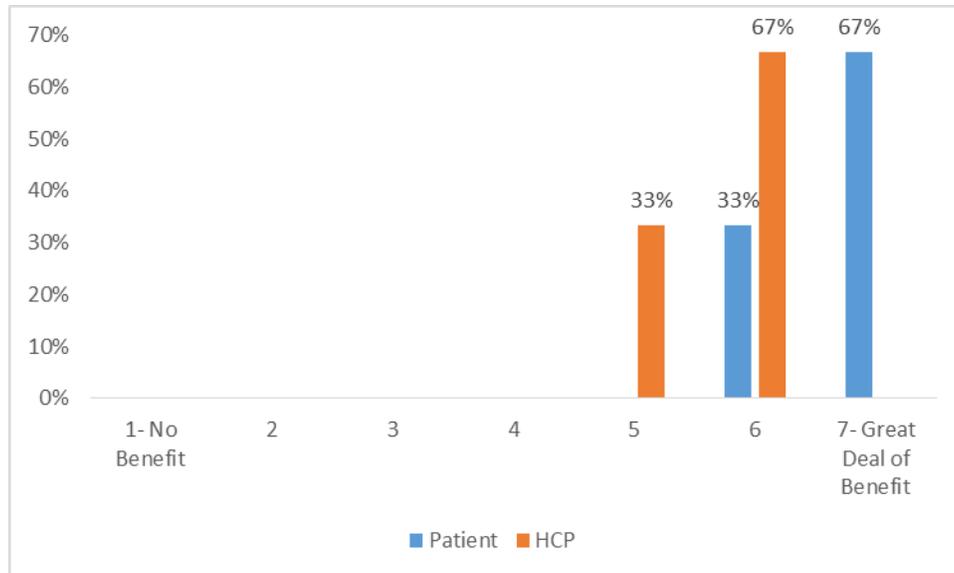

Figure 6.27. Glaucoma (N=1): Perceived Benefit

ALS

Figure 6.28 shows benefit scores reported by patients and their certifying HCPs for ALS patients for whom both scores were available (n=3). Comparison of proportions of patients and HCPs reporting each benefit score shows general agreement about degree of benefit experienced: 100% of patients and 67% of HCPs report scores of 6 or 7.

Figure 6.28. ALS (N=3): Perceived Benefit

Benefits Reported on Surveys: Conclusions

Of 1491 patients making a purchase in the first program year, 53% completed a survey three months after the first purchase. Among respondents, 43% reported experiencing the highest degree of benefit from medical cannabis and 87% reported at least a moderate degree of benefit (score of 4 or greater on a 1 to 7 scale). Patients reported the types of benefits experienced, which were predominantly (64%) various types of symptom improvement; many patients (25%) also reported global health benefits as the most important benefits from medical cannabis.

For patients making a purchase in the first six months of the program (n=774), 32% of HCP surveys were submitted. Overall, HCP reports of benefit were more conservative than those of patients, but 20% reported that the patient experienced the highest degree of benefit from medical cannabis and 60% reported at least a moderate degree of benefit. Among patients purchasing in the first six program months, 126 patients had both patient and HCP surveys completed and comparison of benefit scores indicated general agreement between the two scores for most patients.

Benefits Reported on the Patient Self-Evaluation

The Patient Self-Evaluation (PSE) contains questions that allow the Office of Medical Cannabis (OMC) to look for improvements in symptoms over time. Patients are required to complete a PSE prior to each medical cannabis purchase (including before their first medical cannabis purchase). This allows for capture of the patients’ symptoms at baseline – prior to taking any medical cannabis, as well as prior to each subsequent medical cannabis purchase. Hence, symptom change over time can be analyzed during the patients’ participation in the program.

All patients received a standard set of 8 symptom measures on the PSE. In addition, some patients received additional symptom questions depending on their qualifying medical condition(s). These two sets of symptom measures will be subsequently discussed below. Data from the PSE were extracted from patients who enrolled during the first program year (enrolled between July 1, 2015 and June 30, 2016; 1660 patients enrolled during this time period).

Standard 8 Symptom Measures

The standard 8 symptom measures that all patients received are answered on a 0-10 numerical rating scale (NRS), with 0 indicating absence of the symptom to 10 indicating that the symptom is as bad as the patient can imagine (see Box 6.1). Therefore, higher scores on these measures indicate poorer management of these symptoms. Patients are asked to rate symptom severity over the past 24 hours.

Box 6.1. Listing of the Standard 8 symptom measures that all patients answer, including the responses options available to patients.

<u>Standard 8 Symptom Measures:</u>											
Anxiety									Fatigue		
Lack of Appetite									Nausea		
Depression									Pain		
Disturbed Sleep									Vomiting		
<u>Response Options (0 – 10 NRS):</u>											
	0	1	2	3	4	5	6	7	8	9	10
Symptom not present											Symptom as bad as one can image

To understand whether patients derived any symptom benefits during their participation in the program, the following three questions were explored for each Standard 8 symptom measure:

QUESTION 1

Of those patients who experienced moderate to severe symptoms at baseline (score of 4 or higher at baseline), what percentage of them experienced at least a 30% improvement in symptoms within four months of their first medical cannabis purchase? The threshold of $\geq 30\%$ reduction on a 0-10 point scale was chosen because this threshold has been documented in clinical trials to represent clinically meaningful change – especially for pain reduction and spasticity reduction. Examples of $\geq 30\%$ change include moving from a score of 10 to a score of 7, from 9 to 6, from 8 to 5, from 7 to 4, etc.

QUESTION 2

If a patient achieved at least a 30% improvement on symptoms within 4 months of their first medical cannabis purchase (determined in Question 1), what percentage of them will, on average, still maintain that level of improvement in the four months following that initial 30% symptom improvement? [Four-month follow-up period]

QUESTION 3

What medical cannabis products were purchased just *prior* to the patient’s initial report of symptom improvement (first time patient indicated $\geq 30\%$ improvement on the PSE)? What was the average daily intake of delta-9-tetrahydrocannabinol (THC) and cannabidiol (CBD) for these product types?

To address Question 1 the following procedure was adopted for each standard 8 measure: all patients who scored 4 or higher at baseline were identified as those experiencing moderate to severe symptoms, and all standard 8 responses that were submitted within 4 months of their first medical cannabis purchase were retained. From this dataset, each patient’s standard 8 responses were compared to their baseline response over time. The first instance a patient achieved at least a 30% symptom improvement was recorded, effectively demonstrating when – during the first 4 months following their first medical cannabis purchase – the patient achieved symptom improvement, if at all.

Calculating the percentage of patients who achieved $\geq 30\%$ symptom improvement within 4 months of their first medical cannabis purchase (Question 1) was done in two ways. In one method, the number of patients who achieved $\geq 30\%$ symptom improvement within 4 months was divided by the total number of patients that ever made a first purchase (patients with baseline PSE data). In the other method, the number of patients achieving $\geq 30\%$ symptom improvement within 4 months was divided by patients who had submitted additional PSE data (beyond their baseline response) within 4 months of their first purchase. The denominator in

the former method includes all patients who made a first purchase (all patients with a baseline PSE submission), while the latter method effectively restricts the denominator to those patients who submitted additional PSE symptom data following their baseline submission and within 4 months of their first purchase. Therefore, the former method allows for a more conservative estimation of symptom benefit. In the text of this report, we present results using the former, more conservative estimate of benefit. Those who made no additional purchases after their first purchase may have discontinued use because of lack of effectiveness, though they may have discontinued use for other reasons as well (i.e., medical cannabis cost, side effects, etc.).

Since Question 1 examines symptom improvement within 4 months of their first medical cannabis purchase, patients who had not been enrolled in the program for at least 4 months since their first medical cannabis purchase were not included in the analysis. When PSE data were extracted in late December 2016, 1512 patients from the first year cohort (91.1% of the 1st year cohort) had been enrolled for at least 4 months since their first medical cannabis purchase—results on the standard 8 symptom measures are reported on this cohort subset.

Question 2 was addressed by observing all symptom responses in the four months *following* the time point when the patient first achieved $\geq 30\%$ symptom improvement. For each patient, all symptom responses identified during those follow-up four months were averaged together. Patients who, on average, still maintained at least a 30% symptom improvement from baseline were identified as those showing persistence in their symptom benefits.

For Question 3, products that were purchased just *prior* to each patient's initial $\geq 30\%$ symptom improvement were identified and categorized by their THC/CBD ratio and intended route of administration (ROA). See Box 6.2 for definitions of these categories.

Box 6.2. Categories to describe medical cannabis products purchased by patients.

Medical Cannabis Products Categorized by THC:CBD Content Ratio:

- **Very High THC to CBD** = 100:1 or higher
- **High THC to CBD** = >4:1 up to 99:1
- **Balanced** = 1:1 up to 4:1
- **High CBD to THC** = \geq 1:1 up to 99:1
- **Very High CBD to THC** = 100:1 or higher

Product Routes of Administration (ROA):

- **Enteral:** for absorption through the gastrointestinal tract (includes capsules and oral solutions to swallow).
- **Inhalation:** for absorption through the lungs (includes products for vaporization)
- **Oromucosal:** for absorption through the oral mucosa (includes sublingual sprays and tinctures to hold in the mouth)

Overall Results on Standard 8 Symptom Measures

Data on the Standard 8 symptom measures were first analyzed across all patients regardless of their qualifying condition(s) and are displayed in Table 6.14 (n = 1512). The third and fourth column respectively display the number and percentage of patients (out of 1512 patients) experiencing moderate to severe symptoms at baseline (baseline response \geq 4) on a given Standard 8 measure. With the exception of vomiting, the responses from patients indicated a high degree of burden on all symptom measures at baseline (~60-90% patients indicated moderate to severe symptoms).

The fifth column in Table 6.14 shows the percentage and number of patients (out of those reporting at moderate to severe levels at baseline) who had achieved at least a 30% symptom improvement at any time within 4 months of their first medical cannabis purchase. Anywhere from 36% to 60% of patients reported achieving at least a 30% improvement in symptoms within 4 months of their first medical cannabis purchase. Improvements in pain and fatigue were the least likely to reach \geq 30% improvement in patients (respectively at 36.3% and 40.2%), with the greatest proportion of patients reaching \geq 30% improvement in nausea (55.6%), depression (56.8%), and vomiting (60.2%).

The number of patients who had symptom data in the 4-month period *following* their initial \geq 30% symptom improvement are listed in the sixth column in Table 6.14. All symptom responses during this time period were averaged together within each patient. The seventh column shows the percentage and number of patients who had achieved \geq 30% symptom improvement that had – on average – maintained at least that level of improvement in the 4-

month follow-up period. Roughly a half to two-thirds of the patients who achieved at least 30% symptom improvement had maintained it in the following 4 months. Lastly, the right-most column shows the percentage of all patients who both achieved and maintained at least a 30% symptom improvement in the 4-month follow-up period. For the majority of all symptoms, roughly a third of all patients experiencing moderate to severe symptoms will both achieve and maintain at least a 30% improvement in symptoms for at least 4 months.

For a more detailed look on overall results from the eight standard symptom measures, please refer to *Appendix D: Symptom Results from the Patient Self-Evaluation*. This Appendix shows the following for each Standard 8 measure: 1) a figure showing the distribution of patient responses at baseline, 2) a figure showing the cumulative percentage of patients achieving at least 30% symptom improvement at 2 weeks, 1 month, 2 months, 3 months, and 4 months (the denominator is different between the orange and blue bars; orange bars include all moderate to severe scoring patients at baseline while blue bars restrict analyses to only those patients who submitted data by the time point indicated on the x-axis), and 3) a figure showing the frequency distribution of patients by the average symptom change (%) each patient experienced in the 4-month follow-up period since they initially achieved $\geq 30\%$ symptom reduction.

Table 6.14. Overall standard 8 symptom results.

Condition	Standard 8 Symptom Measure	# of Patients Reporting at Moderate to Severe Levels at Baseline	% of Patients Reporting at Moderate to Severe Levels at Baseline	% of Patients Achieving $\geq 30\%$ Symptom Improvement within 4 months of First Purchase out of all Moderate to Severe Baseline Scorers (n)	# of Patients with Data in 4-mo Period Following Initial $\geq 30\%$ Symptom Improvement	% of Patients Who Achieved $\geq 30\%$ Symptom Improvement that Maintained it for at Least 4 months (n)	% of Patients that Both Achieved $\geq 30\%$ Symptom Improvement and Retained that Degree of Improvement for at Least 4 months
All Patients - Collapsed Across Conditions (n = 1512)	Anxiety	1185	78.4	53.8 (638)	460	53.1 (339)	28.6
	Appetite Lack	963	63.7	53.7 (517)	383	57.1 (295)	30.6
	Depression	1000	66.1	56.8 (568)	419	56.7 (322)	32.2
	Disturbed Sleep	1323	87.5	50.3 (665)	519	52.0 (346)	26.2
	Fatigue	1381	91.3	40.2 (555)	415	48.6 (270)	19.6
	Nausea	864	57.1	55.6 (480)	362	59.2 (284)	32.9
	Pain	1312	86.8	36.3 (476)	329	45.0 (214)	16.3
	Vomiting	480	31.7	60.2 (289)	213	57.8 (167)	34.8

Results on Standard 8 Symptom Measures Stratified by Qualifying Condition

Data on the Standard 8 symptom measures were also analyzed separately by qualifying condition. Results are presented in Table 6.15 below. The first column indicates the qualifying condition and the total number of patients who had been enrolled in the program for at least 4 months since their first medical cannabis purchase. For some conditions, results are further broken down by condition subcategories (i.e., breakdown cancer patients based on whether their certifying condition was accompanied by pain, nausea/vomiting, etc.); condition subcategories are preceded by a star (*). The third and fourth columns in Table 6.15 indicate the number and percentage of patients who experienced moderate to severe symptoms (score ≥ 4) at baseline for each symptom.

The fifth column in Table 6.15 indicates the percentage and number of patients (out of those reporting at moderate to severe levels at baseline) that had achieved at least a 30% symptom improvement at any time within 4 months of their first medical cannabis purchase. The number of patients who had symptom data in the 4-month period *following* their initial $\geq 30\%$ symptom improvement are listed in the sixth column in Table 6.15. All symptom responses submitted during this time period were averaged together within each patient. The seventh column shows the percentage and number of patients that had achieved at least a 30% symptom improvement that had subsequently maintained it, on average, for at least 4 months. Lastly, the right-most column shows the percentage of all patients that had both achieved and maintained at least a 30% symptom improvement for at least 4 months.

Results generally show a high degree of burden for these eight symptoms at baseline. The instances where symptom severity is noticeably lower tend to be as expected; for example, nausea and vomiting in patients with Tourette syndrome and in patients with glaucoma. Among baseline responses to the eight symptom measures, those with the highest proportion rated as moderate to severe (score ≥ 4) include fatigue, disturbed sleep, pain, and anxiety. For each of the medical conditions, a substantial proportion of patients achieved $\geq 30\%$ reduction in most of the eight symptoms. Improvement was generally a bit higher in patients with seizures and with Tourette Syndrome and a bit lower in patients with cancer. Overall, a smaller proportion of patients achieved $\geq 30\%$ reduction of pain and fatigue and a higher proportion of patients achieved $\geq 30\%$ improvement in appetite and reduction in vomiting. For each medical condition, roughly half to three-quarters of the patients who experienced a $\geq 30\%$ reduction in a particular symptom within the first four months maintained that level of improvement over the following four months.

Table 6.15. Standard 8 symptom results stratified by qualifying condition.

Condition	Standard 8 Symptom Measure	# of Patients Reporting at Moderate to Severe Levels at Baseline	% of Patients Reporting at Moderate to Severe Levels at Baseline	% of Patients Achieving ≥30 Symptom Improvement within 4 months of First Purchase (n)	# of Patients with Data in 4-mo Period Following Initial ≥30% Symptom Improvement	% of Patients Who Achieved ≥30% Symptom Improvement that Maintained it for at Least 4 months (n)	% of Patients that Both Achieved ≥30% Symptom Improvement and Retained that Degree of Improvement for at Least 4 months

Appendix D: Symptom Results from the Patient Self-Evaluation shows the following for each Standard 8 measure stratified by qualifying medical condition: 1) a figure showing the distribution of patient responses at baseline, 2) a figure showing the cumulative percentage of patients achieving at least 30% symptom improvement at 2 weeks, 1 month, 2 months, 3 months, and 4 months (the denominator is different between the orange and blue bars; orange bars include all moderate to severe scoring patients at baseline while blue bars restrict analyses to only those patients who submitted data by the time point indicated on the x-axis), 3) a figure showing the frequency distribution of patients by the average symptom change (%) each patient experienced in the 4-month follow-up period since they initially achieved $\geq 30\%$ symptom reduction, and 4) a table of medical cannabis products patients purchased just prior to achieving $\geq 30\%$ symptom improvement for the first time, along with the average daily THC and CBD dose taken by patients.

Medical cannabis products that were purchased just prior to the initial 30% symptom improvement are discussed only briefly in this section (Question 3), and the reader is encouraged to see *Appendix D: Symptom Results from the Patient Self-Evaluation* for the full table of results. Here, only a few results regarding medical cannabis purchases are discussed as examples—some in relation to improvements on a particular Standard 8 measure, and others in relation to a particular condition-specific symptom measure.

Table 6.16 below shows the most common medical cannabis products that were purchased by cancer patients just prior to achieving the initial 30% reduction in nausea symptoms. The second column from the right indicates the number of patients who purchased specific products just prior to that initial symptom reduction (products purchased indicated by “X”s). The table also shows the average daily amount of THC and CBD (mg) patients consumed (right-most column), which was derived from manufacturer-supplied product information and pharmacist-entered calculations of how long the purchased supply would last. Very High THC:CBD vaporization products were purchased most frequently (n = 20), followed by a combination of Very High THC:CBD enteral products and Very High THC:CBD vaporization products (n = 12). See *Appendix D: Symptom Results from the Patient Self-Evaluation* for full results.

Table 6.16. Top 5 medical cannabis product(s) purchased by cancer patients just prior to achieving the initial 30% reduction in the Standard 8 nausea measure.

Very High THC to CBD	Enteral				Inhalation				Oromucosal				% of Patients out of 109 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)		
	High THC to CBD	Balanced	High CBD to THC	Very High CBD to THC	High THC to CBD	High THC to CBD	Balanced	High CBD to THC	Very High CBD to THC	High THC to CBD	High THC to CBD	Balanced			High CBD to THC	Very High CBD to THC
					X										18.3 (20)	55.9 mg/0.4 mg
X					X										11.0 (12)	71.6 mg/0.5 mg
										X					8.3 (9)	86.3 mg/0.4 mg
		X													6.4 (7)	135.5 mg/83.2 mg
X		X			X			X							4.6 (5)	61.4 mg/15.6 mg

Table 6.17 below shows the most common medical cannabis products that were purchased by terminal illness patients just prior to achieving the initial 30% reduction in nausea symptoms. The most frequently purchased products were a combination of both Very High THC:CBD products for oral administration and vaporization (n = 3), followed by Balanced THC:CBD products for inhalation only (n = 3). See *Appendix D: Symptom Results from the Patient Self-Evaluation* for full results.

Table 6.17. Top 7 medical cannabis product(s) purchased by terminal illness patients just prior to achieving the initial 30% reduction in the Standard 8 nausea measure.

Enteral			Inhalation			Oromucosal			% of Patients out of 26 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)
Very High THC to CBD	High THC to CBD	Balanced	Very High CBD to THC	High CBD to THC	Balanced	Very High THC to CBD	High THC to CBD	Balanced		
X						X			11.5 (3)	67.1 mg/0.5 mg
						X			11.5 (3)	44.5 mg/0.4 mg
X		X				X			7.7 (2)	45.5 mg/37.5 mg
		X			X				7.7 (2)	110.1 mg/5.9 mg
		X						X	7.7 (2)	78.6 mg/61.1 mg
		X							7.7 (2)	49.0 mg/46.0 mg
			X						7.7 (2)	4.4 mg/206.7 mg

Table 6.18 below shows the most common medical cannabis products purchased by HIV/AIDS patients just prior to their initial 30% reduction in pain symptoms. Balanced THC:CBD products were purchased most frequently (n = 6), followed by Very High THC:CBD products for inhalation (n = 3). See *Appendix D: Symptom Results from the Patient Self-Evaluation* for full results.

Table 6.18. Top 4 medical cannabis product(s) purchased by HIV/AIDS patients just prior to achieving the initial 30% reduction in the Standard 8 pain measure.

Enteral			Inhalation			Oromucosal			% of Patients out of 18 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)
Very High THC to CBD	High THC to CBD	Balanced	Very High CBD to THC	High CBD to THC	Balanced	Very High THC to CBD	High THC to CBD	Balanced		
		X							33.3 (6)	23.1 mg/22.1 mg
			X						16.7 (3)	65.2 mg/0.3 mg
X		X							11.1 (2)	5.0 mg/0.0 mg
			X		X				11.1 (2)	51.7 mg/18.2 mg

Condition-Specific Symptom Measures

In addition to the Standard 8 measures, some patients received additional symptom questions on the PSE to more adequately address condition-specific symptoms. These include, among others, questions on seizure frequency for seizure patients, questions on spasm frequency for muscle spasm and ALS patients, and Crohn’s activity in Crohn’s patients. While patients received the same response options on the Standard 8 measures (respond from 1-10 on a

numerical rating scale), response options for condition-specific measures varied and will be described in this section. All condition-specific measures were investigated within the same framework as the Standard 8 measures: 1) what percentage of patients achieved symptom improvement within the four months since their first medical cannabis purchase compared to their baseline responses, 2) what percentage of those achieving symptom improvement showed general persistence in the 4-month follow-up period, and 3) what medical cannabis products were purchased just prior to the patient reporting initial symptom improvements. A summary of results are similarly presented in a table like those presented for the Standard 8 measures (see Table 6.19 below).

The first column in Table 6.19 lists each condition that received additional symptom questions beyond the Standard 8. The second column briefly indicates the nature of these additional condition-specific symptom measures, with the number of patients included in the analysis at baseline indicated in the third column (baseline, meaning patients who provided data and met criteria on these measures at the beginning of the program – prior to purchasing any medical cannabis). The fourth column indicates the percentage and number of patients achieving a specified threshold of symptom improvement within four months of purchasing their first medical cannabis (denominator is patients included in the analysis at baseline). The threshold to determine symptom improvement for these analyses are subsequently described below, found in the descriptive section for each condition. The number of patients who had symptom data in the 4-month period following their initial symptom improvement are listed in the fifth column in Table 6.19. All symptom responses during this time period were averaged together within each patient. The sixth column indicates the percentage and number of patients who had achieved symptom improvement that subsequently still maintained that improvement for at least 4 months. Lastly, the right-most column shows the percentage of all patients who both achieved and maintained symptom improvements for at least 4 months. A more detailed discussion of these condition-specific results will follow Table 6.19.

Table 6.19. Condition-Specific Measures.

Condition	Condition-Specific Symptom Measure	# of Patients Included in Analysis	% of Patients Achieving Threshold Symptom Improvement within 4 months of First Purchase (n)	# of Patients with Data in 4-mo Period Following Initial Threshold Symptom Improvement	% of Patients Who Achieved Threshold Symptom Improvement that Maintained it for at Least 4 months (n)	% of Patients that Both Achieved Threshold Symptom Improvement and Retained that Degree of Improvement for at Least 4 months
Muscle Spasms	Weekly Spasms Frequency	629	48.0 (302)	225	57.6 (174)	27.6
	0-10 Spasticity Scale	618	36.4 (225)	197	47.1 (106)	17.2
Cancer: Nausea/Vomiting	Chemo-Induced Nausea	147	37.4 (55)	29	34.5 (19)	12.9
	Chemo-Induced Vomiting	77	41.6 (32)	20	56.3 (18)	23.4
Cancer: Cachexia/Wasting	Weight	147	13.6 (20)	15	45.0 (9)	6.1
Seizures	Weekly Seizure Frequency	262	68.3 (179)	150	70.9 (127)	48.5
Crohn's Disease	# Liquid Stools	41	51.2 (21)	17	57.1 (12)	29.3
	Abdominal Pain	73	53.4 (39)	29	35.9 (14)	19.2
	General Well-Being	15	46.7 (7)	5	28.6 (2)	13.3
	Measures Combined	102	51.0 (52)	41	42.3 (22)	21.6
	Weight	102	20.6 (21)	18	57.1 (12)	11.8
Terminal Illness: Cachexia/Wasting	Weight	29	20.7 (6)	5	50.0 (3)	10.3
HIV/AIDS	Weight	48	14.6 (7)	3	42.9 (3)	6.3
Tourette Syndrome	Weekly Tic Frequency	28	60.7 (17)	15	76.5 (13)	46.4
ALS	Weekly Spasms Frequency	18	33.3 (6)	4	66.7 (4)	22.2
	0-10 Spasticity Scale	15	20.0 (3)	3	100.0 (3)	20.0

Severe and Persistent Muscle Spasms

Patients with muscle spasms were given two questions to assess the severity of their muscle spasms. First, patients were given the option to respond to the number of muscle spasms they experienced the day before or the number of muscle spasms they experienced within the last week. These allowed for the calculation of weekly spasm frequency. Secondly, patients were asked to rate the severity of their muscle spasms on a 0-10 numerical rating scale (NRS), with 0 indicating absence of spasms to 10 indicating spasticity being as bad as the patient could imagine. For the analysis in Table 6.19 above, responses to the 0-10 spasticity measure were restricted to patients experiencing moderate to severe spasticity at baseline (score of 4 or higher), while all patients responding to the weekly spasms frequency question were included in the analysis. In the analysis of both measures, symptom improvement was defined as achieving at least a 30% reduction in symptoms (30% decrease in weekly spasm frequency; 30% decrease on the 0-10 NRS spasticity measure) compared to baseline.

Weekly spasm frequency was reduced by $\geq 30\%$ in nearly half (48.0%) of the muscle spasm patients. Among patients who achieved $\geq 30\%$ reduction, 58% (27.6% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Severity of muscle spasticity was reduced by $\geq 30\%$ for 36.4% of the patients with moderate to severe muscle spasticity at baseline. Among patients who achieved $\geq 30\%$ reduction, 47% (17.2% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Table 6.20 below shows the top 5 medical cannabis product types that were purchased by muscle spasm patients just prior to achieving $\geq 30\%$ weekly spasm reduction for the first time, including the number of patients who purchased those specific product types (second column from right). It also shows the average daily amount of THC and CBD (mg) patients consumed (right-most column), which was derived from manufacturer-derived product information and pharmacist-entered calculations of how long the purchased supply would last. Full purchasing details are in *Appendix D: Symptom Results from the Patient Self-Evaluation*. The most frequently purchased product types preceding the initial symptom improvement were a combination of Balanced THC:CBD products for oral administration and Balanced THC:CBD products for vaporization (n = 34), followed by Very High THC:CBD products for vaporization (n = 30).

Table 6.20. Top 5 medical cannabis product types purchased by muscle spasm patients just prior to achieving $\geq 30\%$ reduction in weekly spasms. Last column shows the average daily THC/CBD dose that was used by patients purchasing those product types (second column from right).

Enteral					Inhalation					Oromucosal					% of Patients out of 301 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)
Very High THC to CBD	High THC to CBD	Balanced	High CBD to THC	Very High CBD to THC	Very High THC to CBD	High THC to CBD	Balanced	High CBD to THC	Very High CBD to THC	Very High THC to CBD	High THC to CBD	Balanced	High CBD to THC	Very High CBD to THC		
		X					X								11.3 (34)	55.3 mg/35.1 mg
					X										10.0 (30)	77.8 mg/0.5 mg
		X			X										9.6 (29)	79.6 mg/30.0 mg
		X													8.3 (25)	23.6 mg/22.4 mg
					X		X								7.0 (21)	99.8 mg/17.5 mg

Cancer: Nausea and Vomiting

Patients certified for cancer accompanied by severe and persistent nausea or vomiting were asked to assess the severity of chemotherapy-induced nausea and vomiting on a 0-10 numerical rating scale. Patients who experienced chemotherapy-induced nausea and vomiting at moderate to severe levels at baseline (score of 4 or higher) were included in the analysis in Table 6.19, with symptom improvement being defined as achieving at least a 30% improvement in symptoms (30% decrease on the 0-10 nausea/vomiting NRS) compared to baseline.

Severity of chemotherapy-induced nausea was reduced by $\geq 30\%$ for 37.4% of the patients with moderate to severe chemotherapy-induced nausea at baseline. Among the patients who achieved $\geq 30\%$ reduction, 35% (12.9% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Severity of chemotherapy-induced vomiting was reduced by $\geq 30\%$ for 41.6% of the patients with moderate to severe chemotherapy-induced vomiting at baseline. Among the patients who achieved $\geq 30\%$ reduction, 56% (23.4% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Cancer: Cachexia and Severe Wasting

Body weights were analyzed for patients certified for cancer accompanied by cachexia and/or severe wasting. Symptom improvement was defined as achieving at least a 3% increase in body weight compared to baseline weight.

An increase of at least 3% in body weight was reported by 13.6% of patients. Among the patients who achieved $\geq 3\%$ increase in body weight, 45% (6.1% of patients included in analysis at baseline) retained that increase over the next four months.

Seizures

Patients with seizures were given two questions to assess the severity of their seizures. First, patients were given the option to respond to the number of seizures they experienced the day before or the number of seizures they experienced within the last week. These allowed for the calculation of weekly spasm frequency. Table 6.19 shows results from the weekly seizure frequency measure, with symptom improvement defined as achieving at least a 30% improvement in symptoms (30% decrease in weekly seizure frequency) compared to baseline.

Weekly seizure frequency was reduced by $\geq 30\%$ in 68.3% of the seizure patients. Among patients who achieved $\geq 30\%$ reduction, 71% (48.5% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Table 6.21 below shows the top 5 medical cannabis product types that were purchased by seizure patients just prior to achieving $\geq 30\%$ symptom improvement for the first time, including the number of patients who purchased those specific product types (second column from right). It also shows the average daily amount of THC and CBD (mg) patients consumed (right-most column), which was derived from manufacturer-derived product information and pharmacist-entered calculations of how long the purchased supply would last. Full purchasing details are in *Appendix D: Symptom Results from the Patient Self-Evaluation*. The most frequently purchased product types preceding the initial symptom improvement were skewed towards relatively high CBD:THC products, with preference for oral administration of these products.

Table 6.21. Top 5 medical cannabis product types purchased by seizure patients just prior to achieving ≥30% reduction in weekly seizures. Last column shows the average daily THC/CBD dose that was used by patients purchasing those product types (second column from right).

Enteral				Inhalation				Oromucosal				% of Patients out of 178 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)

		X										48.3 (86)	7.6 mg/159.5 mg
										X		16.9 (30)	13.2 mg/407.4 mg
	X				X							4.5 (8)	56.0 mg/37.4 mg
		X	X									3.4 (6)	4.9 mg/282.5 mg
	X											2.8 (5)	19.3 mg/15.9 mg

Crohn's Disease

Three questions from the Harvey-Bradshaw Index (HBI), which measures Crohn's disease activity, were included on the PSE for Crohn's disease patients. These three questions addressed the following: 1) the number of liquid or soft stools experienced yesterday, 2) general well-being yesterday (response options: "Very well", "Slightly below par", "Poor", "Very poor", "Terrible"), and 3) abdominal pain yesterday (response options: "None", "Mild", "Moderate", "Severe"). Responses to these three questions were summed into a combined score for each patient (combined according to HBI scoring guidelines) as well as analyzed separately in Table 6.19. The three questions were selected from the HBI because they were patient-reported measures (versus clinician assessments). The HBI has been validated, but since only three questions from the HBI were used, the clinical significance of these aggregate and individual scores is unclear. Lastly, body weight data submitted through the PSE were analyzed and included in Table 6.19.

Patients who indicated they experienced five or more liquid/soft stools at baseline were included in the analysis, with symptom improvement defined as achieving at least a 30% reduction in liquid/soft stools. Patients who indicated their general well-being was "Very Poor" or "Terrible" at baseline were included in the well-being analysis, with symptom improvement defined as feeling "Slightly Below Par" or "Very Well". Patients who indicated they experienced "Moderate" or "Severe" abdominal pains were included in the abdominal pain analysis, with symptom improvement defined as experiencing "Mild" to "No" abdominal pain. For the combined Crohn's activity measure (combined score on the three HBI measures), symptom improvement was defined as those achieving at least a 30% symptom improvement (30% decrease in the combined score compared to baseline). Lastly, body weight improvement was defined as a 3% increase in body weight.

Number of liquid/soft stools per day decreased by $\geq 30\%$ for 51.2% of patients with at least five liquid/soft stools per day at baseline. Among patients who achieved $\geq 30\%$ reduction, 57% (29.3% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Severity of abdominal pain improved for 53.4% of patients with moderate or severe abdominal pain at baseline. Among patients who reported an improvement in abdominal pain, 36% (19.2% of patients included in analysis at baseline) retained that improvement over the next four months.

General well-being improved for 46.7% of patients who described their baseline well-being as "Very Poor" or "Terrible" at baseline. Among patients who reported an improvement in general well-being, 29% (13.3% of patients included in analysis at baseline) retained that improvement over the next four months.

On the combined Crohn's activity measure (number of liquid/soft stools, abdominal pain, general well-being), 51.0% of Crohn's Disease patients achieved $\geq 30\%$ improvement. Among

patients who achieved $\geq 30\%$ reduction, 42% (21.6% of patients included in analysis at baseline) retained that level of improvement over the next four months.

An increase of at least 3% in body weight was reported by 20.6% of patients. Among the patients who achieved $\geq 3\%$ increase in body weight, 57% (11.8% of patients included in analysis at baseline) retained that increase over the next four months.

Terminal Illness

Body weight measures on the PSE were analyzed in patients certified for terminal illness: accompanied by cachexia or severe wasting. Symptom improvement was defined as a 3% increase in body weight from their baseline body weight.

An increase of at least 3% in body weight was reported by 20.7% of patients. Among the patients who achieved $\geq 3\%$ increase in body weight, 50% (10.3% of patients included in analysis at baseline) retained that increase over the next four months.

HIV/AIDS

Body weight measures on the PSE were analyzed in HIV/AIDS patients. Similar to all body weight measures of improvement discussed previously, symptom improvement was defined as a 3% increase in body weight compared to their baseline body weight.

An increase of at least 3% in body weight was reported by 14.6% of patients. Among the patients who achieved $\geq 3\%$ increase in body weight, 43% (6.3% of patients included in analysis at baseline) retained that increase over the next four months.

Tourette Syndrome

Patients with Tourette Syndrome were given two questions to assess the severity of their tics. First, patients were given the option to respond to the number of tics they experienced the day before or the number of tics they experienced within the last week. These allowed for the calculation of weekly tic frequency. For Table 6.19, weekly tic frequency was analyzed in all patients, with symptom improvement defined as a 30% improvement in symptoms (30% decrease in weekly tics compared to baseline).

Weekly tic frequency was reduced by $\geq 30\%$ in 60.7% of the Tourette Syndrome patients. Among patients who achieved $\geq 30\%$ reduction, 76% (46.4% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Table 6.22 below shows the top 4 medical cannabis product types that were purchased by Tourette patients just prior to achieving $\geq 30\%$ symptom improvement for the first time, including the number of patients who purchased those specific product types (second column from right). It also shows the average daily amount of THC and CBD (mg) patients consumed (right-most column), which was derived from manufacturer-derived product information and pharmacist-entered calculations of how long the purchased supply would last. Full purchasing details are in *Appendix D: Symptom Results from the Patient Self-Evaluation*. The most frequently purchased product types preceding the initial symptom improvement were Very High THC:CBD oromucosal products (4 patients) and a combination of Balanced THC:CBD oral products and Very High THC:CBD oral products (2 patients)

Table 6.22. Top 4 medical cannabis product types purchased by Tourette patients just prior to achieving $\geq 30\%$ reduction in weekly tics. Last column shows the average daily THC/CBD dose that was used by patients purchasing those product types (second column from right).

Enteral			Inhalation			Oromucosal			% of Patients out of 17 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)
Very High THC to CBD	Balanced	High CBD to THC	Very High THC to CBD	Balanced	High CBD to THC	Very High THC to CBD	Balanced	High CBD to THC		
						X			23.5 (4)	147.3 mg/0.7 mg
X	X								11.8 (2)	24.0 mg/15.0 mg
	X								11.8 (2)	11.5 mg/8.5 mg
			X						11.8 (2)	64.6 mg/0.2 mg

Glaucoma

Intraocular pressure results were collected on the PSE from Glaucoma patients and are presented in Table 6.23 for each of the 21 patients included in this analysis. At the first PSE (prior to first medical cannabis purchase) patients were asked to provide the date and results of the most recent intraocular pressure test. On subsequent PSEs patients were asked to provide the date and results of any intraocular pressure test done since submission of the last PSE.

Results for seven of the 21 patients (33%) suggest a decrease in intraocular pressure after initiation of medical cannabis: patients #4, 8, 9, 14, 16, 17, and 19. One of those seven did not show a decrease at 5 months, but did show a decrease at 9 months. Four of them had measurement results after the date of the result that indicated a decrease: patients #4, 16, 17, and 19. Of those four, three have results indicating persistence of reduction over several months. The fourth (#19) had a reduction in month 2 but returned toward pre-medical cannabis levels at month 4. More detailed study, including accessing medical record data, would be needed to confirm measurement results and to assess whether observed improvements could have been due to changes in glaucoma therapy other than medical cannabis use.

Table 6.23. Intraocular pressure test results (left eye/right eye) from glaucoma patients (n = 21). Test results are noted by the month they occurred prior to or after the patients' first medical cannabis purchase ("First Visit").

Patient	Before 1st Medical Cannabis Purchase							First Visit	After 1st Medical Cannabis Purchase										
	12-mo	11-mo	5-mo	4-mo	3-mo	2-mo	1-mo		1-mo	2-mo	3-mo	4-mo	5-mo	6-mo	7-mo	9-mo	10-mo	11-mo	13-mo

ALS

Patients with ALS were given two questions to assess the severity of their muscle spasms. First, patients were given the option to respond to the number of spasms they experienced the day before or the number of spasms they experienced within the last week. These allowed for the calculation of weekly spasm frequency. Table 6.19 presents results on weekly spasm frequency and spasm severity (0-10 NRS). For the spasticity scale measure, patients who experienced moderate to severe spasms at baseline (scored 4 or higher) were included in the analysis, with symptom improvement defined as achieving at least a 30% symptom improvement (30% decrease on the 0-10 NRS compared to baseline).

Weekly spasm frequency was reduced by $\geq 30\%$ in 33.3% of the ALS patients. Among patients who achieved $\geq 30\%$ reduction, 67% (22.2% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Severity of muscle spasticity was reduced by $\geq 30\%$ for 20.0% of the ALS patients with moderate to severe muscle spasticity at baseline. Among the three patients who achieved $\geq 30\%$ reduction, all three retained that level of improvement over the next four months (20.0% of patients included in analysis at baseline).

Table 6.24 below shows the top 5 medical cannabis product types that were purchased by ALS patients just prior to achieving $\geq 30\%$ weekly spasm reduction for the first time, including the number of patients who purchased those specific product types (second column from right). It also shows the average daily amount of THC and CBD (mg) patients consumed (right-most column), which was derived from manufacturer-derived product information and pharmacist-entered calculations of how long the purchased supply would last. Full purchasing details are in *Appendix D: Symptom Results from the Patient Self-Evaluation*. The most frequently purchased product types preceding the initial symptom improvement were skewed towards balanced THC:CBD products and relatively high THC:CBD products.

Table 6.24. Top 5 medical cannabis product types purchased by ALS patients just prior to achieving $\geq 30\%$ reduction in weekly spasms. Last column shows the average daily THC/CBD dose that was used by patients purchasing those product types (second column from right).

Enteral			Inhalation			% of Patients out of 6 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)
Very High THC to CBD	High THC to CBD	Balanced	Very High THC to CBD	High THC to CBD	Balanced		
		X				33.3 (2)	12.8 mg/5.1 mg
X			X			16.7 (1)	59.8 mg/0.3 mg
	X	X	X		X	16.7 (1)	67.0 mg/6.0 mg
	X	X				16.7 (1)	37.5 mg/8.1 mg
			X			16.7 (1)	42.2 mg/0.3 mg

Benefits Reported on the Patient Self-Evaluation: Conclusions

Similar to survey results, the PSE also demonstrated improvements on symptoms in medical cannabis patients. Patients enrolling in the program initially report a high degree of symptom burden with anywhere from roughly 40-60% of patients reporting symptom improvements within the 4 month period following their first medical cannabis purchase. If patients experienced improvements in symptoms, roughly half to three-quarters of them maintained those levels of improvement in the 4-month period following their initial report of improvement.

There are some limitations on the PSE to consider when interpreting results. Firstly, there is no symptom data on patients who decide over time not to purchase medical cannabis any longer (or for extended periods of time). As discussed earlier, patients must complete a PSE prior to each medical cannabis purchase. If a patient stops purchasing medical cannabis, there will be a parallel pause in symptom data to understand whether there may have been a lack of symptom improvements to halt purchases. This is the reason for presenting many analyses on symptom improvements in the context of the initial baseline patient pool – regardless of whether they provided any subsequent symptom data or not. This allows for more of a conservative estimate of symptom benefit over time. A second limitation on the PSE has to do with the patient’s approach and conscientiousness in completing the PSE—all symptom measures are self-reported which involves cognitive resources and motivation for the patient to complete the surveys as accurately as possible.

7. Adverse Side Effects

Summary

This chapter provides insight into the frequency and severity of adverse (negative) side effects through three sources of information: the Patient Self-Evaluation completed by the patient prior to each medical cannabis purchase, patient and health care practitioner surveys, and adverse event reports to the two medical cannabis manufacturers.

The three information sources tell a similar story. Around 20-25% of enrolled patients report negative physical or mental side effects of some kind, with the majority – around 60% - reporting only one and 90% reporting 3 or fewer unique side effects. The vast majority of adverse side effects, around 90%, are mild to moderate in severity. An assessment of the 30 patients reporting severe side effects, meaning “interrupts usual daily activities,” found no apparent pattern in patient age, medical condition, or type of medical cannabis product used. Results reported in this chapter are generally similar to those reported in published clinical trials of cannabis and cannabinoids, though with a somewhat lower frequency of occurrence reported in the program. Fortunately, up to the present no serious adverse events (life threatening or requiring hospitalization) have been reported.

Some limitations of the data should be mentioned. For example, when the patient completes a Patient Self-Evaluation and has it reviewed in consultation with pharmacist staff, the completeness and accuracy of reported side effects (on the Patient Self-Evaluation) ultimately depend on the attention and good communication of the patient. Perhaps a more significant risk for under-reporting through Patient Self-Evaluation data is the situation when a patient has an intolerable side effect and decides to make no more purchases of medical cannabis. If the patient doesn't go to a cannabis patient center for another purchase, the patient doesn't fill out another Patient Self-Evaluation, so the side effect is not documented through this mechanism. From anecdotal report and survey responses, we know this does occur. However, inquiries made of patients who have discontinued medical cannabis purchasing suggests this does not happen often. Finally, a weakness of the survey data is that many responders did not complete the question on most significant negative effect and a substantial proportion who did indicated cost or access issues, rather than physical or mental side effects. Though physical or mental side effects were probably minor or not present if the respondent indicated cost or access issues as the most significant negative effect, we don't know that for sure. We are unable to characterize most significant negative effect for those who did not submit a response.

Though the limitations mentioned in the paragraph above no doubt undercount the frequency of physical and mental side effects to some degree, their impact does not seem likely to

significantly change the main conclusions of the analyses reported in this section: at this point, the safety profile of the medical cannabis products available through the Minnesota program seems quite favorable.

Adverse Side Effects Reported on the Patient Self-Evaluation

Patients have the opportunity to report adverse side effects they attribute to medical cannabis on the Patient Self-Evaluation (PSE). Patients must complete a PSE prior to each medical cannabis purchasing transaction. Therefore, the administration of the PSE is timed so that patients can reflect on their experience with the medication they purchased previously and report those experiences on the following patient self-evaluation. A pharmacist at one of the eight medical cannabis dispensaries can then review PSE-reported information, which includes an opportunity to discuss side effects with the patient prior to approving that patient for another medical cannabis purchase. When reporting side effects on the PSE, patients are able to choose side effects from a pre-made list of options or write in side effects that do not fit one of the listed options. In addition, patients also indicate the severity with which each side effect is experienced (see Box 7.1).

Box 7.1. Definitions on severity provided to patients for adverse side effect reporting.

Adverse side effects were examined within the 1st program year cohort (n = 1660). Patients who had made at least their first medical cannabis purchase were identified, and from these patients, all PSEs that were

Adverse Side Effect Severity: Definitions

Mild: Symptoms do not interfere with daily activities

Moderate: Symptoms may interfere with daily activities

Severe: Symptoms interrupt usual daily activities

submitted within the four months following their first medical cannabis purchase were included in a dataset. This led to a total of 1502 patients (90.5% of the cohort) being represented. For the following analyses, each side effect was counted once for a given patient if it was reported multiple times. If a side effect was reported multiple times, the observation that was categorized at the highest severity level was included in the analyses for this report. In cases where a patient opted to write in their side effects (rather than choosing from the pre-made list of options), their responses were assessed carefully for adjudication for coding purposes. Therefore – while not affecting a substantial number of side effect responses – it should be noted that one limitation for accurate coding is the patient’s ability to adequately articulate their experiences.

Of the 1502 patients, 18.1% (n = 272) reported any adverse side effects within the four month period following their first medical cannabis purchase. Of those 272 patients reporting any adverse side effects, the majority reported only one (n = 164, 60.3%), with approximately 90% of them reporting three or fewer different, adverse side effects (Figure 7.1).

Figure 7.1. Distribution of patient counts by number of different, adverse side effects reported (out of 272 patients).

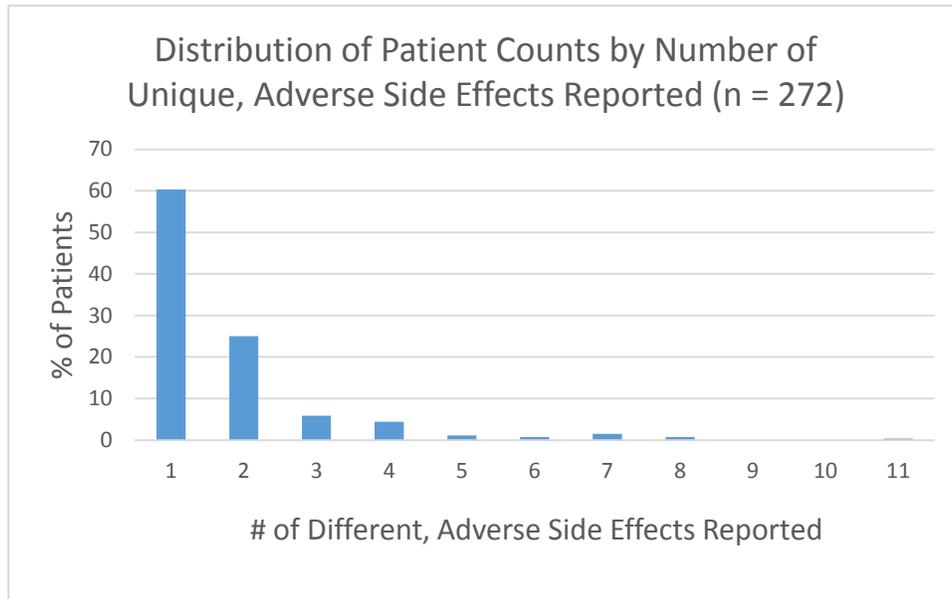

Figure 7.2 shows the percentage of patients reporting specific adverse side effects (Table 7.1 below lists adverse side effects that were reported by less than 2% of all patients). Of all side effects reported, dry mouth and drowsiness/somnolence/sedation were the most commonly reported side effects among patients. Overall, the frequency distribution of unique side effects mirrors typical clinical trial data on side effects from cannabis/cannabinoid use (see [“A Review of Medical Cannabis Studies relating to Chemical Compositions and Dosages for Qualifying Medical Conditions”](#) on the [Office of Medical Cannabis](#) website).

Figure 7.2. The most commonly reported adverse side effects represented by the percentage of patients reporting them (out of 272 patients).

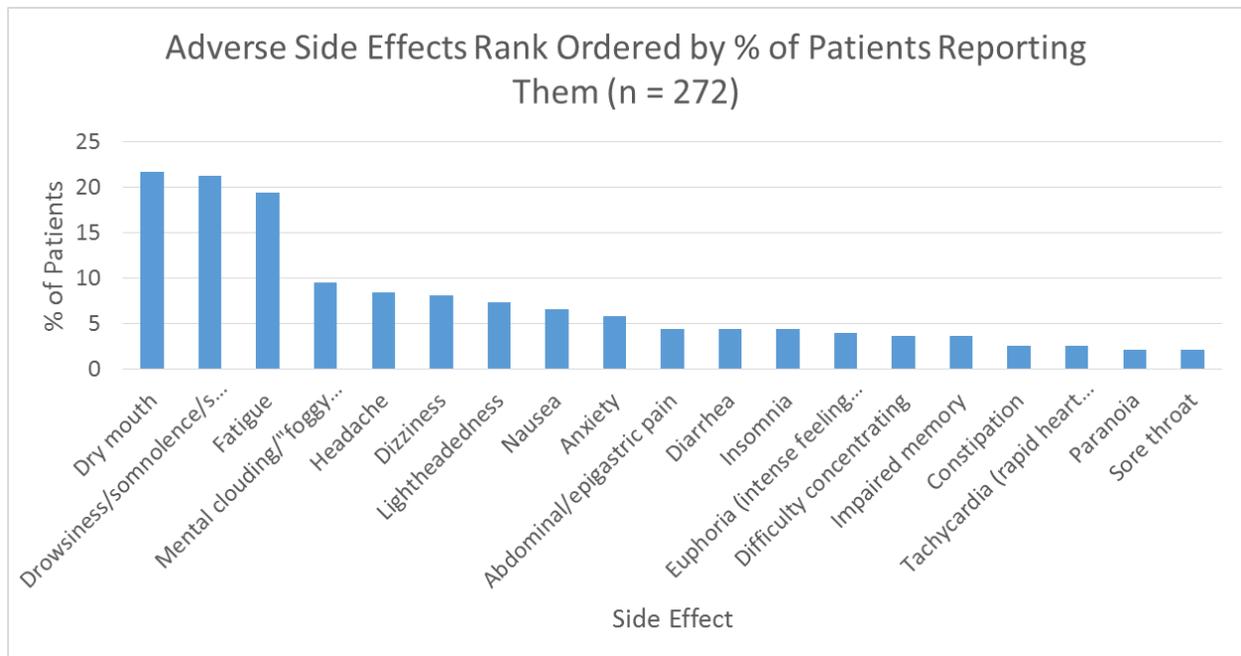

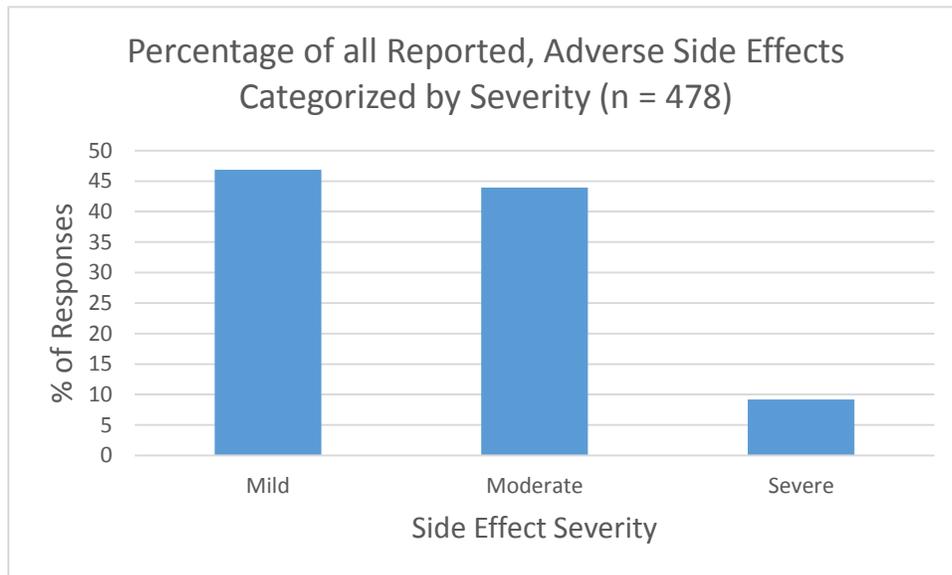

Table 7.1. Adverse side effects that were reported by less than 2% of patients (out of 272 patients).

Side Effect	% of Patients (n)
Asthenia (muscle weakness)	1.8% (5)
Chest pain	1.8% (5)
Confusion	1.8% (5)
Disorientation	1.5% (4)
Eye redness	1.5% (4)
Lethargy	1.5% (4)
Blurred Vision	1.1% (3)
Decreased muscle coordination/balance	1.1% (3)
Increased agitation	1.1% (3)
Numbness	1.1% (3)
Panic attack	1.1% (3)
Personality/mood change	1.1% (3)
Tinnitus (ringing perception in the ears)	1.1% (3)
"Stoned" feeling	0.7% (2)
Body stiffness	0.7% (2)
Coughing/lung irritation	0.7% (2)
Decreased appetite	0.7% (2)
Dry eyes	0.7% (2)
Feeling cold	0.7% (2)
Increased seizures	0.7% (2)
Tremors	0.7% (2)
"Wired" feeling	0.4% (1)
Bloating	0.4% (1)
Burping	0.4% (1)

Side Effect	% of Patients (n)
Change in quality of seizures	0.4% (1)
Chest colds	0.4% (1)
Cognitive change	0.4% (1)
Cramping with bowel movement	0.4% (1)
Dysphoria (intense feeling of unease or unpleasantness)	0.4% (1)
Exacerbation of lymphedema	0.4% (1)
Eye muscle twitching	0.4% (1)
Hives	0.4% (1)
Hyperactive bowel sounds	0.4% (1)
Hypomania	0.4% (1)
Increase in mucus secretions	0.4% (1)
Increased aggression	0.4% (1)
Increased urine output	0.4% (1)
Increased yelling	0.4% (1)
Mouth irritation/burning	0.4% (1)
Rash on face	0.4% (1)
Repressed immune system	0.4% (1)
Sleep disturbance	0.4% (1)
Sneezing	0.4% (1)
Thrush	0.4% (1)
Urinary retention	0.4% (1)
Vomiting	0.4% (1)
Worsening acne	0.4% (1)

The 272 patients reporting any adverse side effects submitted a combined total of 478 side effect responses within 4 months of their first medical cannabis purchase. When aggregating all side effect responses across patients, only 9.2% (44) of all responses were reported as severe (see Figure 7.3).

Figure 7.3. Percentage of all reported, adverse side effect responses categorized by severity.

Severe Adverse Side Effects

All adverse side effect responses that were categorized as severe are further broken down by the percent of patients categorizing them as such—please see Table 7.2 below.

Table 7.2. Table shows the number of patients reporting the listed side effects along with the percentage of those respondents who indicated that the side effect was severe.

Side Effect	# of Patients Reporting	% of Patients Reporting as Severe (n)
Dry mouth	59	6.8% (4)
Drowsiness/somnolence/sedation	58	5.2% (3)
Fatigue	53	3.8% (2)
Mental clouding/"foggy brain"	26	7.7% (2)
Headache	23	4.3% (1)
Dizziness	22	9.1% (2)
Lightheadedness	20	0% (0)
Nausea	18	11.1% (2)
Anxiety	16	12.5% (2)
Abdominal/epigastric pain	12	8.3% (1)
Diarrhea	12	16.7% (2)
Insomnia	12	8.3% (1)
Euphoria (intense feeling of well-being or pleasure)	11	9.1% (1)
Difficulty concentrating	10	20% (2)
Impaired memory	10	10% (1)
Constipation	7	14.3% (1)
Tachycardia (rapid heart rate)	7	28.6% (2)
Paranoia	6	16.7% (1)
Sore throat	6	0% (0)
Asthenia (muscle weakness)	5	60% (3)
Chest pain	5	20% (1)
Confusion	5	0% (0)
Disorientation	4	0% (0)
Eye redness	4	0% (0)
Lethargy	4	50% (2)
Blurred Vision	3	0% (0)
Decreased muscle coordination/balance	3	33.3% (1)
Increased agitation	3	0% (0)
Numbness	3	33.3% (1)
Panic attack	3	33.3% (1)
Personality/mood change	3	0% (0)
Tinnitus (ringing perception in the ears)	3	0% (0)
"Stoned" feeling	2	50% (1)
Body stiffness	2	0% (0)

Table 7.2 Continued. Table shows the number of patients reporting the listed side effects along with the percentage of those respondents who indicated that the side effect was severe.

Side Effect	# of Patients Reporting	% of Patients Reporting as Severe (n)
Coughing/lung irritation	2	0% (0)
Decreased appetite	2	0% (0)
Dry eyes	2	0% (0)

Vomiting	1	0% (0)
Worsening acne	1	0% (0)

The 44 severe side effect responses (9.2% of total side effect responses) were attributed to 30 patients (11.0% of patients reporting any side effects). Patients experiencing severe side effects represent a wide range of ages, including children and elderly patients; 14 patients were male and 16 patients were female. Their age, gender, and certifying conditions generally matched the whole first year cohort. Half of patients reporting severe side effects were taking a form of balanced THC:CBD product (n=15); 10 patients were using a high CBD product, 9 patients were using a very high THC product and 4 patients were using a high THC product. Seven of 30 patients (23%) were using a combination of products with varying THC:CBD ratios (the most common combination was very high THC products and 1:1 THC:CBD products); 9 patients used a combination of products with different routes of administration (the most common combination was enteral and inhaled). Refer to Table 7.3 for details on the patients reporting severe side effects, along with the product types that were purchased just prior to experiencing the severe side effect.

PSE-Reported Adverse Side Effects: Conclusions

Less than a quarter of patients from the cohort (~18%) reported adverse side effects within the first 4 months since purchasing their first medical cannabis products. Roughly 90% of those that do report any side effects report 3 or fewer unique side effects during that time period. Results also suggest that relatively few patients experience severe, adverse side effects, with less than 10% of all responses (attributed to 30 patients) being categorized as severe.

Table 7.3. Patients reporting “severe” side effects: patient age, gender, and condition, product types purchased at most recent visit, and type of side effect reported.

Adverse Side Effects Reported on Surveys

Patient-Reported Negative Effects of Medical Cannabis

For overall patient response rate to the survey three months after first purchase and comparison of responders and non-responders see the section with survey results in the Benefits chapter above.

The Patient Experience survey asks respondents to report the degree, or severity, of any negative effects they believe the patient received from using medical cannabis, on a scale from 1 (no negative effects) to 7 (a great deal of negative effects). The survey then asked the respondent to describe, in their own words, the most significant negative effect. Table 7.4 shows the distribution of negative effects by severity score within three broad categories: physical side effects (including dry mouth, fatigue, headache, dizziness, blurred vision); mental side effects (including mental clouding, paranoia, sedation or symptoms related to “high”); and issues related to accessing the medications (distance to distribution center, inconvenient operating hours for distribution centers, etc.). Based on anticipated reports on the high cost of medication, patients were asked to report on the affordability of the medication separately. However, 53 (7%) patients included cost in their estimation of the most significant negative effects related to medical cannabis; these reports are excluded from Table 7.4 but included in *Appendix E: Patient-Reported Negative Effects from Surveys*. Finally, please see the chapter titled, “Affordability and Suggestions for Improvement” for patient perceptions of medication affordability.

Of 792 completed patient surveys, 744 responses (94%) included a negative effects score and 441 (56%) included a response regarding most important negative effect, including comments stating “no negative effect.” Of 744 negative effect scale responses, 452 (61%) reported a score of 1, or “no negative effect.” This includes 13 patients who, though they entered a score of 1, entered a narrative description of physical or mental side effects. A total of 195 responses (25% of all patient responses) reported physical or mental negative effects. These reports generally mirrored side effects reported in clinical trials of medical cannabis (see “[A Review of Medical Cannabis Studies relating to Chemical Compositions and Dosages for Qualifying Medical Conditions](#)” on the [Office of Medical Cannabis](#) website). Reports of the most severe negative effects were as follows: scores of 7 (great deal of negative effects) were associated with reports of allergic reaction (n=1), pain (n=1), severe diarrhea (n=1), change in mood/behavior (n=1) and decreased awareness of surroundings (n=1). Scores of 6 were associated with reported physical side effects of dizziness or related symptoms (n=3), severe diarrhea (n=1), stomach pain (n=1), burning sensation with sublingual product (n=1), sleeping problems (n=1) and worsening seizures (n=2), and mental side effects of crying and irritability (n=1). Scores of 5 which reported physical negative effects included drug interactions, increased seizure activity, allergic reaction, lightheadedness, fatigue, headaches, visual impairment, dry mouth, a report that the

product “made me sick” and pain related to vaping (n=1 each). Scores of 5 which reported mental negative effects included reports of paranoia (n=2), inability to concentrate (n=1), and increased anxiety (n=1).

Apart from physical or mental negative effects, some patients reported issues related to program access, including distance to the nearest cannabis patient center (n=13). Other negative effects (not included in Table 7.4) were reported including issues related to the program design (n=9), negative attitudes of others toward the patient’s use of medical cannabis (n=17) and fear of legal or employment-related consequences related to program participation (n=5). Finally, 16 reports of negative effects were related to lack of efficacy of the medicine in treating the patient’s condition. A full listing of patient-reported negative effect comments is available in *Appendix E: Patient-Reported Negative Effects from Surveys*.

Table 7.4. Summary of most significant negative effects experienced by the patient, per patient reports.

	1: No Negative Effects	2	3	4	5	6	7: Great Deal of Negative Effects	Total
Physical Side Effects	10 (1%)	57 (7%)	15 (2%)	26 (3%)	10 (1%)	9 (1%)	3 (0%)	130 (16%)
Mental Side Effects	3 (0%)	18 (2%)	14 (2%)	19 (2%)	4 (1%)	1 (0%)	2 (0%)	61 (8%)
Access-Related Issues	4 (1%)	3 (1%)	1 (0%)	2 (0%)	1 (0%)	1 (0%)	1 (0%)	13 (2%)

Note: Results are broken down by negative effect scale scores. Percentages are calculated based on the total number of patient survey responses received (n=792).

HCP-Reported Negative Effects from Medical Cannabis

Like the Patient Experience survey, the HCP survey asks respondents to report the degree, or severity, of any negative effects they believe the patient received from using medical cannabis, on a scale from 1 (no negative effects) to 7 (a great deal of negative effects). Table 7.5 shows the distribution of negative effects by severity score within three broad categories: physical side effects (including dry mouth, fatigue, headache, dizziness, blurred vision); mental side effects (including mental clouding, paranoia, sedation or symptoms related to “high”); and issues related to accessing the medications (long distance to distribution center, inconvenient operating hours for distribution centers, etc.).

Of 251 total HCP survey responses, 200 responses (80%) included a negative effects score and 107 responses (43%) included a description of any negative effect(s). Of 200 negative effect scale responses, 128 (64%) reported a score of 1, or “no negative effect.” This includes 6 HCP

reports which entered a narrative description of physical or mental side effects. There were 33 HCP reports (13% of all HCP survey responses) of physical or mental negative effects resulting from medical cannabis treatment. As seen in the patient survey results, these generally mirrored side effects described in clinical trials (see [“A Review of Medical Cannabis Studies relating to Chemical Compositions and Dosages for Qualifying Medical Conditions”](#) on the [Office of Medical Cannabis](#) website). Healthcare providers describing negative effects with high scores reported the following: a score of 7 was associated with a report of “abdominal discomfort”; dizziness (n=1) and sedation (n=1) were reported with scores of 6; finally, constipation, lethargy and worsened seizure activity (n=1) and a report of “too strong per patient” (n=1) were associated with a score of 5. Four HCP responses reported access-related issues as a negative effect. Additionally, 25 HCP reports (10% of all HCP survey responses) described cost as a negative effect related to medical cannabis (these reports are not included in Table 7.5).

A full listing of all negative effect comments from HCPs can be found in *Appendix F: Healthcare Practitioner-Reported Negative Effects from Surveys*.

Table 7.5. Summary of most significant negative effects experienced by the patient, per HCP reports.

Negative Effects By Score (1-7 Scale)	1 (No Negative Effects)	2	3	4	5	6	7 (Great Deal of Negative Effects)	Total
<i>Physical Side Effects</i>	4 (2%)	5 (2%)	6 (2%)	2 (1%)	1 (0%)	1 (0%)	1 (0%)	20 (8%)
<i>Mental Side Effects</i>	2 (1%)	6 (2%)	3 (1%)	1 (0%)	-	1 (0%)	-	13 (5%)
<i>Access Issues</i>	1 (0%)	2 (1%)	1 (0%)	-	-	-	-	4 (2%)

Note: Results are broken down by negative effect scale scores. Percentages in each cell are based on the total number of HCP survey responses (n=251).

Adverse Side Effects Reported on Surveys: Conclusions

Based on data from surveys completed by patients and their certifying healthcare practitioners three months after the patient’s first medical cannabis purchase, 25% of patient respondents report physical or mental side effects related to medical cannabis use. A minority of healthcare provider responders (13%) report physical or mental side effects. Both groups describe negative effects related to medical cannabis use including the cost of products and issues related to

accessing medicine. Most patients and HCPs reporting physical or mental side effects report low degrees of severity (negative effect scale scores of 1-3).

Adverse Event Reporting to Manufacturers

There is potential for enrolled patients, their family and caregivers, and health care practitioners to be concerned about an adverse event potentially caused by medical cannabis and to want to register their concern quickly. Both manufacturers have processes in place to receive these messages by telephone and by email. They collect and document information related to the incident and report it to the Office of Medical Cannabis. In nature and severity these reports have been similar to the adverse events reported in Patient Self-Evaluations and surveys.

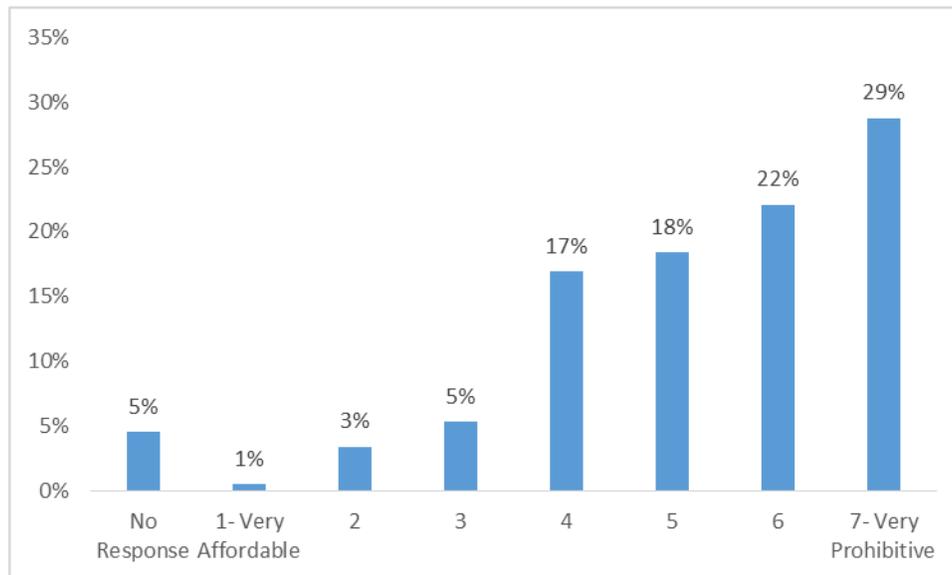

Patients, their registered caregivers, and certifying health care practitioners have a duty as program participants to report serious adverse events. Called “serious adverse incidents” in the program’s rules (4770.4002), these are essentially occurrences that lead to hospitalization or are life-threatening events. As of the date of this report, no reported adverse events have met the definition of “serious adverse incident.”

8. Affordability and Suggestions for Improving the Program

Patient Perceptions of Affordability

Unlike traditional pharmaceuticals whose costs are often covered through insurance reimbursement, medical cannabis must be purchased solely out of pocket. The Patient Experience survey asked patients to rate the cost of the medication on a scale from 1, or very affordable, to 7, or very prohibitive. Responses to this question are displayed in Figure 8.1. Of 792 respondents, 683 (86%) reported that they found medical cannabis to be at least somewhat unaffordable (score of 4 or greater).

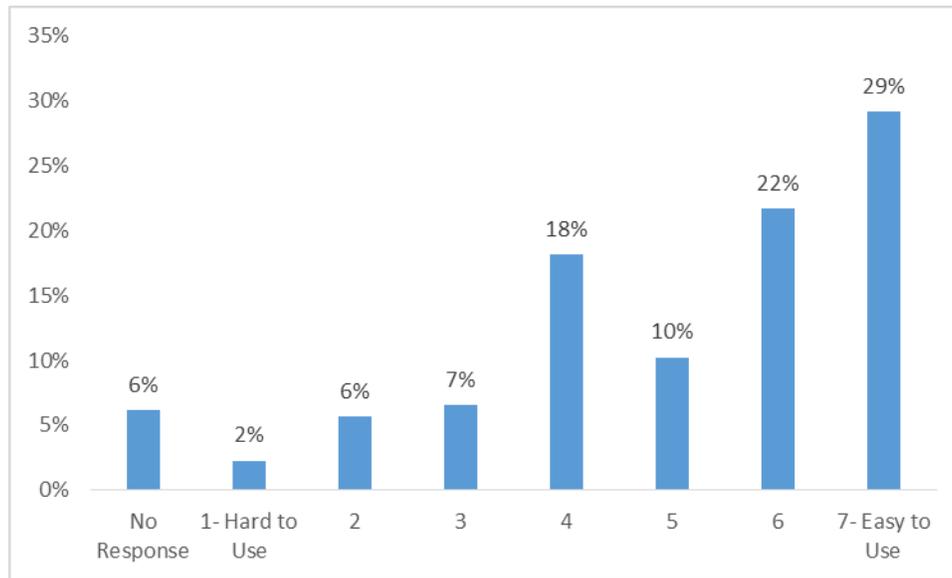

Figure 8.1. Patient Perceptions of Product Affordability

Patient Perceptions of Online Registry

Patients were asked how easy or difficult the online registry system, through which the Minnesota Medical Cannabis program is administered, is to use. Patients were asked to rate usability on a scale from 1, or very difficult to use, to 7, or very easy or intuitive to use. Responses were generally positive (Figure 2), with 51% of patients reporting high scores of usability (6 or 7).

Figure 8.2. Online Registry Ease of Use

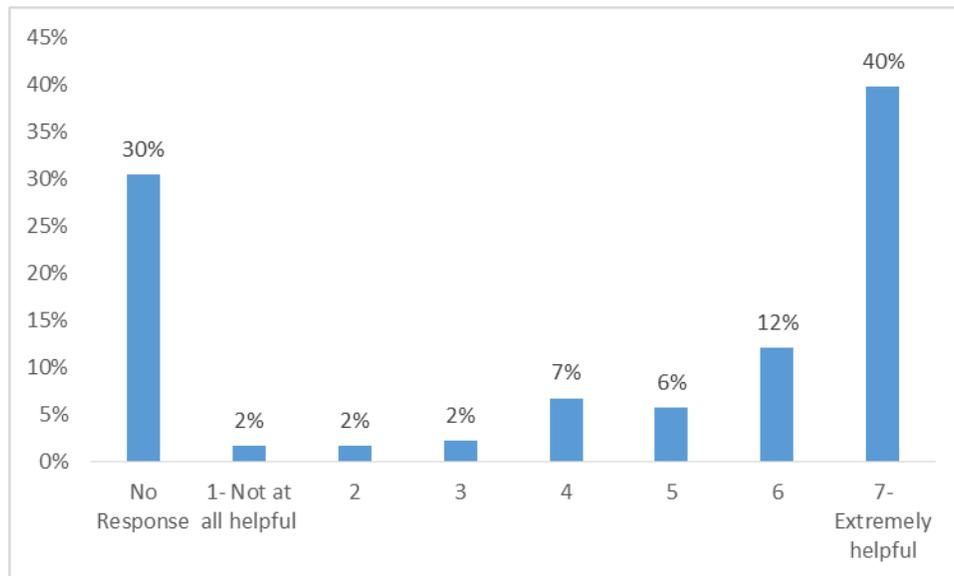

Patient reports on the ease of use of the Medical Cannabis Registry online system (1=very difficult to use; 4=neither difficult nor easy to use; 7=very easy/intuitive to use). Note: percentages are based on total number of patient responses; 49 patients did not complete this question and are not represented in the figure.

Patient Perceptions of Office of Medical Cannabis Call Center

Patients were asked to rate the helpfulness of the Office of Medical Cannabis Call Center (also known as the Support Center), which provides support for patients, caregivers and providers in navigating the registration and enrollment process as well as assisting with other program-related inquiries. The Patient Experience survey asked patients to rate the helpfulness of the call center on a scale from 1, or not very helpful, to 7, or very helpful. Over half of all patient responses reported high scores of helpfulness (6 or 7).

Figure 8.3. Call Center Helpfulness

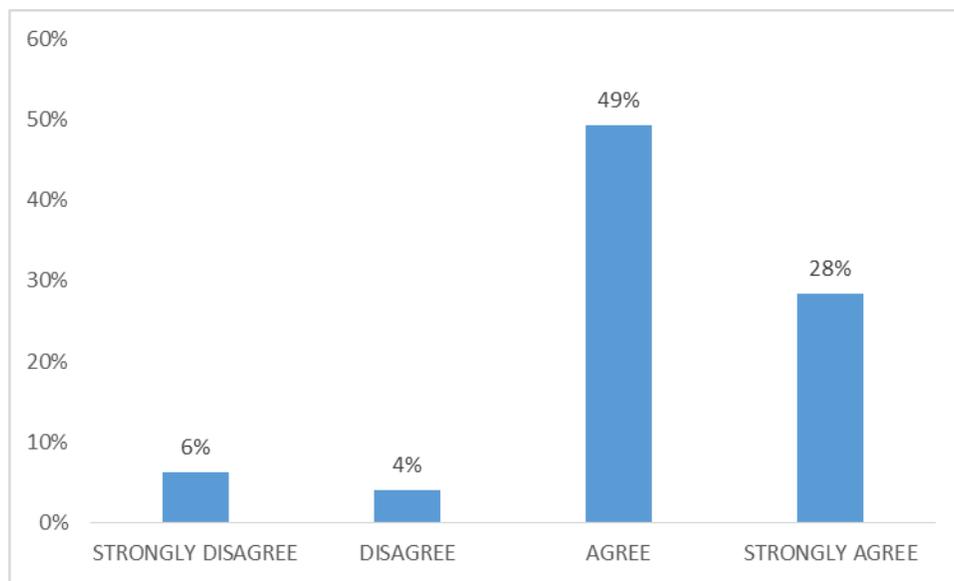

Patient reports on the helpfulness of the Office of Medical Cannabis Patient Support Center (1=not very helpful; 4=somewhat helpful; 7=very helpful). Note: percentages are based on total number of patient responses; 241 patients did not complete this question (several indicated no experience with the call center) and are not represented in the figure.

Patient Perceptions of Office of Medical Cannabis Website

Patients were asked to state their level of agreement with the statement: “The Office of Medical Cannabis website provides me with the information I need to understand and participate in the program.” Among all patient respondents, 49% agreed and 28% strongly agreed that the website met their needs for information; however 10% expressed that they did not feel the website met their needs for program participation (Figure 8.4) and 12% did not respond to the survey question.

Figure 8.4. “The website provides the information I need to understand and participate in the program”

Patient Suggestions

Patients were asked to provide feedback on the program; all responses submitted from the first year cohort are tabulated in *Appendix G: Patient Suggestions for Improving the Program from Surveys*. Many patients used this space to elaborate on the program’s impact on their lives; others suggested changes to the program’s administration or reported concerns related to product cost or access to cannabis patient centers.

Suggestions and Information Requests from Healthcare Practitioners

Healthcare practitioners were asked to provide suggestions for improving the program, and were also asked if any additional information from the program would be useful to them. The full tabulation of comments is available in *Appendix H: Healthcare Practitioner Suggestions for Improving the Program and Requests for Additional Information from Surveys*. Many comments reported in these sections of the survey mirrored those reported as clinical observations; there were 39 additional comments relating to affordability of the products. Other common responses included requests for information on medical cannabis dosing and specific information on what products their patient was purchasing. Other responses included requests for more patient education regarding products, information on drug interactions, and data on efficacy in specific patient populations.

Overview – 3

Generalized Anxiety Disorder: Prevalance, Burden, and Cost to Society - 4

Final Agency Decision: Petitions to Establish Additional Debilitating Medical Conditions Under the New Jersey Medicinal Marijuana Program – New Jersey Department of Health - 17

Overview

General Anxiety Disorder (GAD) is a debilitating condition that has proven difficult to treat. The burden created by GAD has been compared to that of major depression.

As recently as March of 2018, the New Jersey Department of Health determined that GAD and anxiety as a broader set of conditions are so debilitating, and evidence of medical marijuana's effectiveness so persuasive, that they add anxiety to the state's qualifying conditions list.

GAD has also been shown to have a significant impact on society at large. The social routines of patients suffering from GAD and those around them can be severely interrupted. Additionally, work productivity has been shown to decrease in those with GAD creating an economic consequence for society when treatment isn't adequate.

The attached documents seek to explain New Jersey's reasoning for adding anxiety as a qualifying condition and explain the burden of GAD.

Research Article

GENERALIZED ANXIETY DISORDER: PREVALENCE, BURDEN, AND COST TO SOCIETY

Hans-Ulrich Wittchen, Ph.D.*

Generalized anxiety disorder (GAD) is a prevalent and disabling disorder characterized by persistent worrying, anxiety symptoms, and tension. It is the most frequent anxiety disorder in primary care, being present in 22% of primary care patients who complain of anxiety problems. The high prevalence rate of GAD in primary care (8%) compared to that reported in the general population (12-month prevalence 1.9–5.1%) suggests that GAD patients are high users of primary care resources. GAD affects women more frequently than men and prevalence rates are high in midlife (prevalence in females over age 35: 10%) and older subjects but relatively low in adolescents. The natural course of GAD can be characterized as chronic with few complete remissions, a waxing and waning course of GAD symptoms, and the occurrence of substantial comorbidity particularly with depression. Patients with GAD demonstrate a considerable degree of impairment and disability, even in its pure form, uncomplicated by depression or other mental disorders. The degree of impairment is similar to that of cases with major depression. GAD comorbid with depression usually reveals considerably higher numbers of disability days in the past month than either condition in its pure form. As a result, GAD is associated with a significant economic burden owing to decreased work productivity and increased use of health care services, particularly primary health care. The appropriate use of psychological treatments and antidepressants may improve both anxiety and depression symptoms and may also play a role in preventing comorbid major depression in GAD thus reducing the burden on both the individual and society. Depression and Anxiety 16:162–171, 2002. © 2002 Wiley-Liss, Inc.

Key words: *generalized anxiety disorder; prevalence; health care utilization; comorbidity*

INTRODUCTION

Generalized anxiety disorder (GAD) is a persistent and often severe mental disorder of the anxiety spectrum, characterized by persistent (6 months or more), excessive worrying, anxiety, tension associated with symptoms of hypervigilance, and other somatic symptoms of anxiety. The symptomology is associated with substantial and enduring subjective suffering, and the feeling of loss of control over the worrying and symptoms as another criterion. Clinical reports suggest that fewer than 20% of sufferers experience complete remission of their symptoms, and typically patients will have had their symptoms for between 5 and 10 years before they are diagnosed and effectively treated [Ballenger et al., 2001; Kessler et al., 2001a; Rogers et al., 1999]. Patients with GAD have been found to be frequent utilizers of primary care resources rather than

mental health specialist settings and have been associated with over-utilization of general health care resources [Maier et al., 2000; Roy-Byrne and Katon, 1997; Wittchen et al., 2000; Wittchen et al., 2002]. Further primary care studies conducted in the early

Published online in Wiley InterScience (www.interscience.wiley.com). DOI 10.1002/da.10065

1990s have suggested that GAD is rarely recognized and diagnosed, and if it is diagnosed it is usually not, or only inappropriately, treated [Üstün and Sartorius, 1995]. This is particularly significant as GAD is associated with a substantial degree of social disability [Wittchen et al., 2000].

Yet, there has been some debate concerning the nosological status of GAD because of past reports of its low diagnostic reliability using standard criteria [DiNardo et al., 1993] and the fact that clinical studies have found that GAD is usually seen in comorbid presentations with major depression. Furthermore, there have been reports that pure GAD is both an extremely rare phenomenon with few indications of disorder-specific impairments (for examples, see discussions in Kessler et al., 2001a; Noyes et al., 2001). However, one needs to take into account that these reservations against GAD, being an independent clinical disorder of critical significance, are based on studies that have mostly used older diagnostic criteria for GAD and/or stem from highly selective clinical samples that might suffer considerable selection bias.

Since the current diagnostic definition of GAD is a relatively recent addition to diagnostic classification systems, few studies have up to now reconsidered the nature and true burden of GAD, as defined by the current DSM-IV criteria, on the individual and society. This paper aims to address the question “what is the prevalence, level of disability and burden to society associated with GAD, as defined by DSM-IV criteria?”

PREVALENCE

The concept and diagnostic criteria of GAD have changed significantly since it was first codified in the Diagnostic and Statistical Manual of Mental Disorders [American Psychiatric Association, 1994] in 1980 and to date there are still small differences in the criteria used in the USA and Europe. In the USA and in research, the DSM-III-R/DSM-IV criteria prevail, whereas in Europe the use of the 10th International Classification of Diseases [ICD-10; World Health Organization (WHO) 1992], which has broader criteria, is preferred at least in routine clinical settings. However, it is remarkable that despite the many changes in diagnostic criteria and the differences between these two diagnostic classification systems, the reported lifetime prevalence rates for GAD are remarkably consistent. This is in contrast to the considerable variance observed with other psychiatric disorders, such as depression and phobias.

COMMUNITY STUDIES

The US National Comorbidity Survey [NCS; Kessler et al., 1994] and the German National Health Interview and Examination Survey, Mental Health Supplement [GHS; Carter et al., 2001; Jacobi et al., 2002] are the largest community epidemiological studies of GAD to date. and, together, include over

TABLE 1. Twelve-month and lifetime prevalence in the NCS of GAD in males and females by age group [Wittchen et al., 1994]

Age (yr)	Male (%)	Female (%)	Total (%)
12-month prevalence			
15–24	1.3	1.5	1.4
25–34	3.2	5.0	4.1
35–44	2.3	4.5	3.4
≥45	0.9	6.3	3.5
Total	2.0	4.3	3.1
Lifetime prevalence			
15–24	1.5	2.5	2.0
25–34	4.7	7.1	6.0
35–44	4.6	7.2	5.9
≥45	3.6	10.3	6.9
Total	3.6	6.6	5.1

69,400 patients. The 12-month and lifetime prevalence rates of GAD (DSM-III-R) in the NCS were estimated to be 3.1% and 5.1%, respectively. The lowest lifetime prevalence rate was found in the 15–24 year age group (2.0%), while the highest rate was reported for the 45–55 year age group (6.9%) [Table 1; Wittchen et al., 1994]. This survey also demonstrated that women were twice as likely to have GAD than their male counterparts, with total lifetime prevalence rates of 6.6% and 3.6%, respectively [Wittchen et al., 1994]. The prevalence rate increased to 10.3% for women aged ≥45 years, but was unchanged for men aged ≥45 years (3.6%).

These findings are relatively consistent with findings from a previous GAD community survey that used earlier diagnostic criteria and different instruments [see review by Carter et al., 2001]. The most recent epidemiological study using DSM-IV criteria [GHS; Carter et al., 2001] has reported slightly lower 12-month prevalence rates for GAD than the NCS (12-month prevalence 1.5% vs. 3.1%). However, this finding was found to be entirely due to methodology because the inclusion of subjects with lifetime GAD and partially remitted subthreshold GAD accounts for this difference. The highest rates were again found in women and older subjects [Carter et al., 2001].

Although in the past there was some speculation about GAD being a characterological disorder [Akiskal, 2001] being best grouped under DSM axis II personality disorders, there has been little supporting evidence to date. Reports concerning the prevalence of GAD as defined by the DSM-III-R and the more stringent DSM-IV criteria in children and adolescents have generally found low rates of GAD in this age group [Müller, 2001, doctoral dissertation; Wittchen et al., 1998]. The prospective-longitudinal 5-year Early Developmental Stages of Psychopathology (EDSP) study in adolescents and young adults [Wittchen et al., 1998], which to our knowledge is the only DSM-IV-based study of this sort, examined the prevalence of GAD and patterns of age of onset among subjects aged

14–24 years at intake. This study found that GAD is rare in children and adolescents and that unlike most anxiety disorders, onset of GAD before the age of 25 years was uncommon. These findings are in agreement with those of most of the previous adult studies that report age of first onset data as well as surveys in children.

PRIMARY CARE

There is consistent evidence that patients with GAD are highly prevalent in primary care settings [Ormel et al., 1994; Schonfeld et al., 1997]. The international WHO multi-center study on Psychological Problems in General Health Care (PPGHC) assessed GAD using ICD-10 criteria with the Composite International Diagnostic Interview [CIDI; WHO, 1991] and estimated the current prevalence of GAD across centers to be approximately 8% of all primary care attenders [Üstün and Sartorius, 1995]. This was confirmed in a more recent reanalysis [Maier et al., 2000]. Of those patients visiting primary care physicians for a psychological problem, 25% presented with pure GAD in the absence of any comorbid psychiatric disorder [Maier et al., 2000]. In a subset of almost 2,000 individuals attending five of the European centers in this study [Weiller et al., 1998], 22% of all primary care patients who complained of any anxiety problems were found to have GAD. In this analysis, the overall current prevalence of GAD among primary care attenders was 8.5% with a further 4.1% of individuals having sufficient clinical problems to justify a diagnosis of subthreshold GAD.

The most recent primary care study of over 500 primary care centers and over 20,000 primary care attenders (Generalised Anxiety Disorder and Depression in Primary Care [GAD-P] study) has confirmed these findings on the basis of DSM-IV criteria for GAD [Hoyer et al., 2001; Wittchen et al., 2001; Wittchen et al., 2002]. The point prevalence of threshold GAD was estimated to be 5.3%, with highest estimates in those primary care attenders aged 35–60 years. The study also confirmed, even more impressively than the report by Weiller et al., [1998], that GAD is a) the most frequent anxiety disorder seen in primary care (more than 50% of all anxiety disorders), b) rarely correctly diagnosed (only 28% were correctly diagnosed as having GAD by their GP), and c) rarely appropriately managed in terms of type and duration of pharmacological and non-pharmacological treatments [Wittchen et al., 2001].

These findings of increased prevalence of GAD in primary care compared to the general population are in contrast to most other anxiety disorders where the prevalence rate in the general population is much higher than in primary care. This suggests, in line with previous speculations [Schonfeld et al., 1997] that GAD patients are high utilizers of primary care resources (Fig. 1).

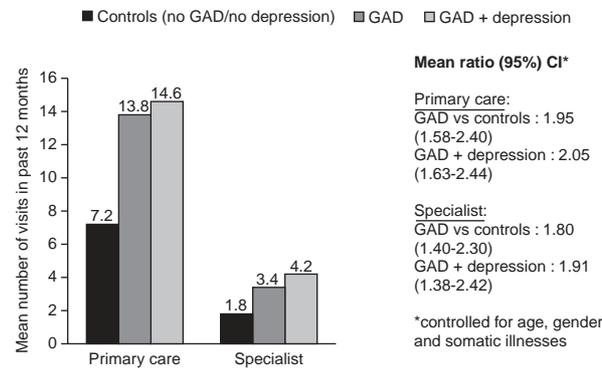

Figure 1. Increased utilization rates of primary care attenders with GAD ($n=14,532$) [Wittchen et al., 2001].

COMORBIDITY

A consistent finding in clinical and epidemiological studies of GAD is the high proportion of comorbidity (Table 2), with common comorbid diagnoses including major depression, panic disorder, social and specific phobia, and post-traumatic stress disorder (PTSD). However, there is no remarkable association with substance use disorders. As many as 66% of patients with current GAD have an additional concurrent psychiatric diagnosis and they almost invariably (90%) have a lifetime history of another psychiatric diagnosis [Wittchen et al., 1994]. The GHS confirmed these findings and reported that comorbidity of DSM-IV GAD includes other anxiety disorders in 55% of cases and depression in 59% of cases [Carter et al., 2001]. Brawman-Mintzer and colleagues [1993] pointed out in this respect that 42% of patients with GAD had experienced at least one major depressive episode during their lifetime. Data from the GHS showed a similar pattern; 40.5% of GAD patients had comorbid current major depression, 59% had comorbid 12-month major depression, and 60% had comorbid lifetime major depression [Carter et al., 2001].

TABLE 2. Comorbidity of current and lifetime DSM-III-R-GAD [Noyes, 2001]

Comorbid disorder	Current GAD (%)	Lifetime GAD (%)
Mania	12.1	10.5
Major depression	38.6	62.4
Dysthymia	22.1	39.5
Panic disorder	22.6	23.5
Agoraphobia	26.7	25.7
Simple phobia	24.5	35.1
Social phobia	23.2	34.4
Alcohol	11.2	37.6
Drug	5.1	27.6
Any of the above	66.3	90.4

GAD, generalized anxiety disorder.

TABLE 3. Proportion of NCS and DSM-III-R disorders with lifetime comorbidity and proportion of temporally primary cases[†]

Disorder	Proportion with lifetime comorbidity (%)	Proportion of temporally primary disorders (%)
Mood disorders		
Mania	99.4	20.2
Dysthymia	91.3	37.7
Major depressive episode	83.1	41.1
Any mood disorder	82.2	—
Anxiety disorders		
Panic disorder	92.2	23.3
Generalized anxiety disorder	91.3	37.0
Agoraphobia	87.3	45.2
Simple phobia	83.4	67.6
Social phobia	81.0	63.1
Post-traumatic stress disorder	81.0	52.1
Any anxiety disorder	74.1	—

Even slightly higher comorbidity rates have been reported for clinical samples [Noyes, 2001; Roy-Byrne and Katon, 1997]. Although these high rates of anxiety-mood disorder comorbidity have stimulated some controversy over whether GAD should be regarded as a distinct disorder or should more appropriately be conceptualized as a prodromal, residual stage or as a severity marker of depression, there has been little supporting evidence for the latter. Kessler et al. [2001a] have reviewed the available evidence for this controversy and come to the conclusion that GAD and depression are distinct disorders based on the following findings: 1) twin studies do not support the lumping of both conditions, 2) exceedingly high comorbidity rates are confined to selected clinical studies with potential patients' self-selection bias that have used early definition of GAD and not DSM-IV position, 3) conditional rates of comorbidity among GAD cases are not higher

than those observed for other disorders, and 4) there is an abundance of studies revealing that pure and comorbid presentations differ considerably with regard to their clinical and other correlates (Table 3). For example, 50% of all adult GAD cases were found to be temporally primary to mood disorders [Fava et al., 2000; Wittchen et al., 2000]. Comorbidity, especially with depression, significantly lowers the probability of GAD being successfully diagnosed and treated and patients experience more severe symptoms. Comorbid, as opposed to pure, GAD is associated with increased disability and dysfunction, and has a worse prognosis and impairment [Bakish, 1999; Wittchen et al., 2000]. Thus, there is considerable evidence that GAD is a distinct disorder that deserves special research and clinical attention. There is also a need for further studies that provide a better and fuller understanding of the pathogenic and clinical management implications of these patterns of comorbidity.

INDIVIDUAL BURDEN OF DISABILITY

Another key finding that provides further evidence for GAD being a particularly clinically significant mental disorder in itself was the recent demonstration that GAD is associated with a significant burden of disability for individuals, even if they do not have a comorbid condition. This is most notable in terms of diminished functioning both socially and at work. General population studies have considered the degree of impairment caused by pure GAD. The NCS and Midlife Development in the United States Survey both reported that the level of impairment associated with DSM-III-R GAD is substantial and comparable to that of pure major depression [Table 4; Kessler et al., 2001a, 1994, 1997].

A combined analysis of data from these two studies confirmed their findings and showed that even "pure" GAD was associated with marked impairment in role functioning and social life [Kessler et al., 1999]. Moreover, this impairment was equivalent to that caused by major depression (Fig. 2). The highest levels of impairment were seen when GAD was comorbid with major depression (Figure 3).

TABLE 4. Odds ratios of 12-month GAD with major depression without GAD in predicting impairment[†]

Impairment	GAD without MD		MD without GAD		Risk of GAD alone relative to MD alone	
	NCS	MDUSS	NCS	MDUSS	NCS	MDUSS
Fair or poor perceived mental health	6.0*	4.8*	3.3*	5.2*	1.6	0.8
High level of work impairment	3.5	3.5	3.5*	8.5*	0.9	0.5
High level of social impairment	2.5*	1.2	2.0*	1.6*	1.5	1.0

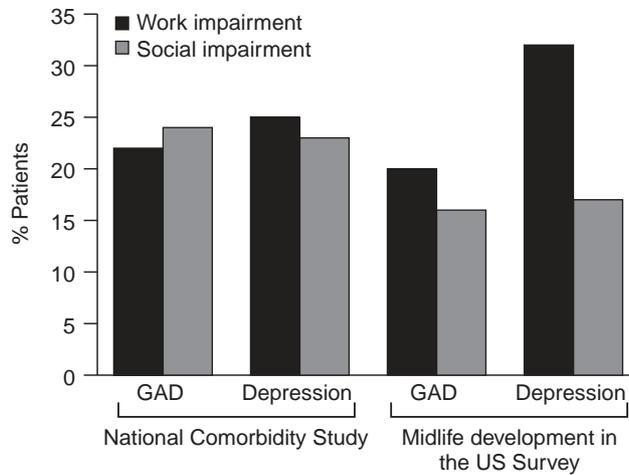

Figure 2. Work and social impairment in GAD and depression [Kessler et al., 1999].

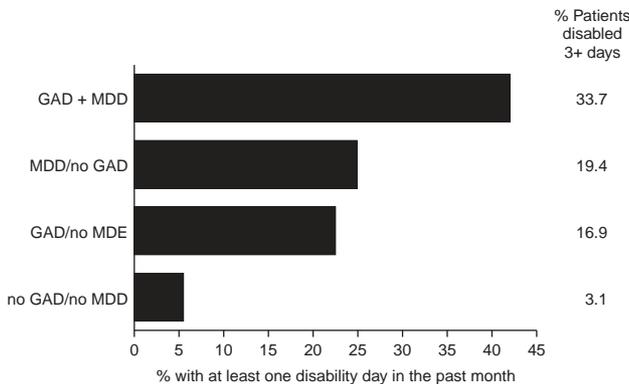

Figure 3. Impairment associated with DSM-III-R GAD [Kessler et al., 1999].

Similar findings were recently reported for DSM-IV GAD from the GHS [Wittchen et al., 2000], which also confirmed similar findings with regard to work productivity as well as other measures of impairment and quality of life [Figure 4; Wittchen et al., 2000].

In the PPGHC study, patients with GAD (and subthreshold GAD) showed greater severity of symptoms and had a greater degree of disability than primary care subjects with no current psychiatric symptoms [Weiller et al., 1998]. Twenty-seven percent of all GAD sufferers reported moderate or severe social disability (assessed by the Brief Disability Questionnaire) and this proportion rose to 59% when GAD was comorbid with major depression.

COST TO SOCIETY

While the level of social disability associated with GAD is as severe as that seen with chronic somatic diseases [Kessler et al., 2001a; Maier et al., 2000], GAD

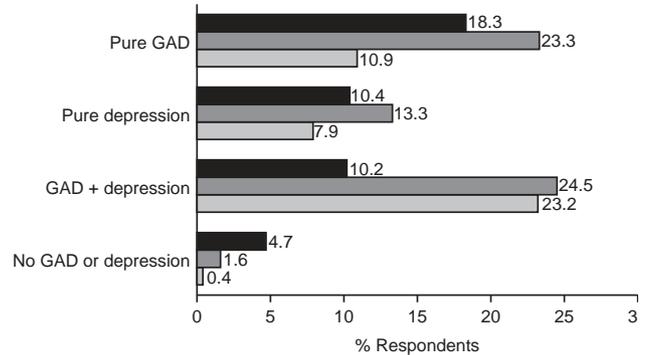

Figure 4. Overall work productivity reductions in pure and comorbid 12-month GAD [Wittchen et al., 2000]. Black bars, 0–10%; gray bars, 11–49%; light gray bars ≥50%.

also has a major impact on society in terms of decreased work productivity and increased health care utilization.

Impact on work productivity. GAD is associated with a significant economic burden owing to particularly decreased work productivity [Kessler et al., 1999; Greenberg et al., 1999; Sou tre et al., 1994; Judd et al., 1998]. A recent analysis using data from the GHS study (see above) considered disability in terms of reduced work productivity in individuals with pure GAD and GAD comorbid with major depression [Wittchen et al., 2000]. Approximately 34% of patients with 12-month pure GAD, 21% of those with depression, and 48% of those with comorbid GAD and depression showed a reduction in work productivity of 10% or more and a reduction of at least 50% in activity during the past month was reported by approximately 11% of respondents with pure GAD and 8% of those with pure major depression (Fig. 4). Thus, GAD is associated with considerable impairment even when no comorbid depression is present. Of those individuals with comorbid GAD and depression, 23% had experienced reductions of at least 50% in the activities of the previous month. In the PPGHC study, the mean number of workdays lost to disability was 4.6 for pure GAD and rose to 8.0 when GAD was comorbid with major depression [Weiller et al., 1998].

Further evidence has been presented by an Australian study, which reported that the burden of mental disorders was third after the burden of heart disease and cancer and, of these mental disorders, the two most relevant were GAD and depression [Andrews et al., 2000]. This was confirmed by Kessler et al. [2001b; Table 5].

This indicates that the presence of GAD is a significant factor that leads to complete disability, diminished productivity at work and that the burden of GAD on society is at least equivalent to, if not greater than, the burden caused by depression.

Health care utilization. The high prevalence of GAD in the primary care setting, compared with the general population, suggests that patients with the disorder are likely to be high users of health care

TABLE 5. Prevalence of 30-day work impairment for selected conditions in the Midlife Development in the United States Survey [Kessler et al., 2001b][†]

Condition	Prevalence of condition (%)	Any work impairment days (%)	Mean number of impairment days	Average per capita number of work impairment days
Physical conditions				
Arthritis	19.4	38.8	8.3	3.2
Hypertension	18.2	34.6	9.0	3.1
Asthma	12.6	44.7	7.7	3.5

services and particularly primary care health services [Maier et al., 2000; Weiller et al., 1998]. According to the most recent primary care study [Wittchen et al., 2002], patients with pure GAD reported a two-fold higher than average number of visits to primary care doctors compared with depressed patients and significantly more visits to non-mental health specialists in the previous 12 months, even when controlling for the presence of physical illnesses. Similarly, GAD ranks third among anxiety disorders (after PTSD and panic disorder) in the rate of use of primary care physicians' time [Kessler et al., 1999]. Approximately one third of patients with GAD seek medical help for their somatic GAD symptoms [Judd et al., 1998], most commonly from primary care physicians. Comorbidity with GAD is reported to increase the rate of help-seeking behavior by more than 50% [Bland et al., 1997].

It has been reported that the specialists seen most often by GAD patients are gastroenterologists [23%; Kennedy and Schwab, 1997]. This was significantly greater than for patients with other anxiety disorders (16% panic disorder, 3% obsessive compulsive disorder; $P < .05$). Only 10% of patients with GAD had seen a psychiatric specialist. These observations were attributed to the considerable overlap between the anxiety symptoms of GAD and the symptoms associated with other conditions, for example, irritable bowel syndrome [Kennedy and Schwab, 1997]. Fifty percent of patients with GAD had seen 1–2 medical specialists (other than primary care physicians) in the preceding year, while 10% had visited 3–5 specialists [Kennedy and Schwab, 1997]. These results show that many patients with GAD visit a number of physicians before they are definitively diagnosed and treated.

It is noteworthy that, despite the high primary care utilization rates of GAD, sufferers are rarely specifi-

cally diagnosed and treated for their disorder either directly by the primary care doctor or after referral to mental health specialists. In the NCS conducted in the early 1990s, only 48% of all pure GAD subjects had received health care intervention at some point in their life, and only 25% had at some point taken medication for their GAD symptoms. The recent GAD-P study (conducted during the year 2000) confirmed this finding and revealed that despite high utilization rates in primary care, less than 10% of GAD patients receive adequate non-pharmacological or pharmacological treatments for their disorder [Wittchen et al., 2001].

Economic burden. The economic cost of anxiety disorders has been examined [DuPont et al., 1996; Greenberg et al., 1999; Rice and Miller, 1998] in elaborate and complex secondary data analyses. These studies indicated that the annual cost of anxiety disorders was \$42–47 billion in the USA in 1990. The three largest components of the total cost comprised \$23 billion (54%) in non-psychiatric medical treatment, \$13 billion (31%) in psychiatric treatment, and over \$4 billion (10%) in indirect workplace costs. Prescription pharmaceutical costs were a minor factor, accounting for less than \$1 billion (2%) of the total cost of anxiety disorders [Greenberg et al., 1999].

The \$4 billion indirect workplace costs reflect an average annual (1990) cost in the workplace of \$256 per affected worker [Greenberg et al., 1999]. A total of 88% of this cost per individual was attributed to lost productivity while at work, as opposed to actual absence from work. Therefore, work productivity may provide a more accurate assessment of the economic cost of GAD than absence from work [Greenberg et al., 1999].

Primary care patients with DSM-III-R anxiety or depressive disorders have been reported to have

markedly higher associated costs (\$2,390/patient) than patients with subthreshold disorders (\$1,098/patient) or those with no anxiety or depressive disorder (\$1397/patient) [Simon et al., 1995]. These cost differences reflected greater utilization of general medical services rather than higher treatment costs.

It is to be expected that the high prevalence of GAD comorbid with depression would lead to increased economic costs. An evaluation of the direct and indirect health care costs in GAD patients found that over 60% were experiencing one or more symptoms of comorbidity that resulted in a high rate of health care utilization that was affected by both the level of comorbidity and symptom severity [Sou tre et al., 1994]. In GAD patients, hospitalizations were significantly more prevalent in those with comorbidity than in those without (11.8% vs. 5.1%, respectively; $P < .001$), with internal medicine and emergency admission being the most frequently used services [Sou tre et al., 1994]. Hospitalization costs accounted for 35% of total costs and over 53% of direct health care costs in patients with comorbidities. The economic cost was also increased in GAD patients with comorbidity in terms of increased absenteeism from work (33.6% with comorbidity vs. 26.6% without; $P < .05$). Absenteeism from work accounted for 34.4% and 33.1% of total costs for patients with and without comorbidity, respectively.

REDUCING THE BURDEN

The debate that existed concerning the status of GAD as a discrete anxiety disorder has meant that less attention has been focused on identification of adequate treatment for the disorder than for other anxiety disorders. Improving the recognition and treatment of GAD is key to reducing the burden of the disorder on the individual and society. The challenges of GAD as a chronic, and after several years, usually complex disorder with a substantial degree of impairment, disability, and comorbid complications are a) its early recognition before substantial complications develop and b) appropriate combined acute and long-term management strategies to reduce the suffering caused by the GAD symptoms and comorbid presentations as well as reducing the associated disability as a major source of relapse. Thus therapeutic interventions should aim at reducing the core symptoms of GAD, the prevalence of comorbidity, and the associated disabilities.

In addition to several well-established, effective non-pharmacological, mostly cognitive-behavioral treatments, there are various traditional drug treatments, most of which have significant limitations, as well as several new drug therapies of first choice.

Benzodiazepines have traditionally been used to treat acute anxiety disorders but they are not ideal for the treatment of chronic GAD. Following long-term therapy, benzodiazepines have the potential to produce

dependency and withdrawal symptoms [Lydiard et al., 1997]. Initial findings in patients with GAD generally showed that buspirone was as efficacious as the benzodiazepines in treating anxiety disorders [Petra ca et al., 1990; Strand et al., 1990] but appeared to lack the side effects and withdrawal symptoms [Laakman et al., 1998]. Although buspirone is effective in most (but not all) studies of GAD [Davidson et al., 1999; Lydiard, 2000], its lack of efficacy against comorbid conditions is the main reason for it not being recommended as a first-line treatment for GAD [Ballenger et al., 2001].

The use of buspirone for the treatment of anxiety disorders is limited to short-term treatment only and therefore is inadequate for the treatment of GAD. In a placebo-controlled study to investigate the use of both buspirone and hydroxyzine in patients with GAD, a significant difference was shown only between hydroxyzine and placebo with respect to improvement of the primary efficacy measurement (improvement on the Hamilton Anxiety Scale). However, both buspirone and hydroxyzine were shown to be more effective than placebo for the secondary efficacy measurement (improvement in CGI and HAD scale ratings) [Lader and Scotto, 1998]. Treatment with benzodiazepines or buspirone is ineffective when comorbid depression is present [Bakish, 1999; Lydiard et al., 1987].

There is evidence that the tricyclic antidepressants (TCAs) are at least as effective as benzodiazepines in the treatment of GAD and may be superior in long-term therapy [Kahn et al., 1986; Hoehn-Saric et al., 1988; Rickels et al., 1993]. The tertiary TCAs, which have dual serotonergic-noradrenergic effects (e.g., imipramine and amitriptyline), appear to be consistently effective in the treatment of anxiety [Feighner, 1999]. However, side effects, such as anticholinergic events, preclude the use of TCAs in many patients, namely, the elderly or those with cardiovascular disease.

Clinical studies have shown that the selective serotonin reuptake inhibitor (SSRI) paroxetine and the serotonin norepinephrine reuptake inhibitor (SNRI) venlafaxine are as effective in the treatment of GAD as they are for most other anxiety disorders studied so far [Bellew et al., 2001; Davidson et al., 1999; Davidson, 2001; Feighner, 1999; Gelenberg et al., 2000; Pollack et al., 2001; Rocca et al., 1997], resulting in a reduction of the symptoms of anxiety and depression. An important advantage of these drugs is that it is useful in the treatment of the depression and anxiety disorders frequently comorbid with GAD, such as panic disorder, social anxiety disorder, or OCD [Ballenger et al., 2001]. Paroxetine, which has proven efficacy across the spectrum of depression and anxiety disorders (panic disorder [Lecrubier et al., 1997], OCD [Zohar and Judge, 1996], social anxiety disorder [Lydiard and Bobes, 2000], and PTSD [Beebe et al., 2000]), has also been shown to be effective in patients with GAD [Bellew et al., 2000; Pollack et al., 2001; Rocca et al., 1997] and has been the first SSRI to be

specifically licensed for the treatment of GAD. A large clinical program involving 1,264 patients in three 8-week studies has shown that paroxetine significantly reduces HAM-A total scores compared with placebo and reduces the core GAD symptoms (worry, anxiety, and tension). Paroxetine treatment results in a significant improvement in quality of life in GAD [Pollack et al., 2001]. The EuroQol visual analogue scale (EQ-5D VAS) provides a measure of quality of life by assessing general well-being and the mean change from baseline in EQ-5D VAS scores was significantly greater with paroxetine than with placebo [Bellew et al., 2000].

Controlled studies have also demonstrated that the SNRI, venlafaxine extended release (XR) (which is also licensed for GAD) are effective in both the short- and long-term treatment of GAD [Allgulander et al., 2001; Davidson et al., 1999; Gelenberg et al., 2000; Rickels et al., 2000; Silverstone and Salinas, 2001].

In the first of these studies, the mean adjusted HAM-A anxious mood and tension scores were significantly lower for both doses of venlafaxine XR at week 8 compared with placebo [$P < .05$; Davidson et al., 1999]. However, the adjusted mean total HAM-A scores for all the treatment groups compared to placebo were not significantly different.

In the study by Rickels et al. [2000], venlafaxine XR 75, 150, and 225 mg/day over 8 weeks were significantly more effective than placebo in the treatment of GAD in 377 outpatients without major depressive disorder.

The study by Gelenberg et al. [2000] evaluated flexible doses of venlafaxine XR over 6 months. The results showed that the efficacy of venlafaxine XR 75–225 mg/day could be sustained in 238 patients with GAD over a 28-week maintenance period. Similarly, in the 24-week placebo-controlled study by Allgulander et al. [2001], venlafaxine XR 37.5, 75, and 150 mg/day were significantly more effective than placebo in the treatment of GAD in 541 outpatients.

The placebo-controlled study by Silverstone and Salinas [2001] compared the efficacy of venlafaxine XR (75–225 mg) over 12 weeks in patients with major depression and patients with comorbid GAD. In the comorbid patients, venlafaxine significantly decreased both HAM-D and HAM-A scores compared with placebo.

The rapidly increasing evidence that SSRIs and SNRIs are highly effective treatments for GAD and are also equally effective in the treatment of major depression and the other anxiety disorders (which frequently comorbid with GAD) suggests that these strategies are the drug treatments of first choice for current practice. They also have the potential greatly to reduce the individual and economic burden of GAD.

CONCLUSIONS

GAD is a recognizable and distinct anxiety disorder that is associated with a significant burden of disability on the individual, the magnitude of which is at least

equivalent to that of major depression [Kessler et al., 1999; Wittchen et al., 2001]. However, a comprehensive and sound estimation of the burden of GAD on the individual and society is complicated by the high prevalence of comorbid disorders. Patients with comorbid GAD and depression are particularly likely to demonstrate disability and dysfunction. The presence of GAD in other somatic and mental disorders seems to magnify the disability found for the other condition per se. Further investigations into the associated burden of GAD as well as a change in the current approach to the recognition and treatment of the disorder are necessary.

GAD reduces work productivity and increases the utilization of health care services [Greenberg et al., 1999; Souëtre et al., 1994], and comorbidity, particularly with depression, further increases levels of impairment and cost [Bakish, 1999; Greenberg et al., 1999; Souëtre et al., 1994; Weiller et al., 1998]. In addition, patients with GAD who present to medical practitioners with somatic symptoms may not be diagnosed as suffering from a psychiatric condition, leading to increased medical utilization until the true condition is revealed [Lydiard, 2000].

Although there is growing emphasis on the identification of new agents for the treatment of GAD, further research on the response of comorbidity to management is crucial. Of the current drug treatment options, the SSRI paroxetine and the SNRI venlafaxine are the most convenient treatment to use in the primary care setting and is specifically licensed for the treatment of GAD (DSM-IV definition). Both agents have proven efficacy across the spectrum of depressive and anxiety disorders that are frequently comorbid with GAD (panic disorder, social anxiety disorder, obsessive-compulsive disorder, and PTSD; Brawman-Mintzer et al., 1993; Ballenger et al., 2001; Davidson, 2000).

Prompt recognition and effective treatment of GAD are central to reducing the burden of this chronic, prevalent, and disabling condition. Greater availability of effective outpatient treatment for GAD will improve symptoms and functionality, reduce disability and health care utilization, and could substantially reduce the economic and social burden of this common and disabling disorder.

Re: Final Agency Decision: Petitions to Establish Additional
Debilitating Medical Conditions under the New Jersey Medicinal
Marijuana Program

Dear Petitioners:

This letter sets forth the basis, rationale and final decision in the matter of the Department of Health's (Department) Request for Petitions to establish additional debilitating medical conditions under the New Jersey Medicinal Marijuana Program (MMP). As explained in detail below, I am granting the petitions seeking to add chronic pain conditions that are related to musculoskeletal disorders, chronic pain conditions that are of a visceral origin, as well as Tourette's Syndrome, migraine, and anxiety as debilitating medical conditions under the MMP. However, I am denying the petitions seeking to add asthma and chronic fatigue syndrome to the MMP.

In reaching this decision, I considered the Request for Petitions, the petitions submitted in response to the Request, the MMP panel's recommendations, written and oral public comments received regarding various petitions, as well as the requirements of the New Jersey Compassionate Use Medical Marijuana Act (the Act), N.J.S.A. 24:6I-1 et seq., and the regulations promulgated thereunder. The referenced materials are incorporated herein and made a part of this final decision.

The Request for Petitions

On July 5, 2016, the Department published the Request for Petitions in the New Jersey Register advising that from August 1, 2016 to August 31, 2016, it was accepting petitions to establish additional medical conditions as "debilitating" under the MMP. 48 N.J.R. 1395(a). The Request for Petitions stated that the Department was seeking petitions in accordance with the Act, which authorizes the Department to include additional debilitating medical conditions under the MMP.

In the Request for Petitions, the public was advised that submitted petitions were required to include the following information, pursuant to N.J.A.C. 8:64-5.3:

- (1) The extent to which the condition is generally accepted by the medical community and other experts as a valid, existing medical condition;

(2) If one or more treatments of the condition, rather than the condition itself, are alleged to be the cause of the patient's suffering, the extent to which the treatments causing suffering are generally accepted by the medical community and other experts as valid treatments for the condition;

(3) The extent to which the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting, or otherwise severely impair the patient's ability to carry on activities of daily living;

(4) The availability of conventional medical therapies other than those that cause suffering to alleviate suffering caused by the condition and/or the treatment thereof;

(5) The extent to which evidence that is generally accepted among the medical community and other experts supports a finding that the use of marijuana alleviates suffering caused by the condition and/or the treatment thereof; and

(6) Letters of support from physicians or other licensed health care professional knowledgeable about the condition.

The Department also crafted a Petition Form that petitioners could use for their submissions. The form detailed the above-listed criteria, which each petitioner needed to provide in order for his or her submission to be accepted and considered.

In addition to publishing the request for petitions in the New Jersey Register, the Department also posted it on its website.

Completeness Review

At the close of the petition submission period, the Department received sixty-eight petitions. Thereafter, the Department reviewed each petition to determine whether it contained the information that was required for it to be accepted for consideration. From its review, the Department determined that twenty-three petitions did not meet the criteria for consideration.¹ Accordingly, the Department denied these petitions under separate cover on December 7, 2016, pursuant to N.J.A.C. 8:64-5.3(b). The remaining forty-five petitions met the criteria for consideration and were accepted.

Statutory and Regulatory Criteria

The Act charges the Department with the responsibility of administering the State's MMP, including establishing a registry of qualifying patients and primary care givers. To qualify as a MMP patient, an individual must suffer from one of the debilitating medical conditions set forth in the Act. The Act defines a "debilitating medical condition" as:

(1) one of the following conditions, if resistant to conventional medical therapy: seizure disorder, including epilepsy; intractable skeletal muscular spasticity; post-traumatic stress disorder; or glaucoma;

¹ Legislation was enacted during the pendency of the petitions, which added post-traumatic stress disorder to the list of conditions that qualify as debilitating under the MMP. As a result, the petitions seeking to add this condition to the MMP were deemed moot and not forwarded to the Panel for consideration.

(2) one of the following conditions, if severe or chronic pain, severe nausea or vomiting, cachexia, or wasting syndrome results from the condition or treatment thereof: positive status for human immunodeficiency virus; acquired immune deficiency syndrome; or cancer;

(3) amyotrophic lateral sclerosis, multiple sclerosis, terminal cancer, muscular dystrophy, or inflammatory bowel disease, including Crohn's disease; [or]

(4) terminal illness, if the physician has determined a prognosis of less than 12 months of life.

[N.J.S.A. 24:6I-3.]

In addition to the conditions listed in the Act, the Legislature authorized the Department to establish additional medical conditions as debilitating under the MMP. Ibid. Consistent with its statutory authority, the Department promulgated rules that outline the process for expanding the list of medical conditions that qualify as "debilitating" under the MMP. See N.J.A.C. 8:64-1.1 et seq. Pursuant to these rules, I am required to take into consideration the following factors in order to determine whether a condition should be added to the MMP as a "debilitating" medical condition that is likely to benefit from the use of medical marijuana to treat or alleviate the debilitating effect of the condition:

(1) The extent to which the condition is generally accepted by the medical community and other experts as a valid, existing medical condition;

(2) If one or more treatments of the condition, rather than the condition itself, are alleged to be the cause of the patient's suffering, the extent to which the treatments causing suffering are generally accepted by the medical community and other experts as valid treatments for the condition;

(3) The extent to which the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living;

(4) The availability of conventional medical therapies other than those that cause suffering to alleviate suffering caused by the condition and/or the treatment thereof;

(5) The extent to which evidence that is generally accepted among the medical community and other experts supports a finding that the use of marijuana alleviates suffering caused by the condition and/or the treatment thereof; and

(6) Letters of support from physicians or other licensed health care professionals knowledgeable about the condition.

[N.J.A.C. 8:64-5.3]

The MMP Review Panel Meetings, Public Comments and Panel Recommendations

On May 11, 2017, the MMP Review Panel, which is a panel assembled by the Department to review and make recommendations on petitions seeking to add conditions to the MMP, met to

review and hear public comments on the forty-five accepted petitions. At the meeting, the Panel acknowledged that they reviewed the material submitted with the petitions and that they also conducted their own independent analysis and research for each condition. During the meeting, the Panel also advised that it grouped the petitioned conditions into seven categories, namely chronic pain related to musculoskeletal disorders, chronic pain of a visceral origin, Tourette's Syndrome, migraine, anxiety, asthma and chronic fatigue. After offering a panel discussion on each condition and hearing public comments from two individuals, both of whom expressed support for the MMP, the Panel voted on each petition. Based upon a majority vote of the members who were present at the meeting, the Panel recommended that chronic pain related to musculoskeletal disorders, chronic pain of a visceral origin, Tourette's Syndrome, migraine, and anxiety be approved as debilitating conditions under the MMP and recommended denial of asthma and chronic fatigue.

After the meeting, the Chairman of the Panel reduced the Panel's initial recommendations to writing and submitted it to the Department's Commissioner for consideration. In the initial recommendation letter, the Panel advised that it was recommending that the Commissioner add chronic pain related to musculoskeletal disorders, chronic pain of a visceral origin, Tourette's Syndrome, migraine, and anxiety to the MMP because these conditions are debilitating and medicinal marijuana was more likely than not to have the potential to be beneficial to treat or alleviate the debilitation associated with each condition.

As for asthma and chronic fatigue, the Panel recommended that these conditions not be added to the MMP because medical marijuana was not likely to have the potential to be beneficial to treat or alleviate the debilitation associated with the conditions.

After receiving the Panel's initial recommendation letter, it was posted on the Department's website for a 60-day public comment period to provide the public with an opportunity to submit written comments on the recommendations. At the time the comment period closed, the Department received approximately sixty comments, which were generally supportive of the MMP.

During the 60-day comment period, the Department's MMP Review Panel also convened a public hearing on September 18, 2017, which provided the public with an additional opportunity to comment on the recommendations. During this public hearing, the Panel heard from seven individuals. The comments provided by the commenters did not express any disagreement with the Panel's recommendations.

Upon the conclusion of the public comment period, the Panel reconvened for a final meeting on the petitions. At the meeting, which was held on October 26, 2017, the Panel further deliberated its recommendations on the petitioned conditions, taking into consideration the petitions, information submitted with the petitions, public comments, the factors outlined in N.J.A.C. 8:64-5.3, each member's own research or that done by others, as well as each member's education and training, in order to determine whether any changes should be made to the Panel's initial recommendations. In so deliberating, the Panel discussed each condition in turn and permitted additional public comment on the conditions. Based upon the Panel's extensive and thorough discussions, the majority of the Panel members present at the meeting voted to uphold their initial recommendations on the conditions. As such, the Panel's initial recommendations converted to the Panel's final recommendations to the Commissioner, pursuant to N.J.A.C. 8:64-5.3(f).

Findings and Decisions on the Petitions

For the reasons that follow, I am granting the petitions seeking to add chronic pain that is related to musculoskeletal disorders, chronic pain conditions that are of a visceral origin, as well as Tourette's Syndrome, migraine, and anxiety as debilitating medical conditions under the MMP and denying the petitions seeking to include asthma and chronic fatigue syndrome under the MMP. My decision is consistent with the Panel's recommendations. In reaching my decision, I considered the statutory and regulatory criteria articulated above, the Panel's recommendations and their supporting materials, the petitions with supporting information, public comments and the transcripts of the Panel's meetings, which provides the Panel members' detailed discussions on each condition.

Granted Petitions

Chronic Pain associated with a Musculoskeletal Disorder

Based upon my independent review of the petitions, I am granting those seeking to add chronic pain associated with a musculoskeletal disorder to the MMP.² In coming to this conclusion, I reviewed this condition against the six regulatory criteria cited above and found that it meets the requirements for inclusion in the MMP.

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that chronic pain associated with a musculoskeletal disorder is a valid condition. According to the U.S. Department of Health and Human Services, Centers for Disease Control and Prevention's National Center for Health Statistics (NCHS), chronic pain associated with a musculoskeletal disorder is pain that persists beyond the usual course of an acute condition, which is typically three months or more or past the time for normal healing, and includes injury and inflammatory conditions "that cause pain in the body's joints; ligaments; muscles; nerves; tendons; and structures that support the limbs, neck, and back."³ Moreover, as noted by the Panel, the World Health Organization's International Classification of Diseases, as clinically modified by the NCHS (ICD-10-CM), uses unique alphanumeric codes to identify known diseases and other health problems and lists multiple codes for chronic pain.⁴ Given the fact that chronic pain associated with a musculoskeletal disorder has a common medical definition and maintains several ICD-10-CM codes, which entities covered by the Health Insurance Portability and Accountability Act must use for processing claims pursuant to rules promulgated by the U.S. Department of Health and Human Services, I find that chronic pain associated with a musculoskeletal disorder is a valid condition recognized by the medical community. See 45 C.F.R. 162.

² Thirty-five of the petitions received by the Department concern various forms of chronic pain. After reviewing these petitions, the Panel determined that they fell into two categories: chronic pain associated with a musculoskeletal disorder and chronic pain of a visceral origin. Based upon my review of this matter, I find that the Panel made the appropriate categorizations of these petitions. Thus, I agree with the Panel that the chronic pain conditions sought to be added to the MMP should be generally labeled as chronic pain associated with a musculoskeletal disorder and chronic pain of a visceral origin, rather than the unique, individual conditions set forth in each chronic pain petition. The list of petitions that fall into each category are set forth in the Panel's recommendation letter, which is incorporated herein by reference.

³See <https://www.cdc.gov/nchs/data/nhsr/nhsr098.pdf> (last visited March 13, 2018). See also <https://www.cdc.gov/drugoverdose/prescribing/guideline.html> (last visited March 13, 2018).

⁴ See ftp://ftp.cdc.gov/pub/Health_Statistics/NCHS/Publications/ICD10CM/2018/ (last visited March 13, 2018).

Under the second factor, I must consider whether the treatments for the condition, if the treatments are causing the patient suffering, are generally accepted by the medical community and other experts as valid treatments for the condition. As set forth in the petitions and acknowledged by the Panel, the generally accepted treatments for chronic pain associated with a musculoskeletal disorder are opioids and non-steroid anti-inflammatory drugs (NSAIDs), both of which can have significant side effects. I agree. According to the Centers for Disease Control and Prevention (CDC), NSAIDs, such as ibuprofen, are a common treatment for chronic pain associated with a musculoskeletal disorder.⁵ The CDC also recognizes opioids, such as oxycodone and hydrocodone, as a common and medically accepted treatment for chronic musculoskeletal pain.⁶ Thus, I find that the treatments for chronic pain, namely NSAIDs and opioids, are recognized and accepted by the medical community and relate to a patient's suffering.

As for the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that chronic pain associated with a musculoskeletal disorder itself as well as the treatment for this condition cause severe suffering for patients inflicted with this condition. As the name suggests, a patient with chronic pain associated with a musculoskeletal disorder experiences just that - pain. Specifically, musculoskeletal chronic pain can cause widespread or localized pain that may worsen with movement, stiffness or achiness, fatigue, and/or muscle twitches.⁷ Thus, the condition itself is the main culprit for the suffering experienced by patients with this disorder. While chronic pain, in and of itself, causes extensive pain, the treatment for chronic pain associated with a musculoskeletal disorder can also cause significant suffering. Specifically, prolonged use of NSAIDs can cause gastritis, ulcerative disease, heartburn, nausea, vomiting and dizziness⁸. And, opioids can cause constipation, nausea, respiratory depression, dependency, sedation and dizziness.⁹ All of these side effects can prevent a patient from engaging in activities of daily living, thereby diminishing one's quality of life. Accordingly, I find that musculoskeletal chronic pain as well as the therapies to treat this condition cause severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. Unfortunately, the treatments for chronic musculoskeletal pain that cause the patient suffering, namely NSAIDs and opioids, are essentially the most viable conventional medical therapies offered for this condition, which was noted by the Panel. As such, I find that there is an absence of effective alternative medical therapies to the conventional therapies currently prescribed for chronic musculoskeletal pain that cause patients to suffer.

Regarding the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I agree with the Panel's conclusion that there is extensive research establishing that the use of medical

⁹ See Footnote 6.

cannabis can relieve the chronic pain associated with a musculoskeletal disorder. Specifically, there are several peer-reviewed publications in leading medical journals, including a review published by the National Academies of Sciences, Engineering, and Medicine in 2017, as well as a significant number of clinical trials, which found that the use of medical marijuana was effective in relieving chronic pain.¹⁰ As such, I find that there is general acceptance in the medical community that medicinal cannabis can alleviate the suffering caused by chronic musculoskeletal pain.

As for the final factor, which is whether there were letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of chronic musculoskeletal pain under the MMP, I find that the petitions were submitted with support from medical professionals.

Based upon the above analysis, I find that the condition of chronic pain related to a musculoskeletal disorder is “debilitating” and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the debilitating effect of this condition. As such, I find that chronic pain related to a musculoskeletal disorder should be added to the MMP.

Chronic Pain Conditions of a Visceral Origin

From my detailed review of the petitions, I am granting those seeking to add chronic pain conditions of a visceral origin to the MMP. In coming to this conclusion, I reviewed the petitions against the six regulatory criteria cited above and found that the condition meets the requirements for inclusion in the MMP.

For the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that chronic pain of a visceral origin is a valid condition. Chronic pain of a visceral origin is commonly defined by the medical community as pain that arises from the internal organs of the body and persists beyond the usual course of an acute condition, which is typically three months or more or past the time for normal healing.¹¹ Specifically, visceral pain is pain that results from the activation of nociceptors located in most viscera (internal organs of the body, specifically those within the chest (as the heart or lungs) or abdomen (as the liver, pancreas or intestines)) and the surrounding connective tissue.¹² Moreover, as noted by the Panel, there are multiple ICD-10-CM codes for chronic pain of a visceral origin, such as codes for pancreatitis, pain related to neurogenic bladder and bowel dysfunction, and irritable bowel syndrome. Because there is a common medical definition for chronic visceral pain as well as many ICD-10-CM codes for this condition, I find that chronic pain of a visceral origin is a valid and recognized medical condition.

As for the second factor, I must consider whether the treatments for the condition, if the treatments are causing the patient suffering, are generally accepted by the medical community

¹⁰ See, e.g., The Health Effects of Cannabis and Cannabinoids: the Current State of Evidence and Recommendations for Research, National Academies Press (2017) (<http://nationalacademies.org/hmd/Reports/2017/health-effects-of-cannabis-and-cannabinoids.aspx>) (last visited March 13, 2018); Cannabinoids for treatment of chronic non-cancer pain; a systematic review of randomized trials, British Journal of Clinical Pharmacology (2001) (<https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3243008/>) (last visited March 13, 2018).

¹¹ See <https://medical-dictionary.thefreedictionary.com/visceral+pain> (last visited March 13, 2018).

¹² See <https://www.merckmanuals.com/professional/neurologic-disorders/pain/overview-of-pain> (last visited March 13, 2018).

and other experts as valid treatments for the condition. Like chronic musculoskeletal pain, chronic pain of a visceral origin is generally treated with opioids and NSAIDs, which, as I stated above, can have severe side effects. Indeed, the CDC advises that NSAIDs and opioids are the most common forms of treatment for chronic pain.¹³ Thus, I find that the treatments for chronic pain, namely NSAIDs and opioids, are recognized and accepted by the medical community as the treatments for chronic visceral pain and relate to a patient's suffering.

Regarding the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that both the chronic pain condition itself as well as the treatments for this condition cause severe suffering for patients stuck with this disorder. Specifically, visceral pain due to an obstruction of a hollow organ is poorly localized, deep, and cramping and may be referred to remote cutaneous sites.¹⁴ Visceral pain that is caused by an injury of organ capsules or other deep connective tissues may be more localized and sharp.¹⁵ As such, the actual condition is the main cause for the suffering experienced by patients with this disorder. Although chronic pain itself causes severe pain, the treatment for this condition can also result in significant suffering. As I outlined above, prolonged use of NSAIDs can cause gastritis, ulcerative disease, heartburn, nausea, vomiting and dizziness. And, opioids can cause constipation, nausea, respiratory depression, dependency, sedation and dizziness. So, the condition itself as well as the side effects from the medications used to treat this condition can prevent a patient from engaging in activities of daily living and eviscerate one's quality of life. Accordingly, I find that both the condition of chronic pain as well as the therapies to treat it cause severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. Unfortunately, the treatments for chronic pain that cause the patient suffering, which are NSAIDs and opioids, are the only viable conventional medical therapies offered for this condition.¹⁶ Therefore, I find that there is a lack of medically-accepted, alternative medical treatments to the conventional therapies currently recommended for chronic pain of this nature.

As for the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, the Panel concluded that there is comprehensive research demonstrating that the use of medicinal cannabis can alleviate the pain associated with chronic pain. As stated above, there are peer-reviewed publications in leading medical journals, including a review published by the National Academies of Sciences, Engineering, and Medicine in 2017, and a number of clinical trials that found that the use of medical marijuana was effective in relieving chronic pain. As such, I find that the medical community has generally accepted the use of medicinal marijuana as a likely effective treatment for alleviating the suffering caused by chronic pain.

As for the final factor, which is whether there were letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of chronic

¹⁵ Ibid.

¹⁶ Ibid.

visceral pain under the MMP, I find that the petitions were submitted with support from medical professionals.

Based upon the above analysis, I find that the condition of chronic pain of a visceral origin is “debilitating” and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the debilitating effect of this condition. As such, I find that chronic pain of a visceral origin should be added to the MMP.

Tourette’s Syndrome

After a careful review of the petition seeking to add Tourette’s Syndrome (TS) to the MMP, I have decided to grant this petition. In formulating this determination, I reviewed the condition against the six regulatory criteria cited above and found that it meets the requirements for inclusion in the MMP.

Under the first factor, I must determine whether the condition is generally accepted in the medical community as a valid medical condition. I find that TS meets this requirement. Specifically, TS is commonly defined by the medical community as a neurological disorder characterized by repeated involuntary movements (motor tics) and uncontrollable vocal sounds (vocal tics), with symptoms usually manifesting before the age of eighteen.¹⁷ Moreover, a CDC study found that “1 of every 360 (0.3%) children 6 – 17 years of age in the United States have been diagnosed with TS based on parent[al] report[s],” with boys being “three to five times more likely to have TS than girls.”¹⁸ Accordingly, I find that TS is a valid and recognized medical condition.

Regarding the second factor, I must consider whether the treatments for the condition, rather than the condition itself, are causing the patient’s suffering and the extent to which the treatments causing the patient suffering are generally accepted by the medical community and other experts as valid treatments for the condition. According to the petition and as acknowledged by the Panel, the generally accepted treatments for TS are medication and behavioral treatments, which can help manage the tics.¹⁹ As noted by the Panel, there is no one primary medication to treat TS and, as a result, there is a varying approach to how it is addressed.²⁰ Most medications prescribed for TS have not been approved by the U.S. Food and Drug Administration (FDA) for treating tics and the medications that are approved fall into the category of anti-psychotics, which can have serious adverse side effects that include weight gain, stiff muscles, tiredness, restlessness, and social withdrawal.²¹ As such, I find that the treatments for the symptoms of TS are recognized and accepted by the medical community as the treatments for this condition and relate to a patient’s suffering.

As for the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient’s ability to carry on activities of daily living, I find that both TS itself as well as co-occurring conditions and the treatments for this condition cause severe

²⁰ In Re: Medicinal Marijuana Review Panel Transcript. 55: 4 -6. October 25, 2017.

²¹ See footnote 19.

suffering for patients inflicted with this condition. While the tics caused by TS clearly impair a patient's ability to carry on his or her activities of daily living, the co-occurring conditions that arise with this disorder can be equally if not more devastating to the patient. According to the National Institute of Neurological Disorders and Stroke, many individuals with TS experience additional neurobehavioral problems that often cause more impairment than the tics themselves. These include inattention, hyperactivity and impulsivity (attention deficit hyperactivity disorder — ADHD), problems with reading, writing, and arithmetic, and obsessive-compulsive symptoms such as intrusive thoughts/worries and repetitive behaviors.²² Thus, TS itself along with its co-occurring conditions negatively impact a patient's quality of life. Additionally, as I noted above, the pharmacological treatments for TS can cause serious side effects that negatively impact an individual's quality of life. As recognized by the Panel, TS is difficult to treat and very debilitating.²³ I concur. As such, I find that both the condition of TS as well as the therapies to treat it cause severe suffering.

Under the fourth factor, I must analyze the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. Unfortunately, the only FDA-approved therapies for TS are anti-psychotic medications. While these medications have an 80% rate of tic suppression, which was noted by the Panel, the medications have serious side effects that can include weight gain and social withdraw. And, although behavioral therapy is a treatment that teaches people with TS ways to manage their tics, it is not a cure for tics. As such, the conventional therapies for TS, which are pharmaceutical and behavioral treatment, may not fully suppress or manage tics and the presence of TS may severely impair the patient's ability to carry on activities of daily living. Accordingly, I find that there is a lack of medically-accepted, alternative medical therapies to the conventional therapies currently prescribed for TS that cause suffering for some patients.

Regarding the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I agree with the Panel's conclusion that there is research establishing that the use of medical cannabis can relieve the symptoms associated with TS. Evidence on the use of cannabis for effective symptomatic treatment of movement disorders, including TS, dates to the late 1990s with the work of Dr. Kirsten Müller-Vahl of the Hannover Medical School in Hannover, Germany.²⁴ Dr. Müller-Vahl's studies demonstrated improvements in global functioning and tic severity scores with cannabis use. Specifically, Dr. Müller-Vahl conducted a clinical survey among sixty-four TS patients of whom seventeen had reportedly consumed cannabis and approximately 82% of these patients reported a reduction in symptoms.²⁵ Subsequent studies of single cases confirmed that administration of 10mg of tetrahydrocannabinol (THC), which is one of the active chemical compounds in cannabis, led to an 80% reduction in tics and a simultaneous increase in the attention of patients.²⁶ And, a randomized, placebo-controlled six-week trial of up to 10mg THC

²⁶ *Ibid.*

per day confirmed the previous findings.²⁷ Furthermore, case reports have suggested that cannabis can reduce tics and that the therapeutic effects of cannabis might be due to the anxiety-reducing properties of marijuana rather than to a specific anti-tic effect.²⁸ Moreover, several states, such as Minnesota and Illinois, have approved medical marijuana specifically for the treatment of TS. Even more, a recent systematic review and meta-analysis published in the Journal of the American Medical Association (JAMA) in 2015 suggests there is some evidence that cannabinoids may improve symptoms of TS.²⁹ While the 2015 JAMA review suggests that marijuana may only have a minimal effect on relieving the symptoms of TS, the fact that the study evidenced some relief, even with the limited number of clinical trials available on the medical benefits of marijuana due to the legal restrictions surrounding cannabis, shows promise that marijuana is effective for this condition. As such, I find that the totality of the above research exhibits a general consensus in the medical community that marijuana is likely to alleviate some of the suffering caused by TS.

As for the final factor, which is whether there were letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of TS under the MMP, I find that the petition was submitted with support from medical professionals.

Based upon the above analysis, I find that the condition of TS is “debilitating” and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the debilitating effect of this condition. As such, I find that Tourette’s Syndrome should be added to the MMP.

Migraine

After a thorough review of the petitions, I am granting those seeking to add migraine to the MMP. In coming to this conclusion, I reviewed these petitions against the six regulatory criteria cited above and found that the condition meets the requirements for inclusion in the MMP.

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that migraine meets this criteria. According to the Merck Manual, migraine is an episodic primary headache disorder.³⁰ Symptoms typically last four to seventy-two hours and may be severe.³¹ Pain is often unilateral, throbbing, worsen with exertion, and accompanied by symptoms such as nausea and sensitivity to light, sound, or odors. Auras occur in about 25% of patients, usually just before but sometimes after the headache.³² And, there are approximately 28 million individuals living with migraines in the United States.³³ As such, I find that migraine is a valid and recognized medical condition.

Under the second factor, I must consider whether the treatments for the condition, rather than the condition itself, are causing the patient’s suffering and the extent to which the treatments

³¹ ibid.

³² ibid.

³³ <https://www.hopkinsmedicine.org/otolaryngology/docs/Migraine%20patient%20handout.pdf> (last visited March 13, 2018).

causing the patient suffering are generally accepted by the medical community and other experts as valid treatments for the condition. As stated in the petitions and recognized by the Panel, the generally accepted treatments for migraines are NSAIDs, triptans, opioids and/or ergots (ergot alkaloids), all of which can have significant side effects.³⁴ Specifically, prolonged use of NSAIDs can cause gastritis, ulcerative disease, heartburn, nausea, vomiting and dizziness.³⁵ Side effects of triptans include nausea, dizziness, drowsiness and muscle weakness.³⁶ Furthermore, triptans should not be used by those who have a past history of, or risk factors, for heart disease, high blood pressure, high cholesterol, angina, peripheral vascular disease, impaired liver function, stroke or diabetes.³⁷ Ergots may worsen nausea and vomiting related to migraines, and it may also lead to medication-overuse headaches.³⁸ And, as outlined above, opioids have serious side effects including addiction and nausea.³⁹ Thus, I find that the treatments for migraine, namely NSAIDs, triptans, opioids and ergots, can cause a patient to suffer and are accepted by the medical community as the treatments for this condition.

As for the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that both the migraine condition itself as well as the treatments for this condition cause severe suffering for patients. As stated above, the condition itself causes intense pain, nausea and sensitivity to light, sound, or odors. In fact, the pain and sensitivity may become so intense that the patient may have no other option than to rest in a dark, quiet room until the migraine passes.⁴⁰ Thus, the migraine condition causes severe suffering.

The same holds true for migraine treatments. The side effects caused by the treatments for migraines can be equally if not worse than the symptoms produced by this condition. Specifically, the treatments, which include opioids and triptans, can cause nausea, dizziness, and muscle weakness and may even cause rebound symptoms that are more intense than the original onset of the migraine.⁴¹ Thus, the migraine condition as well as side effects accompanying the treatment for this condition impair or even prevent a patient from engaging in activities of daily living, thereby diminishing one's quality of life. With this, I find not only that the migraine condition in and of itself causes a patient severe suffering but that the therapies to treat it also cause significant suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. The treatments for migraine that cause the patient suffering, namely

³⁴ <https://www.hopkinsmedicine.org/otolaryngology/docs/Migraine%20patient%20handout.pdf> (last visited March 13, 2018). See also <https://www.mayoclinic.org/diseases-conditions/migraine-headache/diagnosis-treatment/drc-20360207> (last visited March 13, 2018).

⁴⁰ <https://www.hopkinsmedicine.org/otolaryngology/docs/Migraine%20patient%20handout.pdf> (last visited March 13, 2018).

⁴¹ *Ibid.*

NSAIDs, triptans, opioids and ergots, are the conventional medical therapies offered for this condition. Furthermore, as noted by the Panel, the conventional therapies are ineffective for some patients, leaving them with a decreased ability to function and a decreased quality of life. Alternatives such as biofeedback, ice packs, acupressure, aromatherapy, adequate sleep, smoking cessation, avoiding any food and environmental triggers are available and may alleviate migraine symptoms.⁴² However, these alternative treatments usually do not treat all of the symptoms associated with a migraine and do not necessarily alleviate the patient's suffering caused by the migraine. Therefore, patients that are not responsive to conventional or alternative therapies may suffer constant unrelenting pain, which produces mental and physical debilitation. As such, I find that there are serious limitations with the medically-accepted, alternative medical therapies and the conventional therapies currently prescribed for migraine.

Regarding the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I agree with the Panel's conclusion that there is extensive research establishing that the use of medical cannabis can relieve the pain associated with migraine. There are studies which found that the use of medical marijuana was effective in decreasing the frequency of migraine headaches and relieving migraine pain.⁴³ Most notably, a recent study recommended that prospective studies should be conducted to explore a cause-and-effect relationship and the use of different strains, formulations, and doses of marijuana to better understand the effects of medical marijuana on migraine headache treatment and prophylaxis.⁴⁴ A majority of the Panel agreed that a review of the literature suggests that marijuana might alleviate some of the symptoms caused by a migraine with less side effects than commonly accepted medical treatment. Based upon this research, I find that there is generally accepted evidence in the medical community that medicinal cannabis can alleviate the suffering caused by migraine.

As for the final factor, which is whether there were letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of migraine under the MMP, I find that the petitions were submitted with support from physicians and an advanced practice nurse. Indeed, one petition was submitted by a board certified anesthesiologist. Thus, I find that this requirement is met.

Based upon the above analysis, I find that the condition of migraine is "debilitating" and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the debilitating effect of this condition. As such, I find that migraine should be added to the MMP.

Anxiety

Based upon my independent review of the petitions, I am granting those seeking to add anxiety to the MMP. In coming to this conclusion, I reviewed these petitions against the six regulatory criteria cited above and found that the condition meets the requirements for inclusion in the MMP.

⁴² *Ibid.* See also <https://migraine.com/complimentary-and-alternative-therapies/> (last visited March 13, 2018).

⁴³ Ethan B. Russo, Clinical Endocannabinoid Deficiency Reconsidered: Current Research Supports the Theory in Migraine, Fibromyalgia, Irritable Bowel, and Other Treatment-Resistant Syndromes, *Cannabis and Cannabinoid Research*, 20a6, 1,1, 154. See <https://www.liebertpub.com/doi/10.1089/can.2016.0009> (last visited March 13, 2018).

⁴⁴ See <https://www.ncbi.nlm.nih.gov/pubmed/26749285> (last visited March 13, 2018).

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that anxiety satisfies this criteria. Specifically, the American Psychiatric Association defines anxiety and anxiety disorders as conditions characterized by excessive fear and behavioral disturbances.⁴⁵ Anxiety results from anticipation of a future threat and may be associated with symptoms of muscle tension, vigilance in preparation for future danger, and overly cautious or avoidant behaviors.⁴⁶ Additionally, there are multiple ICD-10-CM codes for anxiety disorders.⁴⁷ Because anxiety maintains a common definition in the medical community and has ICD-10-CM codes, I find that anxiety is a valid and recognized medical condition.

Under the second factor, I must consider whether the treatments for the condition, rather than the condition itself, are causing the patient's suffering and the extent to which the treatments causing the patient suffering are generally accepted by the medical community and other experts as valid treatments for the condition. From my review of this condition, the generally accepted treatments for anxiety are dependent on the symptoms and the severity of the particular disorder. Mild and moderate forms of anxiety may not require a pharmacologic intervention, but may necessitate other forms of treatment, such as meditation, mindfulness, breathing techniques as well as psychotherapy (counseling) or cognitive therapy.⁴⁸ The most common classes of medications used to combat anxiety disorders are antidepressants, anti-anxiety drugs, and beta-blockers.⁴⁹ Antidepressants are safe and effective but they may be risky for children, teens, and young adults.⁵⁰ Antidepressants also come with a "black box" warning – the FDA's strongest warning - advising that some people may have suicidal thoughts or make suicide attempts while taking the medication.⁵¹ The most common anti-anxiety medications are called benzodiazepines. As noted by the Panel, the common side effects of benzodiazepines include headache, confusion, tiredness, and in some cases nightmares and memory impairments.⁵² And, benzodiazepines carry a risk of dependence and addiction.⁵³ Furthermore, the FDA notes that the number of patients who were prescribed both an opioid analgesic and benzodiazepine increased by 41% between 2002 and 2014.⁵⁴ As a result, the FDA requires black box warnings and patient-focused Medication Guides for prescription opioid analgesics, opioid-containing cough products, and benzodiazepines to inform the patient about the serious risks associated with using these medications at the same time.⁵⁵ Thus, I find that the treatments for anxiety are recognized and accepted by the medical community as the treatments for this condition and relate to the suffering of the patient.

⁵⁵ Ibid.

As for the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that both the anxiety condition itself as well as the treatments for this condition cause severe suffering for patients. Specifically, anxiety may lead to problems that negatively impact an individual's activities of daily living and quality of life and may lead to suicide and depression. Anxiety disorders can also cause significant distress or interfere with social, occupational, and other areas of functioning. In fact, an estimated 31.1% of U.S. adults experience an anxiety disorder at some time in their lives.⁵⁶ Medications, in some instances, may exacerbate the symptoms and are associated with debilitating side effects that can prevent a patient from engaging in activities of daily living, thereby diminishing one's quality of life. Accordingly, I find that both the condition of anxiety as well as the therapies to treat it cause severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. As discussed above, mild and moderate forms of anxiety may be treated with meditation, mindfulness, breathing techniques as well as counseling or cognitive therapy that can be effective. Progression to medication therapy may be initiated; however, in both instances, one must consider the therapeutic response. Failure to respond to therapies or side effects associated with treatments may result in significant impacts on quality of life. As such, I find that there is an absence of medically-accepted, alternative medical therapies to the conventional therapies currently prescribed for migraine that cause suffering.

Regarding the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I find that cannabis is generally accepted as an effective treatment for anxiety. The Panel discussed medical evidence that cannabis may exacerbate anxiety symptoms or that an effect related to cannabis may be associated with anxiety, such as dependence and cravings. Literature suggests that individuals with anxiety sensitivity may be more likely to turn to cannabis as a mechanism for coping with stress, which may in turn lead to problematic use behaviors.⁵⁷ However, the Panel further discussed a review published by the National Academies of Sciences, Engineering, and Medicine in 2017, which found that there is limited evidence that cannabidiol is an effective treatment for the improvement of anxiety symptoms, which was assessed by a public speaking test utilizing individuals with social anxiety disorders.⁵⁸ On balance, the Panel recommended adding anxiety as an allowable condition under the MMP as research suggests that it could be helpful to some patients with this condition. I agree. While marijuana may not be effective for all anxiety sufferers, there is research evidencing that it may be helpful to some, especially those with social anxiety disorders. Thus, I find that there is acceptance in the medical community that marijuana is likely to relieve the suffering associated with some anxiety conditions. However, like any medical condition, the use of medical marijuana to treat anxiety must be explored by the

⁵⁷ Anxiety Sensitivity and Distress Intolerance as Predictors of Cannabis Dependence Symptoms, Problems, and Craving: The Mediating Role of Coping Motives. Farris SG, Metrik J, Bonn-Miller MO, Kahler CW, Zvolensky MJ. *J Stud Alcohol Drugs*. 2016 Nov;77(6):889-897.

⁵⁸ The Health Effects of Cannabis and Cannabinoids: the Current State of Evidence and Recommendations for Research, National Academies Press (2017); Cannabinoids for treatment of chronic non-cancer pain; a systematic review of randomized trials, *British Journal of Clinical Pharmacology* (2001).

medical professional treating the patient to determine whether it is the best and most appropriate course of treatment for the patient.

As for the final factor, which is whether there were letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of anxiety under the MMP, I find that the petitions were submitted with support from medical professionals.

Based upon the above analysis, I find that the condition of anxiety is “debilitating” and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the debilitating effect of this condition. As such, I find that anxiety should be added to the MMP.

Denied Petitions

Asthma

After carefully reviewing the petition seeking to include asthma as a debilitating condition under the MMP, and in accordance with the Panel’s recommendation, I am denying the request. In coming to this conclusion, I reviewed the petition against the six regulatory factors cited above and found that the condition fails to meet the requirements for inclusion in the MMP.

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that asthma meets this requirement. The CDC defines asthma as a chronic lung disease⁵⁹ that “causes repeated episodes of wheezing, breathlessness, chest tightness, and nighttime or early morning coughing.”⁶⁰ Moreover, the Department recognizes asthma as a chronic medical condition with approximately 600,000 adults and 167,000 children suffering from this condition in New Jersey.⁶¹ Thus, I find that asthma is generally accepted by the medical community as a valid medical condition.

Under the second factor, I must consider whether the treatments for the condition, if the treatments are causing the patient suffering, are generally accepted by the medical community and other experts as valid treatments for the condition. In the petition, the petitioner asserts that the use of albuterol to treat asthma causes an individual to experience an increased heart rate and shakiness and that the use of corticosteroids to treat asthma can cause the patient to become addicted to the drug. While corticosteroids and bronchodilators, such as albuterol, are generally accepted treatments for asthma, I do not find that the average patient suffers from the use of these medications. As stated by the Panel, there are several treatments for asthma that are not only effective but also provide minimal side effects. Specifically, asthma is generally treated with inhaled, oral and intravenous corticosteroids and bronchodilators.⁶² Common side effects associated with the use of corticosteroids include acne, weight gain and upset stomach.⁶³ However, these side effects rarely occur with the short-term use of these medications, such as when they are used for acute asthma episodes.⁶⁴ While the use of corticosteroids is accepted

⁶⁴ Ibid.

by the medical community as valid treatments for asthma, I do not find that these treatments cause the vast majority of patients to experience suffering from their use.

The same holds true for bronchodilators. While bronchodilators can cause nervousness or shakiness, headache, throat or nasal irritation, muscle aches and, in rare instances, a rapid heart rate or heart palpitations, these side effects can be greatly reduced and even eliminated by changing the delivery method of the medication and/or reducing the dosage.⁶⁵ Although these side effects could potentially cause a patient to suffer, they can be effectively decreased and even eliminated through medication management. As such, I find that the treatments for asthma do not cause an average asthma patient to experience suffering.

As for the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that asthma can cause severe suffering. Specifically, when asthma is not well-controlled, it can severely impair a patient's ability to engage in his or her activities of daily living, such as limiting the patient's physical activity, cause sleep disturbances and can even result in death. Accordingly, I find that asthma can cause a patient to experience severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. While asthma cannot be cured, it can be well-controlled with self-management education, adequate pharmacological management, and avoidance of exposure to environmental triggers.⁶⁶ Specifically, asthma is commonly and effectively treated with bronchodilators and corticosteroids, which are widely available to patients and have little side effects.⁶⁷ Thus, I find that the conventional medical treatments for asthma are effective and easily attainable by patients.

Regarding the fifth factor, which whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I agree with the Panel's conclusion that there are no reliable clinical trials or research supporting the proposition that medical cannabis is an effective treatment for asthma. While the petitioner points to a study published in the New England Journal of Medicine in 1973, which suggests that marijuana dilates the airway for a short period of time, the study did not evaluate the effect marijuana has on patients suffering from asthma. In fact, the study utilized thirty-two male subjects with no serious medical conditions and advised that "further investigation is required to determine . . . the effects of marijuana smoking and oral THC on the airway of asthmatic subjects." As such, I find that this study does not support the proposition that marijuana is an effective treatment for asthma.

Even more, physicians with the American Thoracic Society recently published an article in the American Journal of Respiratory and Critical Care Medicine advising that marijuana can worsen existing lung conditions and specifically noted that "marijuana smoke can cause an

⁶⁵ See <https://www.mayoclinic.org/diseases-conditions/asthma-attack/expert-answers/albuterol-side-effects/faq-20058088> (last visited March 13, 2018).

⁶⁶ See <https://www26.state.nj.us/doh-shad/topic/Asthma.html> (last visited March 13, 2018).

⁶⁷ See Footnote 62.

asthma attack leading to hospitalization and even death.⁶⁸ Thus, the medical community appears to be opposed to the use of marijuana as a treatment for asthma. Because the petitioner failed to point to any evidence demonstrating that the medical community accepts medical marijuana as a treatment for asthma, and neither I nor the Panel found any reliable trials or research in support of this, I find that the medical community is not in favor of using medicinal cannabis to alleviate the suffering associated with asthma.

As for the final factor, which is whether there are letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of asthma under the MMP, I find that the petition only referenced the 1973 New England Journal of Medicine article and did not include any letters of support from healthcare professionals. While the journal article was authored by three physicians, I do not find that this lone article from 1973 on the general effects of marijuana on the airway constitutes support from a medical professional for the inclusion of asthma to the MMP. Additionally, there were no public comments from medical professionals supporting the inclusion of asthma under the MMP. Thus, I find that there is a lack of support from physicians or other health care professionals for this condition to be added to the MMP.

Based upon the foregoing, I find that asthma can be debilitating if uncontrolled, but that marijuana is not likely to be a beneficial treatment for this condition or alleviate the debilitating effect of this condition. Indeed, as noted by the Panel, inhalation of smoke is a known trigger for asthma exacerbation and, as a result, smoking marijuana may actually increase the suffering of asthma patients rather than alleviate the suffering associated with this condition⁶⁹. And, while I acknowledge that medicinal marijuana is available in non-smokable forms, I am not convinced that there is credible support for its use in treating asthma. Unless and until there is sufficient research and evidence demonstrating that the use of marijuana can be beneficial for an asthma patient, I find that asthma should not be added to the MMP.

Chronic Fatigue Syndrome

From my detailed review of the petition seeking to include chronic fatigue syndrome as a debilitating condition under the MMP, and in accordance with the Panel's recommendation, I have concluded that the petition should be denied. In coming to this conclusion, I reviewed the petition against the six regulatory factors cited above and found that the condition fails to meet the requirements for inclusion in the MMP.

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that chronic fatigue syndrome meets this criteria. According to the CDC, chronic fatigue syndrome, also known as myalgic encephalomyelitis, is a "long-term illness that affects many body systems."⁷⁰ In addition to extreme fatigue, which may worsen with physical or mental activity, but does not improve with rest, an individual with this condition may experience insomnia, depression, joint and muscle pain and memory impairments.⁷¹ In fact, there is an estimated 836,000 to 2.5 million individuals

⁶⁸ Drake MD, Matthew G. and Slatore MD, Christopher G. "Smoking Marijuana and the Lungs." Am. J. Respir. Crit. Care Med., Vol. 195, P5-6 (2017).

⁶⁹ *Ibid.*

⁷⁰ <https://www.cdc.gov/me-cfs/index.html> (last visited March 13, 2018).

⁷¹ <https://www.mayoclinic.org/diseases-conditions/chronic-fatigue-syndrome/symptoms-causes/syc-20360490> (last visited March 13, 2018).

affected with this condition in the United States.⁷² Thus, I find that chronic fatigue syndrome is a valid medical condition.

Under the second factor, I must consider whether the treatments for the condition, if the treatments are causing the patient suffering, are generally accepted by the medical community and other experts as valid treatments for the condition. Unfortunately, there is neither a cure nor an FDA-approved treatment for chronic fatigue syndrome.⁷³ As a result, treatment is largely palliative as the treatment is tailored to relieve the symptoms experienced by each individual patient. For example, a patient experiencing depression as a result of chronic fatigue syndrome could be treated with an anti-depressant and a patient experiencing muscle and joint pain could be prescribed an NSAID to relieve the pain.⁷⁴ Moreover, the symptoms of chronic fatigue are oftentimes treated with nutritional supplements and complementary therapies, such as massage, meditation, tai chi and acupuncture, which may be helpful in increasing the patient's energy level and decreasing his or her pain.⁷⁵ But, these are not treatments for the actual condition but rather treatments for the symptoms associated with the condition. As such, I find that there is no treatment generally accepted in the medical community for this disease that causes suffering.

However, I do find that the above therapies prescribed by healthcare professionals to treat the **symptoms** associated with chronic fatigue syndrome are accepted by the medical community. While I find that the treatments for chronic fatigue symptoms are medically acceptable, the specific treatment prescribed depends on the type and severity of the symptoms presented and can range from anti-depressants and NSAIDs, which can have severe side effects for some patients and thereby cause suffering, to massage therapy and acupuncture, which have little to no side effects. Because there is a vast array of treatment options for chronic fatigue symptoms and no two patients are treated the same, I am unable to conclude that chronic fatigue patients generally suffer from the treatments they receive for their symptoms. However, individuals with severe forms of chronic fatigue syndrome may suffer from the treatments used to alleviate their symptoms.

As for the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that chronic fatigue syndrome can cause severe suffering. Specifically, some individuals suffering from chronic fatigue syndrome can experience severe pain, gross memory loss and even such extreme fatigue that the patient is house-bound or even bed-bound, all of which greatly impacts a patient's ability to engage in activities of daily living and maintain a quality life. Accordingly, I find that chronic fatigue syndrome can cause a patient to experience severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. While chronic fatigue cannot be cured and there is no approved treatment for the condition, there is a wide array of pharmacological therapies available for alleviating the symptoms associated with this condition. Specifically, chronic fatigue symptoms

⁷² Wright Clayton, MD, Ellen, "Beyond Myalgic Encephalomyelitis/Chronic Fatigue Syndrome An IOM Report on Redefining an Illness." JAMA (2015).

⁷³ <https://www.cdc.gov/me-cfs/treatment/index.html> (last visited March 13, 2018).

⁷⁴ <https://www.cdc.gov/me-cfs/index.html> (last visited March 13, 2018).

⁷⁵ Ibid.

can be effectively managed for some patients with NSAIDs, anti-depressants and sleep-aids, depending on the severity and type of symptoms presented. However, depending upon the patient, the pharmacological treatments for chronic pain symptoms may be effective but may also cause the patient to suffer from side effects. Thus, I find that there are available conventional medical therapies to alleviate a chronic fatigue patient's suffering, but those treatments may cause suffering for some patients.

Regarding the fifth factor, whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I agree with the Panel's conclusion that there are no reliable clinical trials or research supporting the proposition that medical cannabis is an effective treatment for chronic fatigue syndrome. While the petitioner points to studies suggesting that medical marijuana can alleviate an individual's pain, which is potentially one symptom a patient inflicted with chronic fatigue syndrome may experience, the studies fail to articulate that marijuana is an effective treatment for the condition of chronic fatigue syndrome as a whole. Because the petitioner failed to point to any evidence demonstrating that the medical community accepts medical marijuana as a treatment for the actual condition of chronic fatigue syndrome, and neither I nor the Panel found any credible clinical evidence in support of this, I find that there is a lack of support in the medical community for the use of medicinal cannabis to alleviate the suffering associated with chronic fatigue syndrome.

As for the final factor, which is whether there are letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of chronic fatigue under the MMP, I find that the petition only referenced the above-mentioned studies reflecting on the effectiveness of medical marijuana to treatment pain and did not include any letters of support from healthcare professionals to have chronic fatigue added to the MMP. Additionally, there was an absence of public comments from medical professionals supporting the inclusion of chronic fatigue under the MMP. Thus, I find that there is a lack of support from physicians or other health care professionals for this condition to be added to the MMP.

Based upon the above analysis, I find that chronic fatigue syndrome can be debilitating for some patients, but that medical marijuana is not likely to be a potentially beneficial treatment for the debilitating effect of this condition or the alleviation of the symptoms associated with this condition. Indeed, as noted by the Panel, this condition has been researched for years and there is yet to be found a solid elucidation of the etiology of this condition or the treatments that are effective for it.⁷⁶ Because there are still so many unknowns with this condition and there is no clinical evidence suggesting that marijuana would be beneficial as a treatment, I find that chronic fatigue syndrome should not be added to the MMP at this time.

Conclusion

Based upon the foregoing, I am adding chronic pain associated with musculoskeletal disorders, chronic pain of a visceral origin, as well as Tourette's Syndrome, migraine, and anxiety to the MMP. However, asthma and chronic fatigue syndrome will not be added to the MMP.

In order to provide patients with relief as soon as possible from the suffering they are experiencing from these debilitating conditions, I am immediately adding chronic pain associated with musculoskeletal disorders, chronic pain of a visceral origin, Tourette's Syndrome, migraine, and anxiety to the MMP in advance of rule promulgation. While I am including these conditions

⁷⁶ <https://www.ncbi.nlm.nih.gov/books/NBK293931/> (last visited March 13, 2018).

under the MMP, please note that this decision is not intended to be a blanket endorsement for every patient inflicted with a condition falling under the MMP to utilize medicinal marijuana as a treatment. As with any condition, the course of treatment must be determined by a medical professional after a thorough evaluation and discussion with the patient regarding the benefits and possible negative effects of the recommended therapy. Accordingly, I encourage patients to discuss the possibility of utilizing medical marijuana as a treatment for their debilitating conditions with the medical professionals treating them. I hope that this decision brings needed relief to those suffering with these conditions.

This is a final agency decision. You have the right to appeal this final agency decision within 45 days to the New Jersey Superior Court, Appellate Division, Richard J. Hughes Justice Complex, P.O. Box 006, Trenton, New Jersey 08625-0006.

Overview – 3

Generalized Anxiety Disorder: When Worry Gets Out of Control – National Institute of Mental Health - 4

Overview

General Anxiety Disorder (GAD) is a mental health disorder that can interfere significantly in a patient's daily life

Generalized anxiety disorder symptoms can vary. They may include:

- Persistent worrying or anxiety about a number of areas that are out of proportion to the impact of the events
- Overthinking plans and solutions to all possible worst-case outcomes
- Perceiving situations and events as threatening, even when they aren't
- Difficulty handling uncertainty
- Indecisiveness and fear of making the wrong decision
- Inability to set aside or let go of a worry
- Inability to relax, feeling restless, and feeling keyed up or on edge
- Difficulty concentrating, or the feeling that your mind "goes blank"

Physical signs and symptoms may include:

- Fatigue
- Trouble sleeping
- Muscle tension or muscle aches
- Trembling, feeling twitchy
- Nervousness or being easily startled
- Sweating
- Nausea, diarrhea or irritable bowel syndrome
- Irritability

Treatments include:

- Psychotherapy including cognitive behavioral therapy
- Medication

GAD is a debilitating disease that is difficult to treat, and it is vital for a patient's quality of life that they're physician have access to all credible treatments, including medical marijuana.

WHAT IS GAD?

Occasional anxiety is a normal part of life. You might worry about things like health, money, or family problems. But people with generalized anxiety disorder (GAD) feel extremely worried or feel nervous about these and other things—even when there is little or no reason to worry about them. People with GAD find it difficult to control their anxiety and stay focused on daily tasks.

The good news is that GAD is treatable. Call your doctor to talk about your symptoms so that you can feel better.

What are the signs and symptoms of GAD?

GAD develops slowly. It often starts during the teen years or young adulthood. People with GAD may:

- Worry very much about everyday things
- Have trouble controlling their worries or feelings of nervousness
- Know that they worry much more than they should
- Feel restless and have trouble relaxing
- Have a hard time concentrating
- Be easily startled
- Have trouble falling asleep or staying asleep
- Feel easily tired or tired all the time
- Have headaches, muscle aches, stomach aches, or unexplained pains
- Have a hard time swallowing
- Tremble or twitch
- Be irritable or feel “on edge”
- Sweat a lot, feel light-headed or out of breath
- Have to go to the bathroom a lot

Children and teens with GAD often worry excessively about:

- Their performance, such as in school or in sports
- Catastrophes, such as earthquakes or war

Adults with GAD are often highly nervous about everyday circumstances, such as:

- Job security or performance
- Health
- Finances
- The health and well-being of their children
- Being late
- Completing household chores and other responsibilities

Both children and adults with GAD may experience physical symptoms that make it hard to function and that interfere with daily life.

Symptoms may get better or worse at different times, and they are often worse during times of stress, such as with a physical illness, during exams at school, or during a family or relationship conflict.

What causes GAD?

GAD sometimes runs in families, but no one knows for sure why some family members have it while others don't. Researchers have found that several parts of the brain, as well as biological processes, play a key role in fear and anxiety. By learning more about how the brain and body function in people with anxiety disorders, researchers may be able to create better treatments. Researchers are also looking for ways in which stress and environmental factors play a role.

How is GAD treated?

First, talk to your doctor about your symptoms. Your doctor should do an exam and ask you about your health history to make sure that an unrelated physical problem is not causing your symptoms. Your doctor may refer to you a mental health specialist, such as a psychiatrist or psychologist.

GAD is generally treated with psychotherapy, medication, or both. Talk with your doctor about the best treatment for you.

Psychotherapy

A type of psychotherapy called cognitive behavioral therapy (CBT) is especially useful for treating GAD. CBT teaches a person different ways of thinking, behaving, and reacting to situations that help him or her feel less anxious and worried. For more information on psychotherapy, visit <http://www.nimh.nih.gov/health/topics/psychotherapies>.

Medication

Doctors may also prescribe medication to help treat GAD. Your doctor will work with you to find the best medication and dose for you. Different types of medication can be effective in GAD:

- Selective serotonin reuptake inhibitors (SSRIs)
- Serotonin-norepinephrine reuptake inhibitors (SNRIs)
- Other serotonergic medication
- Benzodiazepines

Doctors commonly use SSRIs and SNRIs to treat depression, but they are also helpful for the symptoms of GAD. They may take several weeks to start working. These medications may also cause side effects, such as headaches, nausea, or difficulty sleeping. These side effects are usually not severe for most people, especially if the dose starts off low and is increased slowly over time. **Talk to your doctor about any side effects that you have.**

Buspirone is another serotonergic medication that can be helpful in GAD. Buspirone needs to be taken continuously for several weeks for it to be fully effective.

Benzodiazepines, which are sedative medications, can also be used to manage severe forms of GAD. These medications are powerfully effective in rapidly decreasing anxiety, but they can cause tolerance and dependence if you use them continuously. Therefore, your doctor will only prescribe them for brief periods of time if you need them.

Don't give up on treatment too quickly. Both psychotherapy and medication can take some time to work. A healthy lifestyle can also help combat anxiety. Make sure to get enough sleep and exercise, eat a healthy diet, and turn to family and friends who you trust for support.

For basic information about these and other mental health medications, visit <http://www.nimh.nih.gov/health/topics/mental-health-medications>. Visit the Food and Drug Administration's website (<http://www.fda.gov/>) for the latest information on warnings, patient medication guides, or newly approved medications.

What is it like to have GAD?

"I was worried all the time and felt nervous. My family told me that there were no signs of problems, but I still felt upset. I dreaded going to work because I couldn't keep my mind focused. I was having trouble falling asleep at night and was irritated at my family all the time.

I saw my doctor and explained my constant worries. My doctor sent me to someone who knows about GAD. Now I am working with a counselor to cope better with my anxiety. I had to work hard, but I feel better. I'm glad I made that first call to my doctor."

Question 5

Letters of support provided by physicians with knowledge of the disease or condition.

To Whom It May Concern,

We, the undersigned physicians, support adding generalized anxiety disorder to the qualifying conditions list under Ohio's Medical Marijuana Control Program.

We have reviewed the available science, research and information on treating generalized anxiety disorder with medical marijuana and believe it to be an effective treatment, and that the benefits outweigh the risks.

Any physician who has treated a patient with generalized anxiety disorder understands the immense impact this condition can have on a person's quality of life. At its most severe, generalized anxiety disorder can leave a patient bedridden and unable to perform basic daily tasks.

[Studies conducted by Tyrer and Baldwin in 2006 and Yonkers *et al* in 1996 have shown remission rates for generalized anxiety disorder are low.](#)

Given the difficulty of treating this condition, and the detrimental nature of it on a patient's life, we believe adding medical marijuana to the list of treatment options is vital to patient wellbeing.

For these reasons, we ask that the State Medical Board of Ohio add generalized anxiety disorder as a qualifying condition under Ohio's Medical Marijuana Control Program.

Sincerely,

Overview – 3

Generalised Anxiety Disorder in Adults: Management in Primary, Secondary and Community Care.– 4

Achieving Remission in Generalized Anxiety Disorder – 16

Overview

General Anxiety Disorder (GAD) is a mental health disorder characterized by excessive worry and other symptoms ranging from restlessness to irritability. For many patients, chronic GAD can be debilitating, and at its worst leave a patient unable to go about their daily life.

Treating GAD is complicated by the fact that it is often associated with other conditions and sufferers regularly go years without seeking treatment. Nonetheless, when patients do seek treatment, they're results vary based on a range of factors with only 50-60% responding clinically to therapy and even less entering remission.

Attached are two publications detailing both the difficulties in treating GAD and the success rates of current treatment options:

1. **Generalised Anxiety Disorder in Adults: Management in Primary, Secondary and Community Care** – “Most clinical studies suggest that GAD is typically a chronic condition with low rates of remission over the short and medium-term. Evaluation of prognosis is complicated by the frequent comorbidity with other anxiety disorders and depression, which worsen the long-term outcome and accompanying burden of disability (Tyrer & Baldwin, 2006).”
2. **Achieving Remission in Generalized Anxiety Disorder** - “Between 50% and 60% of patients respond clinically to therapy, but only one-third to one-half attain remission or realize full recovery during the acute phase of treatment.”

2 GENERALISED ANXIETY DISORDER

2.1. INTRODUCTION

[Go to:](#)

This guideline is concerned with the treatment and management of adults with a diagnosis of GAD in primary and secondary care. GAD is one of a range of anxiety disorders including panic disorder (with and without agoraphobia), PTSD, OCD, social phobia, specific phobias (for example, of spiders) and acute stress disorder.

GAD commonly coexists with other anxiety disorders and with depressive disorders, as well as a variety of physical health disorders. 'Pure' GAD in the absence of another anxiety or depressive disorder is less typical than comorbid GAD. This guideline is relevant to both people with pure and comorbid GAD. The NICE guideline on case identification and referral for common mental health disorders will provide further guidance on identification ([NICE, 2011](#)).

2.2. THE DISORDER

[Go to:](#)

2.2.1. Symptoms, presentation and patterns of illness

Anxiety is a prominent symptom of many psychiatric disorders but it is only comparatively recently that several distinct anxiety disorders have been recognised in classificatory systems. The key feature of GAD is worry and apprehension that is out of proportion to the circumstances. The worries are typically widespread, involve everyday issues and have a shifting focus of concern. The affected person finds the worries difficult to control, and this can result in decreased occupational and social functioning ([Tyrrer & Baldwin, 2006](#); [Bitran et al., 2009](#)).

As well as worry that is excessive, generalised and difficult to control, people with GAD experience other psychological and somatic symptoms of anxiety. Psychological symptoms include irritability, poor concentration, increased sensitivity to noise and sleep disturbance, typically difficulty falling asleep. Somatic symptoms of GAD can manifest in many different ways. For example, an overactive autonomic nervous system can lead to sweating, dry mouth, palpitations, urinary frequency, epigastric discomfort and frequent and/or loose bowel motions, while hyperventilation may result in feelings of shortness of breath and dizziness. Increased muscle tension is a common accompaniment of persistent anxiety and may be experienced as restlessness, inability to relax, headaches and aching pains, particularly in the shoulders and back ([Gelder et al., 2006](#)).

GAD is frequently comorbid with other mental disorders, which can complicate its presentation. The rates of comorbidity vary between studies with estimates of between 68 and 93% of comorbidity with another axis 1 mental health disorder ([Carter et al., 2001](#); [Hunt et al., 2002](#); [ESEMED/MHEDEA 2000 Investigators, 2004](#)). Comorbid disorders that are particularly common include depressive disorders (specifically major depression and dysthymia), other anxiety disorders (especially panic disorder, social phobia and specific phobias) and somatoform disorders ([Bitran et al., 2009](#); [Carter et al., 2001](#); [Hunt et al., 2002](#); [Grant et al., 2005](#); [Kessler et al., 2005b](#)). There is also significant comorbidity with substance misuse especially among men ([Grant et al., 2005](#); [Kessler et al., 2005b](#)).

GAD also often co-occurs with physical health problems such as arthritis and gastrointestinal and respiratory disorders and may mimic the presentation of some

physical conditions (for example, hyperthyroidism) (Culpepper, 2009; Roy-Byrne *et al.*, 2008; Sareen *et al.*, 2006). Due to the somatic symptoms of anxiety, which are central to GAD, and physical comorbidities, people with GAD who present in primary care may emphasise somatic problems or sleep disturbance, rather than excessive worry or psychological symptoms of anxiety (Rickels & Rynn, 2001).

2.2.2. Course and prognosis

Most clinical studies suggest that GAD is typically a chronic condition with low rates of remission over the short and medium-term. Evaluation of prognosis is complicated by the frequent comorbidity with other anxiety disorders and depression, which worsen the long-term outcome and accompanying burden of disability (Tyrer & Baldwin, 2006). In the Harvard-Brown Anxiety Research Program, which recruited participants from Boston hospitals, the mean age of onset of GAD was 21 years, although many participants had been unwell since their teens. The average duration of illness in this group was about 20 years and despite treatment the outcome over the next 3 years was relatively poor, with only one in four showing symptomatic remission from GAD (Yonkers *et al.*, 1996). The proportion of people who became free from all psychiatric symptomatology was smaller, about one in six. In people who remitted from GAD the risk of relapse over the next year was about 15%, increasing to about 30% in those who achieved only partial symptomatic remission (Yonkers *et al.*, 1996).

The participants in the above study were recruited from hospital services and may not be representative of GAD in general. In a naturalistic study in the UK, Tyrer and colleagues (2004) followed up people with anxiety and depression identified in psychiatric clinics in primary care and found that 12 years later 40% of those initially diagnosed with GAD had recovered, in the sense that they no longer met criteria for any *Diagnostic and Statistical Manual of Mental Disorders* 3rd edition (DSM-III; American Psychiatric Association [APA], 1980) psychiatric disorder. The remaining participants remained symptomatic, but GAD was still the principal diagnosis in only 3% of trial participants; in the vast majority conditions such as dysthymia, major depression and agoraphobia were now more prominent. This study confirms the chronic and fluctuating symptomatic course of GAD in clinically-identified people. It should be noted, however, that the majority of people with GAD in the community do not seek medical help for their symptoms (Wittchen & Jacobi, 2005), and the course of the illness in these circumstances is not established.

2.2.3. Disability and mortality

As is the case with major depression, GAD is associated with a substantial burden of disability, equivalent to that of other chronic conditions such as arthritis and diabetes (Wittchen, 2002). Outcome studies suggest that anxiety disorders are more chronic than other common mental disorders (Tyrer *et al.*, 2004) and there is evidence that comorbid depression and anxiety has a worse prognosis, with more associated disability and more persistent symptoms than either depression or anxiety disorders alone (Kroenke *et al.*, 2007). There is also evidence in the community that anxiety disorders are independently associated with several physical conditions, and this comorbidity is significantly associated with poor quality of life and disability (Sareen *et al.*, 2006). This morbidity comes with high associated health and social costs (Simon *et al.*, 1995).

Studies have shown that the presence of GAD is also associated with significant impairments in occupational and social functioning. For example, over 30% of people with GAD showed an annual reduction of work productivity of 10% or more compared with 8% of people with major depression. The figure for people with comorbid GAD and depression was over 45% (Wittchen *et al.*, 2000). A large part of the economic cost of anxiety disorders is attributable to the costs of non-medical psychiatric treatment. People with GAD have increased numbers of visits not only to primary care doctors but also to hospital specialists, particularly gastroenterologists (Kennedy & Schwab, 1997; Wittchen, 2002). This may be a consequence of the distressing somatic symptoms which many people with GAD experience.

GAD also carries a considerable cost in personal suffering – in the Harvard-Brown Anxiety Research Program noted above, one third of people had never married and unemployment was higher than average (Yonkers *et al.*, 1996). Suicidal ideation and suicide attempts are significantly increased in GAD compared with the general population, particularly in women, and this increase is still greater in the presence of comorbid major depression (Cougler *et al.*, 2009).

2.2.4. Incidence and prevalence

The estimated proportion of people in England with GAD was 4.4% in the most recent *Adult Psychiatric Morbidity in England* survey (McManus *et al.*, 2009), a figure that has varied little across the three survey years 1993, 1997 and 2007. This figure is at the upper end of estimates of point and annual prevalence of 2.1 to 4.4% in English speaking countries (Grant *et al.*, 2005; Hunt *et al.*, 2002; Kessler & Wang, 2008) with lower rates of 0.8 to 2.2% reported from other European countries (Lieb *et al.*, 2005; Wittchen & Jacobi 2005). Worldwide estimates of the proportion of people who are likely to experience GAD in their lifetime vary between 0.8% and 6.4% (Lieb *et al.*, 2005; Grant *et al.*, 2005; Kessler & Wang, 2008).

Prevalence rates have generally been found to be between 1.5 and 2.5 times higher in women than men. In the *Adult Psychiatric Morbidity in England* survey (McManus *et al.*, 2009), the rates were 3.4% for men and 5.3% for women. In terms of age, epidemiological studies have generally found GAD to be less common in older age groups (over 55 years) although there are some exceptions. Some studies have also found GAD to be less common in younger adults (younger than 35 years).

Evidence from the US on ethnicity and race differences in GAD rates is inconsistent, with studies finding increased (Blazer *et al.*, 1991), decreased (Grant *et al.*, 2005) and no difference (Wittchen *et al.*, 1994) in rates between white and one or more of black, Asian and Hispanic groups. Numbers of minority ethnic groups sampled in the *Adult Psychiatric Morbidity in England* survey (McManus *et al.*, 2009) were too small to draw conclusions about possible differences, although proportions of the black and South Asian groups with GAD in the sample (both male and female) were higher than the equivalent proportions for white interviewees.

Socioeconomic factors associated with GAD are lower household income (Grant *et al.*, 2005; McManus *et al.*, 2009), lack of tertiary qualifications (Hunt *et al.*, 2002) and unemployment (Hunt *et al.*, 2002). Divorce, separation and death of a partner are also associated with an increased likelihood of GAD.

2.2.5. Diagnosis

Diagnostic criteria and methods of classification of anxiety disorders have changed substantially over the years. Historically what we now consider to be GAD was subsumed under 'anxiety neurosis'. It first appeared as a separate diagnosis in 1980 with the introduction of DSM-III (APA, 1980). In DSM-III it was a residual category to be used only when an anxiety disorder could not be classified under another diagnosis. It was only with the DSM-III revision in 1987 (DSM-III-R; APA, 1987) that it became a well defined condition in its own right. DSM-III-R also changed the DSM-III minimum duration requirement from 1 month to 6 months and introduced excessive worry as a central feature. Some of the developments in DSM-III-R were later reflected in the *International Classification of Diseases – the Classification of Mental and Behavioural Disorders* 10th revision (ICD-10; World Health Organization [WHO], 1992), although without the same focus on worry. The introduction of DSM-IV in 1994 (APA, 1994) further streamlined and refined the criteria, in particular focusing less on somatic symptoms of anxiety and replacing the DSM-III-R criterion that the worry is 'unrealistic' with a criterion that the worry is 'difficult to control'.

DSM-IV and ICD-10 have overlapping but different diagnostic features for GAD. DSM-IV emphasises worry ('apprehensive expectation'), including the feature that the worry is difficult to control, while ICD-10 focuses more on somatic symptoms of

anxiety, particularly autonomic reactivity and tension. DSM-IV requires two major symptoms (6 months or more of excessive anxiety and worry, occurring on more days than not, about a number of events and activities and difficulty controlling the worry) and three or more additional symptoms from a list of six. ICD-10, as operationalised in the *ICD-10 Diagnostic Criteria for Research* (ICD-10-DCR; [WHO, 1993](#)), requires 6 months or more prominent tension, worry and feelings of apprehension, and four from a list of 22 symptoms, of which at least one must be from a list of four autonomic symptoms (palpitations, sweating, trembling, dry mouth).

In line with the previous guideline on GAD ([NICE, 2004a](#)) and other NICE guidelines on anxiety disorders and depression ([NICE, 2005a, b; 2009b](#)) the GDG used DSM-IV, rather than ICD-10 to define the diagnosis of GAD, because the evidence base for treatments nearly always uses DSM-IV.

As there is now greater recognition of the need to consider 'subthreshold' depression in terms of human and economic costs and the risk of future major depression ([Rowe & Rapaport, 2006](#)), there has also been recent attention given to subthreshold GAD. Relaxing the DSM-IV requirements of duration, excessive worry and/or three associated symptoms more than doubles the estimated prevalence of GAD ([Ruscio et al., 2007](#)). Cases of subthreshold GAD have similar but reduced comorbidities, with persistence, impairment and sociodemographic correlates all being significantly associated with an elevated risk of subsequent psychopathology ([Kessler et al., 2005a; Ruscio et al., 2007](#)). The implication is that, in clinical practice, identification of subthreshold GAD may be helpful for prevention of future disorder.

2.3. AETIOLOGY

Go to: 

The aetiology of GAD is multifactorial and involves psychological, social and biological factors. Interpretation of experimental data is complicated by changes in diagnostic practice and the frequent occurrence of comorbidity, particularly with major depression ([Yonkers et al., 1996](#)). On the other hand, anxiety (or more precisely, fear) is readily modelled in animal experimental studies, and the brain circuitry relevant to fear has been characterised in both animals and humans ([Engel et al., 2009](#)). One influential formulation ('the theory of triple vulnerability') regards GAD as arising from three distinct kinds of vulnerability: a generalised biological, a generalised psychological and a specific psychological vulnerability ([Barlow, 2000; Bitran et al., 2009](#)).

Anxiety disorders run in families. For example, a family study found that the risk of GAD in first-degree relatives of people with GAD was five times that in control groups ([Noyes et al., 1987](#)), although specific genes conferring vulnerability to GAD have not yet been reliably identified. Indeed the genes involved in the transmission of GAD appear to increase susceptibility to other anxiety disorders such as panic disorder and agoraphobia as well as major depression ([Kendler, 1996; Hettema et al., 2001; 2005](#)). There is also genetic overlap between GAD and the temperamental trait of neuroticism, which is itself a predisposing factor for GAD ([Hettema et al., 2004](#)). Overall the findings suggest that genetic factors play a significant though moderate role in the aetiology of GAD, that these factors predispose people to a range of anxiety and depressive disorders rather than GAD specifically, and that environmental factors are important in determining the nature of the emotional disorder experienced by a particular person.

Several environmental factors are known to predispose individuals to GAD. These can act remotely or as contemporaneous triggers to the disorder. For example, good parenting experiences are important in providing children with a secure base from which to explore the world, and problems in child-parent attachment have been linked to feelings of diminished personal control of potentially threatening events ([Barlow, 2000](#)). Such feelings could plausibly contribute to the risk of experiencing anxiety disorders. Studies suggest that adults with GAD report experiencing parental styles characterised by overprotection and lack of emotional warmth ([Silove et al., 1991](#)). Similar findings have been reported in other anxiety disorders and depression ([Parker et al., 1995](#)), which suggest that certain parenting

styles may act as a psychological vulnerability factor for a range of subsequent emotional disorders. Similar comments apply to other kinds of childhood adversity such as neglect, abuse, maternal depression and family disruption, which increase the risk of experiencing GAD in adulthood as well as other anxiety and depressive disorders ([Brown & Harris, 1993](#); [Halligan et al., 2007](#); [Safren et al., 2002](#)). More recent stressful life events are also known to be involved in the onset of emotional disorders including GAD ([Roemer et al., 1996](#)). A study by [Kendler and colleagues \(2003\)](#) showed that stressful life events characterised by loss increased the risk of both depression and GAD; however, life events characterised by 'danger' (where the full import of the event was yet to be realised) were more common in those who subsequently developed GAD.

Particular coping and cognitive styles also predispose individuals to the development of GAD, although it is not always easy to distinguish predisposition from the abnormal cognitions seen in the illness itself. As noted above, it is believed that people who lack a sense of control of events and personal effectiveness, perhaps through early life experiences, are more prone to anxiety disorders ([Barlow, 2000](#)). Such individuals may also demonstrate trait-like cognitive biases in the form of increased attention to potentially threatening stimuli, overestimation of environmental threat and enhanced memory of threatening material. This has been referred to as the 'looming cognitive style', which appears to be a general psychological vulnerability factor for a number of anxiety disorders ([Reardon & Nathan, 2007](#)). More recent cognitive formulations have focused on the process of worrying itself, which is of central importance in the diagnosis of GAD. Studies suggest that people at risk of GAD use worry as a positive coping strategy to deal with potential threats, whereby the person worries until they feel reassured that they have appraised all possible dangers and identified ways of dealing with them. However, this can lead to 'worry about worry', when individuals come to believe, for example, that worrying in this way, while necessary for them, is also uncontrollable and harmful. This 'metacognitive belief' may constitute a transitional stage between excessive, but normal, worrying and GAD ([Wells, 2005](#)).

Studies of both animal and human subjects suggest that the amygdala plays a central role in the processing of information relevant to threat and fear ([Le Doux, 2000](#)). Activation of the amygdala can occur prior to conscious appreciation of threat but there are strong connections between the amygdala and areas of prefrontal cortex involved in the conscious experience and regulation of emotion ([Le Doux, 2000](#); [Phillips et al., 2003](#)). Another structure involved in anxiety is the hippocampus, which is important in relating fearful memories to their environmental context ([Fanselow, 2000](#)). The hippocampus forms part of a 'behavioural inhibition system', which is activated by potential threats, and has the ability in these circumstances to suspend ongoing behaviours ([Gray, 1982](#)). Brain imaging studies of individuals with high trait anxiety and people with GAD have shown exaggerated responses in both the amygdala and prefrontal cortex during presentation of emotionally threatening stimuli ([Bishop et al., 2004](#); [Nitschke et al., 2009](#)). It is therefore possible that pre-existing abnormalities in this circuitry might predispose people to GAD and other anxiety disorders.

The neural circuitry involved in fear and anxiety is modulated by brain neurotransmitters and other chemical mediators including hormones ([Dedovic et al., 2009](#)). A relevant hormonal system is the hypothalamo-pituitary-adrenal axis (HPA), which regulates cortisol secretion. Adversity experienced in childhood and current stresses can alter the pattern of cortisol secretion in adult life, and there is an extensive literature on the role of HPA axis dysfunction in major depression (for example, [Pariante & Lightman, 2008](#)). HPA axis activity in people with GAD has been much less studied but there is some evidence that GAD, like depression, is associated with excessive glucocorticoid secretion ([Mantella et al., 2008](#)). The monoamine neurotransmitters, serotonin and noradrenaline, can alter fear processes in animals and have extensive inputs to the relevant neural circuitry, including the amygdala and the behavioural inhibition system ([Bitran et al., 2009](#); [Garner et al., 2009](#)). In addition, selective serotonin reuptake inhibitors (SSRIs) are widely used in the treatment of GAD ([Baldwin et al., 2005](#)). Despite this there is only modest evidence that abnormalities in serotonin and noradrenaline are

involved in the pathophysiology of GAD, though more work needs to be carried out with ligand neuroimaging to resolve this issue ([Garner et al., 2009](#)). In the same way, pharmacological manipulation of gamma-aminobutyric acid (GABA) neurones and their associated benzodiazepine receptors clearly have profound effects on the experience of fear and anxiety in animals and humans ([Kalueff & Nutt, 2007](#)) but again there is only modest evidence that abnormalities in GABA neurotransmission or benzodiazepine receptor function are involved in the aetiology of GAD ([Garner et al., 2009](#)).

Overall there is good evidence that both genetic factors and early life difficulties can predispose people to a range of emotional disorders, including GAD. More specific risk factors for GAD, presumably occurring in combination with these more generalised vulnerabilities, include certain kinds of life events and particular individual cognitive styles involving the use of worrying as a coping strategy. The neural circuitry involved in fear and anxiety has been well delineated in brain imaging studies and abnormalities in both people with GAD and non-clinical subjects with high trait anxiety have been described in relevant brain regions. It seems likely that these neural changes are associated with abnormal cognitions, such as increased attention to threat, that are seen in people with GAD and those at risk of the disorder. There is much knowledge on how particular neuropharmacological manipulations can influence anxiety. While this information has proved helpful in developing pharmacological treatment, the role of neurotransmitters and other chemical mediators in the aetiology of GAD is currently unclear.

2.4. TREATMENT AND MANAGEMENT IN THE NHS

Go to: 

2.4.1. Detection, recognition and referral in primary care

Relative to its prevalence in the community, GAD is more common in primary care occurring in about 5% of attendees, and is the most common anxiety disorder seen in this setting. A recent international review of some of the larger general population surveys reported 12-month prevalence rates of 5.6 to 18.1% for anxiety disorders, of which GAD and panic disorder together accounted for over half of the prevalence figures ([Baumeister & Hartner, 2007](#)).

General practitioner (GP) rates of diagnosis and treatment of anxiety disorders are much lower than expected from the prevalence figures ([Wittchen & Jacobi, 2005](#)). [Wittchen and colleagues \(2002\)](#) found that recognition rates by primary care practitioners were only 34.4% for pure GAD and 43% for GAD with comorbid depression. There are likely to be a variety of reasons why GPs are poor at recognising anxiety disorders in their patients. People with GAD may have symptoms of anxiety, worry, tension, irritability or tiredness, about which they feel reluctant to complain to their GP because they do not view these symptoms as being 'medical', or the GP may identify these as symptoms of a more general malaise and not specifically consider or ask about anxiety as a possible cause ([Arroll & Kendrick, 2009](#)). In addition, many people may present with somatic symptoms associated with their anxiety, considering these to be more legitimate or more troubling. It appears that people with anxiety disorders are often frequent users of primary care resources, but if the anxiety component of their problem is not detected they may not receive the correct treatment and may undergo unnecessary and costly investigations, in particular for their physical symptoms ([Hales et al., 1997](#)). Recognition is increased by factors such as older age, presentation of other psychological problems, and enhanced knowledge, skills and attitudes of practitioners in primary care ([Tylee & Walters, 2007](#)).

There is evidence that GPs may not offer effective evidence-based treatments to people with anxiety disorders as often as may be indicated, and that the treatments offered are more likely to be pharmacological, rather than psychological therapies such as cognitive behavioural therapy (CBT) ([Stein et al., 2004](#)) due to limited availability of such treatments, although this may be changing with increased access to psychological therapies through the Improving Access to Psychological Therapies programme (IAPT).² The majority of treatments offered for anxiety disorders are likely to be based in primary care and may involve the GP and/or a

low-intensity psychological therapist such as a primary care mental health worker or the practice counsellor. Self-help bibliotherapy and web-based interventions may be effective for some people with GAD, although referral to secondary care practitioners, such as a high-intensity psychological therapist, may occur for those more severely affected. Referral to secondary care psychiatric mental health services is likely to be rare and reserved for people with the most treatment-resistant symptoms and severe functional impairment.

In summary, there is evidence that GAD is currently significantly under-detected and under-treated in UK primary care settings. This is a potentially serious omission, given the functional impairment and chronicity that can be associated with this diagnosis, particularly when comorbid with depression or physical health problems. There needs to be an increased emphasis on encouraging people to actively present their anxiety symptoms, and for their GPs to be more attuned to this diagnosis (particularly in people known to have depression or a chronic physical health problem) and the need to provide effective evidence-based treatments as early as possible in the course of this disorder before it becomes a long-term problem.

2.4.2. Assessment and co-ordination of care

Primary care and mental health practitioners need to have skills in the identification of GAD and its differentiation from other anxiety and depressive disorders in order to assess GAD and provide appropriate treatment. Assessment involves evaluation of GAD symptoms, especially worry and somatic symptoms of anxiety, the duration of these symptoms, and the extent of the person's functional impairment and distress and their coping resources. Assessment also needs to include evaluation of the symptoms of other anxiety and depressive disorders (especially panic disorder, hypochondriasis, OCD, social phobia, major depressive disorder and dysthymic disorder) given both the overlap of symptoms (for differential diagnosis) and the comorbidity between GAD and these other disorders.

The majority of treatment takes place in primary care or is linked with primary care, usually by either being directly provided by GPs or by psychological practitioners in liaison with GPs. GPs are accordingly central to the coordination of care. Ensuring a clear collaborative treatment plan between GP and psychological practitioners is important. For a small minority of people with very severe disorders, treatment may be provided by a multi-professional team in secondary care with coordination of care through the Care Programme Approach (CPA).

2.4.3. Aims and non-specific effects of treatment and placebo

The aim of treatment for GAD is to relieve symptoms, restore function and prevent relapse. The latter goal is important because GAD manifests as a chronic, relapsing condition and recurrence of illness is common, even when short-term treatment has apparently been successful ([Yonkers et al., 1996](#)). In clinical trials, the outcome of treatment is often determined on standardised rating scales and can be divided into 'response' (where the symptom score has dropped by at least 50%) and 'remission' (almost complete relief of symptoms). In the treatment of depression, remission rather than response is now seen as the preferred goal because people who are essentially asymptomatic have improved functional outcomes and less risk of relapse. It seems probable that similar considerations will apply to the treatment of GAD.

Many people with GAD have had symptoms for long periods of time. Nevertheless, in short-term studies of medication, pill placebo treatment in the context of the clinical care provided by a controlled trial is certainly beneficial for a proportion of people. For example, in a 12-week placebo-controlled trial of escitalopram and paroxetine, just over 40% of participants responded to placebo and about 30% reached remission ([Baldwin et al., 2006](#)). In contrast, naturalistic follow-up studies of people with GAD in the community have found considerably lower remission rates than this, at about 15% a year ([Yonkers et al., 1996](#)). This suggests that either GAD, despite its chronicity, can respond well to pill placebo and non-specific aspects of good clinical management, or that the people who participate in placebo-controlled trials are not typical of the broad range of people with GAD in the

community. In addition, it is not known whether people who respond to a placebo in the short-term will maintain this level of improvement whereas there is some evidence that continuing drug treatment that proved effective in the short-term can help prevent relapse ([Baldwin et al., 2005](#)).

Non-specific effects of treatment are also important in assessing the benefits of psychological therapies such as CBT and applied relaxation. Often such treatments are assessed against 'waitlist' or 'treatment as usual' control groups, which means that the non-specific effects of factors such as increased professional support and instillation of hope will augment the specific effects of a particular therapy. Thus a meta-analysis showed that while CBT was superior to waitlist control in the treatment of GAD, its superiority to supportive psychological therapy could not be clearly demonstrated ([Hunot et al., 2007](#)).

Consistent with this, a substantial number of other approaches have been employed to help people with anxiety disorders, such as exercise, prayer and homeopathic and herbal remedies ([Jorm et al., 2004](#)). This suggests that numerous non-medical approaches, provided they carry meaning and hope for the person concerned, can enable individuals to use their own coping and healing capacities to overcome anxiety symptoms. At present it is not possible to identify those people who will respond to non-specific, as opposed to specific, pharmacological and psychological treatments. In the treatment of depression it appears that the response to placebo lessens as the condition becomes symptomatically more severe ([Khan et al., 2005](#)); this means that the specific benefits of antidepressants are greater in the most severely ill people. Whether the same is true in people with GAD is not clear.

2.4.4. Pharmacological treatments

Placebo-controlled trials indicate that a wide range of medicines with differing pharmacological properties can be effective in the treatment of GAD ([Baldwin et al., 2005](#)). Traditionally, benzodiazepine drugs, such as diazepam, were employed for this purpose but it became clear that their use was commonly associated with the development of tolerance and dependence ([Royal College of Psychiatrists, 2005](#)). For this reason they are now recommended only for short-term use (2 to 4 weeks). Another drug specifically licensed for the treatment of GAD is buspirone, which acts on a particular subtype of serotonin receptor. However, like benzodiazepines, buspirone is recommended for short-term use only ([British Medical Association & the Royal Pharmaceutical Society of Great Britain, 2009](#)).

In recent years antidepressants such as SSRIs have been increasingly used to treat GAD ([Baldwin et al., 2005](#)). Unlike benzodiazepines, antidepressants do not relieve anxiety from the beginning of treatment and a period of some weeks often needs to elapse before significant clinical improvement is seen. Tolerance and dependence do not seem to be a problem with antidepressant treatment, though it should be noted that, like benzodiazepines, antidepressants can cause discontinuation symptoms on abrupt withdrawal ([MHRA, 2004](#)). As well as SSRIs, serotonin noradrenaline reuptake inhibitors (SNRIs), such as venlafaxine and duloxetine, are also effective in GAD, as are the older and less selective tricyclic antidepressants (TCAs), such as imipramine. However, TCAs are not as well tolerated as newer antidepressant agents and are more dangerous in overdose ([Baldwin et al., 2005](#)).

In addition to the antidepressants, other compounds also have efficacy in the treatment of GAD. These include the antihistamine hydroxyzine, and the anticonvulsant drug pregabalin, which binds to a subtype of calcium channel in the brain ([Baldwin et al., 2005](#)). Both conventional antipsychotic drugs and the newer 'atypical' antipsychotic agents have also been used in the treatment in GAD, both as a sole therapy and as an 'add-on' to SSRI therapy when the latter has proved ineffective ([Pies, 2009](#)). However, the greater side-effect burden of antipsychotic drugs means that their use is currently restricted to people with refractory conditions, with prescribing guided by secondary care.

While many drug treatments have been demonstrated to be effective in GAD relative to placebo, there are very few comparative studies between active

pharmacological agents. In addition there are no reliable clinical or biological predictors of treatment response in individuals. For this reason the selection of pharmacological treatment is usually made on the basis of the side-effect profile and the history of medication response in a particular individual.

2.4.5. Psychological treatments

Developments in psychological treatments for GAD have tended to parallel changes in the conceptualisation and diagnostic criteria for GAD, moving from a more general approach to more specific interventions.

Early psychological treatments for GAD tended to involve non-specific interventions such as supportive psychotherapy and relaxation training. Initial cognitive behavioural packages for the treatment of GAD ([Borkovec & Costello, 1993](#); [Barlow et al., 1992](#)) focused on the treatment of persistent anxious arousal and often included a number of interventions such as applied relaxation, imagery rehearsal (imaginal practice of coping skills in response to anxiety), stimulus control (establishing increased control over worry) and cognitive approaches based on the work of [Beck and colleagues \(1985\)](#).

More recent adaptations of CBT have emphasised the specific role of worry in GAD and have tried to focus treatment more on the processes thought to underlie the disorder. An example of this is CBT targeting the intolerance of uncertainty ([Dugas et al., 2007](#)) or the metacognitive therapy developed by [Wells \(1999\)](#), which emphasises the importance of the beliefs people have about worry and attempts to modify these.

[Borkovec and colleagues \(2002\)](#) have augmented existing CBT protocols with interpersonal/psychodynamic strategies to address problematic relationship patterns often found in people with GAD and the implications of the avoidance theory of worry, suggesting that people with GAD worry in order to avoid experiencing negative emotions.

Other adaptations of CBT have integrated acceptance-based and mindfulness approaches into treatment for GAD, incorporating the acceptance and experience of frequently avoided emotions into treatment protocols ([Orsillo et al., 2003](#)).

2.4.6. Stepped care

Stepped care ([Scogin et al., 2003](#)) is a framework that is increasingly being used in the UK to specify best practice in the design of clinical pathways to care. Stepped care is designed to increase the efficiency of service provision and therefore benefit patient populations. The basic principle is that patients presenting with a common mental health disorder will 'step through' progressive levels of treatment as necessary, with the expectation that many of these patients will recover or improve while undergoing less intensive treatments. The key features of stepped care are that treatments delivered first should be the least restrictive and that the model is self-correcting. The definition of 'least restrictive' may refer to the impact on patients in terms of cost and personal inconvenience, but can also refer to the amount of specialist therapist time required (that is, treatment intensity). High-intensity treatments are reserved for patients who do not benefit from low-intensity treatments, or for those who can be accurately predicted to not benefit from such treatments. 'Self-correcting' in this context means that the decisions about treatment provision and the effects of treatment are monitored systematically, and changes are made ('stepping up') if current treatments are not achieving significant health gain. Thus, stepped care has the potential for deriving the greatest benefit from available therapeutic resources ([Bower & Gilbody, 2005](#)).

Successful implementation of a stepped-care model is crucial for effective implementation of the NICE guidelines ([Lovell & Bee, 2008](#)). There are two conceptualisations of the stepped-care model. The first is a sequential model, where all people move through the steps in a systematic way, regardless of severity, need or choice. All patients initially receive an evidence-based low-intensity treatment and only 'step up' if and when they have not benefited from the low-intensity treatments offered. The second model is a stratified or multiple-access

model, which allows patients to access more intensive treatment initially, without having received less intensive interventions first (Lovell & Richards, 2000). Stratified stepped-care models have been incorporated into previous NICE guidelines, where stratification has been determined by the person's degree of functional impairment (as in the NICE guideline on OCD and body dysmorphic disorder; NICE, 2005b) or severity of the disorder (as in the NICE guidelines on depression; NICE, 2009b; 2009c).

2.4.7. The economic cost of anxiety disorders – focus on generalised anxiety disorder

Anxiety disorders place a significant burden on individuals as well as on the health-care system. Andlin-Sobocki and colleagues (2005) estimated the cost of anxiety disorders in Europe using published epidemiological and economic data from 28 European countries. Data on healthcare resource utilisation (medication, hospitalisation and outpatient care) and productivity losses due to sick leave associated with anxiety disorders were based on a German national health survey. The estimated total cost of anxiety disorders in Europe was reported to reach €41 billion (2004 prices). The average annual additional cost per person with GAD (relative to a person without an anxiety disorder) was estimated at €1,628 in 2004; of this, 76% was associated with provision of healthcare services and the remaining 24% with productivity losses due to sick leave (Andlin-Sobocki & Wittchen, 2005). The additional per-person cost of GAD was found to be the highest among respective costs of other anxiety disorders, such as panic disorder, agoraphobia, social phobia and OCD.

Only limited data on the healthcare resource utilisation by people with anxiety disorders exist in the UK. According to the Hospital Episode Statistics, in the financial year 2007 to 2008, 8,682 admissions were reported for phobic and other anxiety disorders in England, resulting in 121,359 inpatient bed days; of these, 747 admissions and 16,733 bed days were attributed specifically to GAD (NHS, The Information Centre, 2009). According to the most recent *Adult Psychiatric Morbidity in England* survey (McManus *et al.*, 2009), only 34% of people with GAD were receiving any kind of treatment for their condition at the time of the survey. Of them, 53% were receiving medication, 21% counselling or other psychological therapy, and 26% a combination of drugs and psychological treatment. In addition, 1% of respondents with GAD reported that they had used inpatient services for their condition over the past 3 months, 8% had used outpatient services during the same period, while 25% had used community or day care services during the past year.

A number of studies have estimated the cost of anxiety disorders in the US. DuPont and colleagues (1998) estimated this cost at \$46.6 billion in 1990, which accounted for 31.5% of the total cost of mental disorders in the country. The estimated cost was incurred by healthcare resource utilisation such as mental health services, medication, hospitalisation, nursing homes and outpatient visits (23.1%), productivity losses (76.1%) and, to a lesser extent, by provision of other services such as criminal justice services, incarceration, social welfare administration, as well as family care-giving (0.8%). Greenberg and colleagues (1999) provided a more up-to-date figure of the cost of anxiety disorders in the US, at \$63.1 billion in 1998.

A retrospective, multivariate analysis of data derived from a large claims database in the US demonstrated that people with anxiety disorders are more likely to use outpatient mental health services compared with a control group; they are also more likely to visit medical specialists such as cardiologists and neurologists and to use hospital services, including accident and emergency services. Furthermore, compared with controls, people with anxiety disorders were found to miss more days of work or to have a short-term disability (Marciniak *et al.*, 2004). According to the same analysis, the total medical cost per person with any anxiety disorder was estimated at \$6,475 in 1999 (Marciniak *et al.*, 2005). The multivariate model indicated that, controlling for demographics and other disease states, GAD was associated with an increase of \$2,138 in the total medical cost per person.

An Australian study ([Andrews et al., 2004](#)) estimated the total annual cost of routine treatment for GAD in Australia at AUS\$112.3 million in 1997 prices, based on the results of a national survey of mental health and wellbeing, and an estimated treatment coverage of only 38%. By applying optimal treatment (as achieved by operationalising detailed clinical practice guidelines and expert reviews) and increasing treatment coverage to 70%, the total annual direct medical cost of GAD was expected to rise to AUS\$205.1 million.

Anxiety disorders are associated with a wide range of comorbidities, which result in a substantial increase in total healthcare costs. [Sou tre and colleagues \(1994\)](#) estimated the total direct and indirect costs incurred by people with GAD, with and without comorbidities, using data on 999 people participating in a French cross-sectional study. Controlling for confounding variables, the prevalence of healthcare utilisation in terms of hospitalisation, laboratory tests and medications and the respective medical costs were found to be significantly higher in people with GAD and other comorbidities, as opposed to those with GAD without comorbidities. Moreover, comorbidities were associated with increased absenteeism from work. In particular, comorbid depression ([Marciniak et al., 2005](#); [Wetherell et al., 2007](#); [Zhu et al., 2009](#)) and physical pain ([Olson & Gameroff, 2007](#); [Zhu et al., 2009](#)) have been found to have a significant impact on treatment costs incurred by people with GAD.

Efficient use of available healthcare resources will maximise the health benefits for people with GAD and can potentially reduce costs to the healthcare system and society in the long term.

Generalized anxiety disorder (GAD) is a prevalent, chronic, debilitating mental illness associated with marked impairment in daily functioning.¹ An ongoing evolution of the definition of GAD has resulted in a bifurcation of the historical anxiety neurosis designation.² A diagnosis of GAD currently implies chronic,

excessive worry lasting at least 6 months and 3 of the possible 6 somatic or psychological symptoms (restlessness, fatigue, muscle tension, irritability, difficulty concentrating, and sleep disturbance).³ GAD typically presents in an episodic pattern of moderate improvement or remission and relapse characterized by a chronic and complicated clinical course.

Chronic worry, a core component of GAD, is consistently found in 10% of the population, and this subset reports a level of anxiety and tension so significant that it markedly impairs daily function. Epidemiological studies, however, suggest a lifetime GAD prevalence of 4% to 7%, a 1-year prevalence of 3% to 5%, and a current prevalence of 1.5% to 3%.⁴ Discrepancies between the incidence of anxiety-related symptoms and potential subsequent underestimation of GAD prevalence may be attributed to DSM-IV diagnostic criterion of 6 months' duration of worry.

It is the robust association of GAD with psychological and physical comorbidities that potentially contributes to the complexity of the illness as well as the limited treatment success.^{4,5} More than 90% of patients with GAD present with an additional psychiatric diagnosis. The ancillary condition is major depressive disorder (MDD) in 48% of patients.^{4,6}

Three primary care studies found that pure GAD, defined as a current episode of GAD in the absence of any other mood, anxiety, or substance use disorder, was associated with meaningful levels of impairment in several life

found that the mean numbers of disability days in the past month were much higher among primary care patients with pure GAD than among patients with none of the psychiatric disorders assessed in their survey. The 272 patients with pure GAD had more self-reported dysfunction in occupational role fulfillment and physical disability scores.

Remission/treatment goals

Traditionally, the goal of therapy has been to treat patients with GAD until a response is achieved. The response is either a clinically meaningful improvement in symptoms or a specific magnitude of change in a rating scale score from baseline. Given the extensive use of health care resources, the residual subsyndromal symptoms, and the substantial relapse rate of anxious patients, the goal of therapy has evolved to that of achieving remission.¹¹

Remission is a dichotomous concept in that it is an absence or near absence of symptoms in addition to a return to premorbid functionality.^{11,12} Between 50% and 60% of patients respond clinically to therapy, but only one-third to one-half attain remission or realize full recovery during the acute phase of treatment.¹³ Some patients may achieve “durable remission” within the first 4 to 8 weeks of therapy, which may indicate an eventual sustained remission (lasting 4 to 9 months after acute treatment).¹² Patients who achieve a sustained remission are less likely to experience relapse.¹⁴

Response to treatment and attainment of remission is comprehensively quantified both globally and specifically. The magnitude of treatment outcome is primarily measured by changes in the Hamilton Anxiety Rating Scale (HAM-A), the Clinical Global Impression/Improvement (CGI-I) scale, and the total Sheehan Disability Scale (SDS). This multidimensional approach assesses disease-specific anxiety symptoms, quality of life, functioning, and nonspecific symptoms (avoidance).¹² Response generally is defined as at least a 50% reduction in HAM-A score from

baseline, and a “much improved” or “very much improved” rating on the CGI-I.^{11,12,15,16}

Remission is defined as a HAM-A score of 7 or less, with global recovery achieved at a CGI-I score of 1 (“not ill at all” or “borderline mentally ill”), and functional recovery at an SDS score of 5 or less.¹⁴ For this designation of remission to be clinically meaningful, it must incorporate a time component. Remission is not static but rather should be sustainable over a considerable time—at least 8 consecutive weeks.¹⁷

Treatment options

The treatment of GAD involves a sequential process of first resolving the acute, symptomatic anxiety and then maintaining a longer-term constant suppression of chronic anxiety. Historically, benzodiazepines were the mainstay of GAD treatment, although the appropriateness of their use for long-term therapy is now under scrutiny.

Benzodiazepines indirectly affect the release and reuptake of monoamines via enhancement of the inhibitory effects of g-aminobutyric acid, thereby modulating fear, stress, and anxiety responses.¹⁸ Benzodiazepines are indicated for the short-term management of the acute phase of anxiety (2 to 4 weeks) as well as any subsequent exacerbations of anxiety during stable treatment. Their rapid onset and tolerability make them conducive to alleviating anxious symptoms when immediate anxiolytic effects are desired.^{19,20}

A randomized, double-blind study compared response rates among patients treated with imipramine, trazodone, and diazepam. Patients in the diazepam arm had the most significant improvement in anxiety ratings within the first 2 weeks. Within this group, 66% of patients completing the study reported moderate to marked global improvement.²¹ Although more marked improvement was realized in the first 2 weeks of treatment with benzodiazepines, antidepressants consistently afforded the same efficacy as benzodiazepines or even surpassed them after 6 to 12 weeks of treatment, particularly in alleviating psychic symptoms.^{21,22}

Aside from the obvious issue of potential dependence with prolonged use, benzodiazepines are not desirable as first-line therapy because of their potential for withdrawal syndromes and rebound effects on abrupt discontinuation.^{6,23,24} Yet, primary care providers have traditionally used benzodiazepines as first-line treatment of acute anxiety.²⁰

The anxiolytic buspirone has been used with moderate success but has not consistently demonstrated utility in any of the potentially comorbid conditions that can accompany GAD, with the exception of MDD.^{25,26} A retrospective analysis demonstrated significant improvement in HAM-A and global improvement scores relative to baseline, and another study reported buspirone's failure to differ from placebo on numerous outcome measures.^{22,27,28} In addition, buspirone was shown to be superior to placebo in improving anxiety symptoms as well as coexisting depressive symptoms in patients with GAD. The significant anxiolytic effect resulted in more than a 50% response rate, based on reductions in the HAM-A score.²⁹

Buspirone exerts its effect by reducing serotonin (5-HT) release as a partial agonist at 5-HT_{1A} receptors in the hippocampus and as a full agonist at the presynaptic serotonergic auto-receptors.^{14,30} It has been shown to have comparable but slightly weaker efficacy than diazepam, clorazepate, lorazepam, and alprazolam and a slower onset of action.⁶ Its utility is mainly associated with its propensity to relieve the cognitive aspects, but it lacks long-term efficacy, particularly in managing the behavioral and somatic manifestations.¹⁴ In addition, patients who had been previously treated with benzodiazepines, especially recently, tend to have a muted response to buspirone (ie, a reduction in the anxiolytic effects).³¹

Tricyclic antidepressants (TCAs), such as imipramine, are typically more effective at attenuating the psychological symptoms of GAD as opposed to the somatic symptoms. Their inhibition of 5-HT and norepinephrine reuptake produces anxiolytic and antidepressant effects. According to a study conducted by Rickels and colleagues,²¹ significant resolution of anxiety was achieved in

patients who took imipramine between weeks 2 and 8 of therapy, and it afforded effects slightly superior to those of trazodone. Psychic symptoms of tension, apprehension, and worry were most effectively reduced in the imipramine arm: 73% of patients achieved moderate to marked improvement.²¹

The SSRIs are generally regarded as first-line medications, according to domestic and international practice guidelines.^{18,32} Paroxetine, specifically, is FDA-approved for the long-term treatment of depression as well as for GAD at dosages of 20 to 50 mg daily. While the 2- to 4-week delay in onset of therapeutic effect may be discouraging, significant reductions in “anxious mood” have been documented as early as 1 week into treatment.

Remission rates in paroxetine responders at 32 weeks, admittedly a selected population of patients who persevere with treatment, are as high as 73%; relapse rates are only 11%. SSRIs have a sustained therapeutic effect and afford additional incremental improvement over a 24-week period.^{14,33} An 8-week, double-blind, placebo-controlled study examined paroxetine’s impact on HAM-A and SDS scores relative to baseline. The groups that received 20 mg and 40 mg of paroxetine demonstrated a statistically and clinically significant change in the HAM-A and psychic anxiety subscale relative to placebo.

In the intent-to-treat group, 62% in the 20-mg arm and 68% in the 40-mg arm met the criteria for response by week 8 ($P < .001$). Response rates were as high as 80% among patients who completed the study. Remission was achieved in 36% of the patients in the 20-mg group and 42% of the patients in the 40-mg group by week 8 ($P = .004$).²²

An SSRI discontinuation syndrome, characterized by dizziness, insomnia, and flu-like symptoms, occurs in approximately 5% of patients on abrupt discontinuation or significant dose reduction.³² This typically manifests within 1 to 7 days of discontinuation in patients who have been taking an

SSRI for at least 1 month.³⁴ Of the SSRIs, paroxetine is most often implicated in withdrawal symptoms: about 35% to 50% of patients experience discontinuation symptoms on abrupt cessation.³⁵ Reinstating the drug resolves symptoms of withdrawal relatively quickly.³⁶ Tapering the SSRI dosage before discontinuation reduces the likelihood of this syndrome.

A promising alternative in first-line treatment in GAD therapy are the serotonin-norepinephrine reuptake inhibitors, which have been studied in both short- and long-term efficacy trials. Venlafaxine XR at a dosage of 75 to 225 mg daily consistently demonstrated superior efficacy versus placebo in improving anxiety symptoms by measure of a reduction in HAM-A total scores.³⁷ The added benefit of venlafaxine's efficacy in treating symptoms of anxiety in patients with comorbid anxiety and depression, in addition to pure GAD, has elevated its status in the treatment algorithm. Response rates approach 70%, and remission rates are as high as 43% short-term and as high as 61% long-term.^{14,38}

The comorbidity of nonspecific somatic pain complaints is common in patients with GAD, which translates into a compounded negative impact on quality of life. A majority of patients (60%) with GAD and concomitant pain report that they experience a moderate to severe change in their somatic symptoms on days when they feel more anxious or depressed.³⁹ Previous use of benzodiazepines was shown to reduce the probability of a response to venlafaxine in a study by Pollack and colleagues,⁴⁰ although there was no substantial impact on attaining long-term remission.

Abrupt discontinuation of venlafaxine also precipitates a discontinuation syndrome with similar or greater frequency than does paroxetine.³⁵ In addition, more diligent patient monitoring is required secondary to its propensity to precipitate hypertension.³²

Duloxetine is indicated for the treatment of anxiety disorders, MDD, neuropathic pain, and fibromyalgia. Its dual impact on anxious symptoms and somatic pain resulted in 53% to 61% of treated patients who achieved a HAM-A score of 7 or less (symptomatic remission) and an about 47% who achieved an SDS score of 5 or less (functional remission).^{1,41} There is a positive correlation between improvement in pain scores and reduction in SDS scores: most patients who achieved remission also reported greater improvements in visual analog pain scales.³⁹ Venlafaxine or an SSRI have been successfully used as initial monotherapy and long-term therapy; both have been shown to be equally effective.³²

Patients with GAD are considerably more intolerant of normal uncertainty, which results in the formation of negative beliefs about uncertainty.⁴² Thus, these patients could benefit from psychosocial therapy. Numerous psychosocial treatment options are available as monotherapy or as adjunctive therapy in combination with a pharmacological agent. A psychosocial therapy that specifically addresses these cognitive aspects and trains patients to develop and apply coping skills that address psychological and somatic symptoms may be useful.^{43,44}

Overcoming the barriers to remission

A multitude of factors are responsible for worsened outcomes and reduced probability of achieving remission in patients with GAD. Stressful life events, anxiety sensitivity, negative affect, gender, subsyndromal symptoms, and comorbidities all have a palpable impact on the course of illness and outcome. Frequently, patients elect to not complete long-term treatment and thus, life stressors may perpetuate subsyndromal symptoms. Although GAD is characterized by alternating periods of quiescence and exacerbation, the presence of comorbid depression, panic, or any Axis I or Axis II disorder, and a higher initial symptom rating, greatly lessens the possibility of remission.⁴⁵⁻⁴⁷ Pollack and colleagues⁴⁰ found that restlessness predicted a worse treatment outcome, while sleep disturbance was typically associated with a more optimistic outcome.

Most patients who present with GAD have been ill for an average of 15 years before seeking help. As evidenced consistently by the literature, patients with GAD may decide to discontinue medication once they experience some improvement of symptoms.¹⁵ Unfortunately, once they respond positively to treatment, many patients will settle for that level of response instead of continuing therapy. This decision typically arises from fear of dependence on medication.¹⁵ Discontinuation of medication may briefly elicit a mild improvement, secondary to the psychological empowerment of self-management, but it will frequently lead to relapse.⁴⁵ This drives the need for extensive patient education and clear, focused, patient-physician interactions.

Symptomatic remission traditionally precedes functional remission. Patient awareness of this fact should stem the inclination to discontinue therapy prematurely. Most of the first-line, long-term pharmacotherapies for GAD take 2 or more weeks to exert a full pharmacodynamic effect. The interval between the initial prescription of medication and a realization of effect may discourage adherence at an early stage. The likelihood of adherence can be increased by educating the patient about the expected onset of action and by prescribing a benzodiazepine at the start of long-term therapy.⁴⁸

The majority of patients with GAD present to their primary care physician with a somatic complaint that is seemingly unrelated to GAD. This “masquerading” is another potential barrier to treatment.⁴ The inadvertent misdiagnosis of GAD or failure to identify a comorbid disorder results in poor treatment outcomes. Patients who are adherent and do not respond partially or fully to an appropriate medication may need to be reevaluated by a psychiatrist. Reevaluation may well lead to an alternative diagnosis and treatment regimen. Patients who present with predominantly depressive symptoms may be inaccurately labeled as depressed and treated accordingly. Treatment of depressive symptoms alone will not attenuate the somatic or functional aspects of GAD.⁴⁹

Owing to the cyclical pattern of exacerbation and quiescence, many patients present for care during episodic exacerbations when symptoms are most debilitating. The risk is that the perceived acute anxiety will be treated as such, and the underlying, chronic anxiety will not be appropriately resolved.³⁸ Inappropriate resolution of the chronic component of GAD will functionally impede remission and the prevention of relapse. Chronic pharmacotherapeutic treatment, as in MDD, is indicated for most patients who have GAD.

Whether early symptomatic improvement is a potential predictor of future response is currently being explored. A diminution in anxious symptoms within the first 2 weeks of drug therapy may predict remission. Pollack and colleagues¹¹ found that significant improvement by week 2 of treatment translated into an increased likelihood of a clinical HAM-A response and remission of functional disability (SDS). Even moderate symptomatic improvement early on yielded functional remission by the end of week 2.

Conclusions

A constellation of factors influence the likelihood of attaining remission of GAD. The frequent presence of psychiatric or physical comorbidities complicates the clinical picture. Depression is the most prevalent of the psychiatric comorbidities and, as a result, incomplete treatment or misdiagnosis of GAD is often a root cause for treatment failure. Patient nonadherence, high initial symptom ratings, and interpatient variability in clinical presentation of GAD all contribute to the modest remission rates. Perhaps the most consequential factor in determining the propensity for success of GAD treatment is the use of an appropriate drug for an appropriate length of time. The duration of treatment is proportional to the magnitude of the outcome and the potential for realizing symptomatic and functional remission.

While not achievable in all patients, remission is the most appropriate therapeutic goal for GAD. Patients with personality problems and a multitude of comorbidities for whom the illness provides

secondary gain may have difficulty in achieving remission. Although attaining remission is complicated by numerous treatment- and patient-related barriers, overcoming these challenges is feasible in the majority of patients. The diagnosis of GAD must be distinct from any other intervening psychiatric or somatic disorders. While the level of comorbidity is relatively high, the GAD diagnosis must be reliable and not confounded by other disorders. Treatment outcome goals must be clearly established in advance of therapy and should be based on the individual patient's needs.

Psychotropic drug therapy for appropriate treatment duration is the foundation of successful therapy. A single drug is typically initially prescribed for patients who have GAD. Inadequate responses to monotherapy may warrant the addition of a second pharmacological agent or psychotherapy. Augmentation of drug therapy with benzodiazepines for 3 to 4 weeks and then gradually tapering the benzodiazepine may further reduce the reemergence of anxiety symptoms.⁶ Patients who demonstrate incomplete remission or lack of response need to be reevaluated in a timely manner to confirm the GAD diagnosis. In adherent patients for whom an appropriate duration of single drug therapy is unsuccessful, consider augmentation with a benzodiazepine or an anxiolytic with a different mechanism of action. The addition of a psychotherapeutic modality and/or a new pharmacological agent may generate additional benefit. Continuation of pharmacotherapy for 6 to 12 months beyond symptom resolution increases the likelihood of a sustained remission and decreases the likelihood of relapse.

Drugs Mentioned in This Article

Alprazolam (Xanax)

Buspirone (BuSpar)

Clorazepate (ClarazeCaps, others)

Diazepam (Valium)

Duloxetine (Cymbalta)

Imipramine (Tofranil)

Lorazepam (Ativan)

Paroxetine (Paxil)

Trazodone (Desyrel)

Venlafaxine (Effexor)

Taming THC: potential cannabis synergy and phytocannabinoid-terpenoid entourage effects – 145

Patient-Reported Symptom Relief Following Medical Cannabis Consumption – 168

Key Findings

Marijuana's schedule I status makes studies on its medical use difficult to conduct. Because of this, evidence that medical marijuana is effective in treating generalized anxiety disorder is more limited than that of an FDA approved pharmaceutical, but significant evidence of medical marijuana's effectiveness can still be seen.

New Evidence

Cannabidiol in Anxiety and Sleep: A Large Case Series

CBD appears to be better tolerated than routine psychiatric medications. Furthermore, CBD displays promise as a tool for reducing anxiety in clinical populations.

Use of cannabidiol in anxiety and anxiety-related disorders

CBD has consistently demonstrated acute reduction in anxiety-related symptoms in patients, specifically within GAD and SAD. Additionally, the use of CBD for these disorders has shown increasingly minimal adverse effects compared with existing pharmacotherapy.

Cannabis use behaviors and prevalence of anxiety and depressive symptoms in a cohort of Canadian medicinal cannabis users

The vast majority of patients perceived symptom improvement with CMP (cannabis for medical purposes) use and did not believe CMP use was associated with impairment or an inability to control use.

Previously Submitted Evidence

Cannabidiol, a Cannabis sativa constituent, as an anxiolytic drug

Studies using animal models of anxiety and involving healthy volunteers clearly suggest an anxiolytic-like effect of CBD.

The Endocannabinoid System and the Brain

Cannabidiol, which does not bind to either CB1 or CB2, possesses anxiolytic and antipsychotic properties (Mechoulam et al. 2002) both in animals and in humans.

Anxiogenic-like effects of chronic cannabidiol administration in rats

Chronic administration of CBD produced an anxiogenic-like effect in clear opposition to the acute anxiolytic profile previously reported. In addition, CBD decreased the expression of proteins that have been shown to be enhanced by chronic treatment with antidepressant/anxiolytic drugs.

Effects of Cannabidiol (CBD) on Regional Cerebral Blood Flow

These results suggest that CBD has anxiolytic properties, and that these effects are mediated by an action on limbic and paralimbic brain areas.

Multiple mechanisms involved in the large-spectrum therapeutic potential of cannabidiol in psychiatric disorders

In agreement with the results obtained in animal models, clinical studies confirmed that CBD has anxiolytic properties

Cannabidiol as a Potential Treatment for Anxiety Disorders

Overall, current evidence indicates CBD has considerable potential as a treatment for multiple anxiety disorders...

Cannabis Use in HIV for Pain and Other Medical Symptoms

Relief of symptoms of anxiety and depression was common, as was general symptom relief.

Effectiveness of Cannabidiol Oil for Pediatric Anxiety and Insomnia as Part of Posttraumatic Stress Disorder: A Case Report

Cannabidiol oil, an increasingly popular treatment of anxiety and sleep issues, has been documented as being an effective alternative to pharmaceutical medications. This case study provides clinical data that support the use of cannabidiol oil as a safe treatment for reducing anxiety ...

Who Are Medical Marijuana Patients? Population Characteristics from Nine California Assessment Clinics

37.8% of patients in this study reported a benefit of medical marijuana was a reduction in anxiety symptoms.

Therapeutic Benefits of Cannabis: A Patient Survey

Other reported therapeutic benefits [of cannabis] included relief from stress/anxiety (50% of respondents), relief of insomnia (45%), improved appetite (12%), decreased nausea (10%), increased focus/concentration (9%), and relief from depression (7%). Several patients wrote notes (see below) relating that cannabis helped them to decrease or discontinue medications for pain, anxiety, and insomnia.

Therapeutic Benefits of Cannabis: A Patient Survey – Medical Cannabis in Arizona: Patient Characteristics, Perceptions, and Impressions of Medical Cannabis Legalization

82.9% of patients studied reported relief from anxiety symptoms.

Taming THC: potential cannabis synergy and phytocannabinoid-terpenoid entourage effects

The myriad effects of CBD on 5-HT_{1A} activity provide a strong rationale for this and other phytocannabinoids as base compounds for treatment of anxiety

Patient-Reported Symptom Relief Following Medical Cannabis Consumption

The first two regressions shown in Table 2 indicate that people with anxiety and depression report greater relief from using cannabis than people with chronic pain, and users with higher starting symptom levels report greater symptom relief.

Cannabidiol in Anxiety and Sleep: A Large Case Series

ABSTRACT

Context: Cannabidiol (CBD) is one of many cannabinoid compounds found in cannabis. It does not appear to alter consciousness or trigger a “high.” A recent surge in scientific publications has found preclinical and clinical evidence documenting value for CBD in some neuropsychiatric disorders, including epilepsy, anxiety, and schizophrenia. Evidence points toward a calming effect for CBD in the central nervous system. Interest in CBD as a treatment of a wide range of disorders has exploded, yet few clinical studies of CBD exist in the psychiatric literature.

Objective: To determine whether CBD helps improve sleep and/or anxiety in a clinical population.

Design: A large retrospective case series at a psychiatric clinic involving clinical application of CBD for anxiety and sleep complaints as an adjunct to usual treatment. The retrospective chart review included monthly documentation of anxiety and sleep quality in 103 adult patients.

Main Outcome Measures: Sleep and anxiety scores, using validated instruments, at baseline and after CBD treatment.

Results: The final sample consisted of 72 adults presenting with primary concerns of anxiety (n = 47) or poor sleep (n = 25). Anxiety scores decreased within the first month in 57 patients (79.2%) and remained decreased during the study duration. Sleep scores improved within the first month in 48 patients (66.7%) but fluctuated over time. In this chart review, CBD was well tolerated in all but 3 patients.

Conclusion: Cannabidiol may hold benefit for anxiety-related disorders. Controlled clinical studies are needed.

INTRODUCTION

The *Cannabis* plant has been cultivated and used for its medicinal and industrial benefits dating back to ancient times. *Cannabis sativa* and *Cannabis indica* are the 2 main species.¹ The *Cannabis* plant contains more than 80 different chemicals known as cannabinoids. The most abundant cannabinoid, tetrahydrocannabinol (THC), is well known for its psychoactive properties, whereas cannabidiol (CBD) is the second-most abundant and is nonpsychoactive. Different strains of the plant are grown containing varying amounts of THC and CBD. Hemp plants are grown for their fibers and high levels of CBD that can be extracted to make oil, but marijuana plants grown for recreational use have higher concentrations of THC compared with CBD.² Industrial hemp must contain less than 0.3% THC to be considered legal, and it is from this plant that CBD oil is extracted.³

Many different cultures have used the *Cannabis* plant to treat a plethora of ailments. Practitioners in ancient China targeted malaria, menstrual symptoms, gout, and constipation. During medieval times, cannabis was used for pain, epilepsy, nausea,

and vomiting, and in Western medicine it was commonly used as an analgesic.^{4,5} In the US, physicians prescribed *Cannabis sativa* for a multitude of illnesses until restrictions were put in place in the 1930s and then finally stopped using it in 1970 when the federal government listed marijuana as a Schedule I substance, claiming it an illegal substance with no medical value. California was the first state to go against the federal ban and legalize medical marijuana in 1996.⁶ As of June 2018, 9 states and Washington, DC, have legalized recreational marijuana, and 30 states and Washington, DC, allow for use of medical marijuana.⁷ The purpose of the present study is to describe the effects of CBD on anxiety and sleep among patients in a clinic presenting with anxiety or sleep as a primary concern.

CBD has demonstrated preliminary efficacy for a range of physical and mental health care problems. In the decade before 2012, there were only 9 published studies on the use of cannabinoids for medicinal treatment of pain; since then, 30 articles have been published on this topic, according to a PubMed search conducted in December 2017. Most notable was a study conducted at the University of California, San Diego’s Center for Medicinal Cannabis Research that showed cannabis cigarettes reduced pain by 34% to 40% compared with placebo (17% to 20% decrease in pain).⁸ In particular, CBD appears to hold benefits for a wide range of neurologic disorders, including decreasing major seizures. A recent large, well-controlled study of pediatric epilepsy documented a beneficial effect of CBD in reducing seizure frequency by more than 50%.⁹ In addition to endorphin release, the “runner’s high” experience after exercise has been shown to be induced in part by anandamide acting on CB1 receptors, eliciting anxiolytic effects on the body.¹⁰ The activity of CBD at 5-HT_{1A} receptors may drive its neuroprotective, antidepressive, and anxiolytic benefits, although the mechanism of action by which CBD decreases anxiety is still unclear.¹¹ CBD was shown to be helpful for decreasing anxiety through a simulated public speaking test at doses of 300 mg to 600 mg in single-dose studies.¹²⁻¹⁴ Other studies suggest lower doses of 10 mg/kg having a more anxiolytic effect than higher doses of 100 mg/kg in rats.¹⁵ A crossover study comparing CBD with nitrazepam found that high-dose CBD at 160 mg increased the duration of sleep.¹⁶ Another crossover study showed that

plasma cortisol levels decreased more significantly when given oral CBD, 300 to 600 mg, but these patients experienced a sedative effect.¹⁷ The higher doses of CBD that studies suggest are therapeutic for anxiety, insomnia, and epilepsy may also increase mental sedation.¹⁶ Administration of CBD via different routes and long-term use of 10 mg/d to 400 mg/d did not create a toxic effect on patients. Doses up to 1500 mg/d have been well tolerated in the literature.¹⁸ Most of the research done has been in animal models and has shown potential benefit, but clinical data from randomized controlled experiments remain limited.

Finally, the most notable benefit of cannabis as a form of treatment is safety. There have been no reports of lethal overdose with either of the cannabinoids and, outside of concerns over abuse, major complications are very limited.¹⁹ Current research indicates that cannabis has a low overall risk with short-term use, but more research is needed to clarify possible long-term risks and harms.

Given the promising biochemical, physiologic, and preclinical data on CBD, a remarkable lack of randomized clinical trials and other formal clinical studies exist in the psychiatric arena. The present study describes a series of patients using CBD for treatment of anxiety or sleep disturbances in a clinical practice setting. Given the paucity of data in this area, clinical observations can be quite useful to advance the knowledge base and to offer questions for further investigation. This study aimed to determine whether CBD is helpful for improving sleep and/or anxiety in a clinical population. Given the novel nature of this treatment, our study also focused on tolerability and safety concerns. As a part of the evolving legal status of cannabis, our investigation also looked at patient acceptance.

METHODS

Design and Procedures

A retrospective chart review was conducted of adult psychiatric patients treated with CBD for anxiety or sleep as an adjunct to treatment as usual at a large psychiatric outpatient clinic. Any current psychiatric patient with a diagnosis by a mental health professional (psychiatrist, psychiatric nurse practitioner, or physician assistant) of a sleep or anxiety disorder was considered. Diagnosis was made by clinical evaluation followed by baseline psychologic measures. These measures were repeated monthly. Comorbid psychiatric illnesses were not a basis for exclusion. Accordingly, other psychiatric medications were administered as per routine patient care. Selection for the case series was contingent on informed consent to be treated with CBD for 1 of these 2 disorders and at least 1 month of active treatment with CBD. Patients treated with CBD were provided with psychiatric care and medications as usual. Most patients continued to receive their psychiatric medications. The patient population mirrored the clinic population at large with the exception that it was younger.

Nearly all patients were given CBD 25 mg/d in capsule form. If anxiety complaints predominated, the dosing was every morning, after breakfast. If sleep complaints predominated, the dosing was every evening, after dinner. A handful of patients were given CBD 50 mg/d or 75 mg/d. One patient with a trauma history

and schizoaffective disorder received a CBD dosage that was gradually increased to 175 mg/d.

Often CBD was employed as a method to avoid or to reduce psychiatric medications. The CBD selection and dosing reflected the individual practitioner's clinical preference. Informed consent was obtained for each patient who was treated and considered for this study. Monthly visits included clinical evaluation and documentation of patients' anxiety and sleep status using validated measures. CBD was added to care, dropped from care, or refused as per individual patient and practitioner preference. The Western Institutional Review Board, Puyallup, WA, approved this retrospective chart review.

Setting and Sample

Wholeness Center is a large mental health clinic in Fort Collins, CO, that focuses on integrative medicine and psychiatry. Practitioners from a range of disciplines (psychiatry, naturopathy, acupuncture, neurofeedback, yoga, etc) work together in a collaborative and cross-disciplinary environment. CBD had been widely incorporated into clinical care at Wholeness Center a few years before this study, on the basis of existing research and patient experience.

The sampling frame consisted of 103 adult patients who were consecutively treated with CBD at our psychiatric outpatient clinic. Eighty-two (79.6%) of the 103 adult patients had a documented anxiety or sleep disorder diagnosis. Patients with sole or primary diagnoses of schizophrenia, posttraumatic stress disorder, and agitated depression were excluded. Ten patients were further excluded because they had only 1 documented visit, with no follow-up assessment. The final sample consisted of 72 adult patients presenting with primary concerns of anxiety (65.3%; $n = 47$) or poor sleep (34.7%; $n = 25$) and who had at least 1 follow-up visit after CBD was prescribed.

Main Outcome Measures

Sleep and anxiety were the targets of this descriptive report. Sleep concerns were tracked at monthly visits using the Pittsburgh Sleep Quality Index. Anxiety levels were monitored at monthly visits using the Hamilton Anxiety Rating Scale. Both scales are nonproprietary. The Hamilton Anxiety Rating Scale is a widely used and validated anxiety measure with 14 individual questions. It was first used in 1959 and covers a wide range of anxiety-related concerns. The score ranges from 0 to 56. A score under 17 indicates mild anxiety, and a score above 25 indicates severe anxiety. The Pittsburgh Sleep Quality Index is a self-report measure that assesses the quality of sleep during a 1-month period. It consists of 19 items that have been found to be reliable and valid in the assessment of a range of sleep-related problems. Each item is rated 0 to 3 and yields a total score from 0 to 21. A higher number indicates more sleep-related concerns. A score of 5 or greater indicates a "poor sleeper."

Side effects and tolerability of CBD treatment were assessed through spontaneous patient self-reports and were documented in case records. Any other spontaneous comments or complaints of patients were also documented in case records and included in this analysis.

Data Analysis

Deidentified patient data were evaluated using descriptive statistics and plotted graphically for visual analysis and interpretation of trends.

RESULTS

The average age for patients with anxiety was 34 years (range = 18-70 years) and age 36.5 years for patients with sleep disorders (range = 18-72 years). Most patients with an anxiety diagnosis were men (59.6%, 28/47), whereas more sleep-disordered patients were women (64.0%, 16/25). All 72 patients completed sleep and anxiety assessments at the onset of CBD treatment and at the first monthly follow-up. By the second monthly follow-up, 41 patients (56.9%) remained on CBD treatment and completed assessments; 27 patients (37.5%) remained on CBD treatment at the third monthly assessment.

Table 1 provides means and standard deviations for sleep and anxiety scores at baseline and during the follow-up period for adults taking CBD. Figure 1 graphically displays the trend in anxiety and sleep scores over the study period. On average, anxiety and sleep improved for most patients, and these improvements were sustained over time. At the first monthly assessment after the start of CBD treatment, 79.2% (57/72) and 66.7% (48/72) of all patients experienced an improvement in anxiety and sleep, respectively; 15.3% (11/72) and 25.0% (18/72) experienced worsening symptoms in anxiety and sleep, respectively. Two months after the start of CBD treatment, 78.1% (32/41) and 56.1% (23/41) of patients reported improvement in anxiety and sleep, respectively, compared with the prior monthly visit; again, 19.5% (8/41) and 26.8% (11/41), respectively, reported worsening problems as compared with the prior month.

These results demonstrated a more sustained response to anxiety than for sleep over time. Patient records displayed a larger decrease in anxiety scores than in sleep scores. The sleep scores demonstrated mild improvement. The anxiety scores decreased within the first month and then remained decreased during the study duration.

Parameter	HAM-A, mean (SD)	PSQI, mean (SD)
Anxiety (n = 47)		
Baseline	23.87 (9.87)	10.98 (3.43)
1-month follow-up	18.02 (7.56)	8.88 (3.68)
2-month follow-up	16.35 (8.80)	8.59 (2.91)
3-month follow-up	16.36 (9.80)	9.25 (2.46)
Sleep disorder (n = 25)		
Baseline	22.18 (7.55)	13.08 (3.03)
1-month follow-up	17.82 (9.72)	10.64 (3.89)
2-month follow-up	17.36 (10.91)	9.39 (3.81)
3-month follow-up	13.78 (7.86)	9.33 (4.63)

HAM-A = Hamilton Anxiety Rating Scale; PSQI = Pittsburgh Sleep Quality Index; SD = standard deviation.

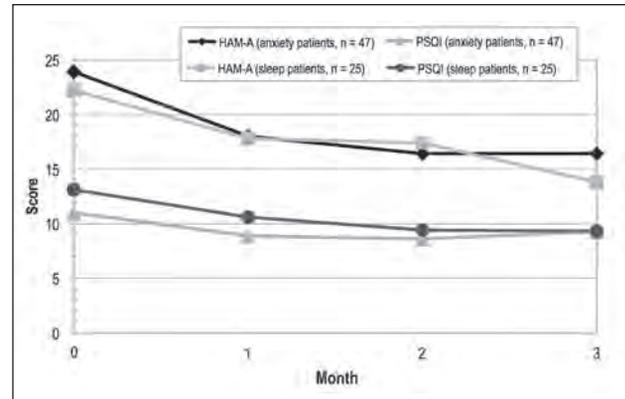

Figure 1. Mean anxiety and sleep scores for adults using cannabidiol treatment. HAM-A = Hamilton Anxiety Rating Scale; PSQI = Pittsburgh Sleep Quality Index.

CBD was well tolerated, with few patients reporting side effects. Two patients discontinued treatment within the first week because of fatigue. Three patients noted mild sedation initially that appeared to abate in the first few weeks. One patient with a developmental disorder (aged 21 years) had to be taken off the CBD regimen because of increased sexually inappropriate behavior. The CBD was held, and the behavior disappeared. The behavior reappeared on redosing 2 weeks later, and the CBD regimen was formally discontinued. The treating psychiatrist thought this was related to disinhibition because the patient's anxiety responded dramatically. One patient noted dry eyes. Reasons for patients not following-up at later assessment points are largely unknown but are probably because of standard attrition experienced in usual clinical practice. There was no evidence to suggest patients discontinued care because of tolerability concerns. The attrition rates were similar in nature and size to those found in routinely scheduled visits in this clinic.

The treatment with CBD was in general well accepted, as judged by the clinicians' and patients' responses. Four patients declined CBD treatment because of religious or ethical concerns about the relation to cannabis. Nearly all patients easily provided informed consent once the nature of the treatment was explained. Most patients appreciated the opportunity to try something natural and avoid further or initial psychiatric medication use.

DISCUSSION

In an outpatient psychiatric population, sleep scores displayed no sustained improvements during the 3-month study. Anxiety scores decreased fairly rapidly, and this decrease was sustained during the study period. These results are consistent with the existing preclinical and clinical data on CBD. CBD was well accepted and well tolerated in our patients. Side effects were minimal (mainly fatigue) and may be related to dosing.

The doses used in this study (25 mg/d to 175 mg/d) were much lower than those reported in some of the clinical literature (300 mg/d to 600 mg/d)^{12-14,17} for 2 reasons. The first is that in our experience lower doses appear to elicit an adequate clinical

response. Second, the current retail cost of CBD would make the use of 600 mg/d cost prohibitive.

Study Limitations

These results must be interpreted cautiously because this was a naturalistic study, all patients were receiving open-label treatment, and there was no comparison group. Concurrent psychiatric medications were employed as in routine clinical care. This is both a limitation and strength, as very few publications exist in this population. Other researchers have noted that the large societal notoriety about cannabis and medical marijuana probably contributes to a larger-than-normal placebo effect.²⁰ Any study that explores efficacy in this therapy probably will struggle with a potentially inflated placebo effect that will make these determinations more difficult. Likewise, the clinical population in this case series is skewed younger than typical for our clinic, and future studies could explore the possible selection bias inherent in this treatment option. Most patients were also taking psychiatric medications and receiving other mental health services, such as counseling, which limits the ability to make any causal links to CBD treatment. Clinical attrition is evident in the dataset. The reason for this might be related to CBD ingestion or not, so the overall component remains unclear. Furthermore, patients at our clinic often express a desire to reduce or to avoid use of psychiatric medications, which may contribute to an enhanced placebo effect or additional bias. The length of clinical monitoring may help to decrease this concern. However, the clinical data in this analysis show a trend toward clinically significant relief of anxiety upon the start of CBD treatment.

Legality of Cannabidiol

The legality of CBD is not clear. Like the issues surrounding the legality of cannabis in general, CBD presents the clinician with a confusing state vs federal legal quandary, and this keeps the issue in question. CBD is legal in the 33 states that have legalized medical or recreational use of marijuana and in 17 other states that have legalized some form of CBD, according to the National Organization for the Reform of Marijuana Laws (NORML).²¹ But like marijuana, it is still not legal at the federal level. The federal government has announced that it is not focused on this compound in terms of enforcement or interdiction.²² However, CBD is interpreted by the Drug Enforcement Administration, Food and Drug Administration, and Congress to be a Schedule I substance, and therefore it is illegal in all 50 states.²³ Pragmatically, CBD is widely available on the Internet, with sales expected to reach \$1 billion by 2020. Pending federal legislation to redefine the legal status of cannabis would clarify this complex issue. Canada's move to legalize cannabis in October 2018 further highlights the need for a speedy resolution to this question.²⁴

CONCLUSION

Formal studies on efficacy and dose finding are much needed. Some urgency exists, given the explosion of lay interest in this topic and the rush to market these compounds. Current

understanding of the physiology and neurologic pathways points to a benefit with anxiety-related issues. The results of our clinical report support the existing scientific evidence. In our study, we saw no evidence of a safety issue that would limit future studies. In this evaluation, CBD appears to be better tolerated than routine psychiatric medications. Furthermore, CBD displays promise as a tool for reducing anxiety in clinical populations, but given the open-label and nonrandomized nature of this large case series, all results must be interpreted very cautiously. Randomized and controlled trials are needed to provide definitive clinical guidance. ❖

Disclosure Statement

Dr Shannon has published several professional books on integrative mental health. Dr Shannon is a Principal Investigator for a Phase 3 study of 3,4-methylenedioxy-methamphetamine (MDMA)-assisted psychotherapy for severe posttraumatic stress disorder and receives compensation for his clinical work from the Multidisciplinary Association for Psychedelic Studies, Santa Cruz, CA. The other authors have no conflicts of interests to disclose.

Acknowledgments

CV Sciences Inc, Las Vegas, NV, provided cannabidiol products for the study. CV Sciences was not involved in the data collection, data interpretation, preparation of the report, or decision to submit the report for publication. No other financial support was provided. The authors would like to express their deep appreciation to the staff and clinicians at Wholeness Center for their professionalism.

Kathleen Loudon, ELS, of Loudon Health Communications provided editorial assistance.

REVIEW

Use of cannabidiol in anxiety and anxiety-related disorders

Jessica W. Skelley*, Crystal M. Deas, Zachary Curren, Jonathan Ennis

ARTICLE INFO

Article history:

Received 31 July 2019

Accepted 8 November 2019

ABSTRACT

Objective: Cannabidiol (CBD) has a proposed novel role in the management of anxiety owing to its actions on the endocannabinoid system. The purpose of this systematic review was to evaluate the current evidence on the safety and efficacy of CBD in anxiety and anxiety-related disorders.

Data sources: A literature search was conducted on PubMed, Google Scholar, and International Pharmaceutical Abstracts from database inception through June 2019. A bibliographic search of relevant articles was also conducted.

Study selection: Articles published from case reports, case series, or randomized controlled trials on human subjects were included in the review if they examined the safety and efficacy of CBD therapy in anxiety and anxiety-related disorders.

Data extraction: Two reviewers independently extracted the following data from the articles: year of publication; study design; patient characteristics (sex; type of anxiety disorder; use of concomitant anxiolytic therapy); dosing strategy and route of CBD administration; and safety and efficacy outcomes.

Results: Eight articles were included in the review: 6 small, randomized controlled trials; 1 case series; and 1 case report. These studies examined the role of CBD in the anxiety response of healthy volunteers; in generalized anxiety disorder; in social anxiety disorder; and in the anxiety component of posttraumatic stress syndrome. No articles that evaluated CBD in panic disorder, specific phobia, separation anxiety, and obsessive-compulsive disorder were identified. In the studies, CBD was administered orally as a capsule or as a sublingual spray and as either monotherapy or adjunctive therapy. Doses varied widely, with studies employing fixed CBD doses ranging from 6 mg to 400 mg per dose. Various anxiety assessment scales were used in the studies to assess efficacy, with CBD demonstrating improved clinical outcomes among the instruments. In general, CBD was well-tolerated and associated with minimal adverse effects, with the most commonly noted adverse effects being fatigue and sedation.

Conclusion: CBD has a promising role as alternative therapy in the management of anxiety disorders. However, more studies with standardized approaches to dosing and clinical outcome measurements are needed to determine the appropriate dosing strategy for CBD and its place in therapy.

Background

Anxiety is an adaptive, emotional response that naturally occurs as a result of a perceived threat.¹ Anxiety becomes maladaptive when it occurs excessively or inappropriately in the absence of relevant threatening stimuli.¹ The exact pathophysiology of anxiety-related disorders is unknown.

Disclosure: The authors declare no relevant conflicts of interest or financial relationships.

However, results from neuroimaging and biochemical studies suggest that the variation between adaptive and maladaptive anxiety responses is modulated by regions of the limbic system—primarily the amygdala—and key neurotransmitters, such as dopamine (DA), norepinephrine (NE), γ -aminobutyric acid (GABA), and serotonin (5-HT).²

Within *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)*, generalized anxiety disorder (GAD), panic disorder (PD), social anxiety disorder (SAD), specific phobia (SP), and separation anxiety are classified as anxiety disorders. Obsessive-compulsive disorder (OCD) and post-traumatic stress disorder (PTSD) share a common symptomatology of excessive anxiety; however, they are reviewed in their own respective chapters within *the DSM-5*, after the

Key Points**Background:**

- As a group, anxiety disorders and anxiety-related disorders are the most common psychiatric conditions in the United States. As such, they pose a serious disease burden to patients and the health care system because of decreased well-being, physical impairment, loss of productivity, and increased health care utilization costs.
- At present, the mainstay agents for treatment of anxiety have limitations in efficacy and are associated with a number of adverse effects, which suggests the need for new pharmacotherapies for these disorders.
- Cannabidiol (CBD) is a nonhallucinogenic chemical compound, derived from the plant *Cannabis sativa*, with a novel role in the management of anxiety.
- This article provides a review of evidence on the clinical efficacy and safety of CBD used to manage anxiety and anxiety-related disorders.

Findings:

- In the studies reviewed, CBD consistently demonstrated improved clinical outcomes in anxiety disorders, with a minimal adverse-effect profile.
- However, optimal dose, route of administration, and dosing strategy (acute vs. chronic use) of CBD in the management of anxiety disorders remain undetermined.
- Pharmacists have an essential role in advising patients and prescribers on the use of alternative therapies. Given the heightened popularity of CBD, it is crucial that pharmacists are knowledgeable about its benefits and are able to provide appropriate recommendations on the place in therapy of CBD in the treatment of common disorders, such as anxiety.

chapter on anxiety disorders. As a group, the anxiety disorders and anxiety-related disorders of PTSD and OCD are the most common psychiatric conditions in the United States.³ Taken together, these disorders have an estimated lifetime prevalence of approximately 29% for U.S. adults.^{3,4} As such, they pose a substantial disease burden to patients and the health care system because of their association with decreased well-being, physical impairment, loss of productivity, and increased health care utilization costs.^{3,4}

At present, the primary pharmacologic treatment for anxiety and anxiety-related disorders involves the use of medications that modulate the activity of DA, NE, GABA, and 5-HT neurotransmitters. Benzodiazepines are prescribed commonly because of their modulation of GABA. Likewise, antidepressants such as selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, tricyclic antidepressants, 5-HT receptor antagonists, monoamine oxidase inhibitors, and buspirone are frequently used for their effects

on DA, NE, and 5-HT. Less commonly prescribed agents for anxiety and anxiety-related disorders include second generation antipsychotics, anticonvulsants, and certain antihistamines, such as hydroxyzine. These pharmacotherapies have limitations in efficacy and are associated with a number of adverse effects (e.g., sexual dysfunction and potential for dependence and tolerance), which suggests the need for novel therapeutic modalities for management of anxiety and anxiety-related disorders.^{5–7}

The endocannabinoid system (ECS) is a promising therapeutic target for anxiolytic-drug development owing to its purported role in modulating synaptic plasticity and neuronal activity involved in the anxiety response.^{4,5,8–12} Primary activity of signaling within the ECS is thought to be because of the action on 2 known cannabinoid receptors, CB1 and CB2.^{4,5,8–12} Cannabidiol (CBD), a chemical compound known as a phytocannabinoid, is derived from the plant *Cannabis sativa* and may have a role in the management of anxiety given its pharmacologic activity within the ECS.^{4,5,8–12} Among the more than 400 chemicals produced by *C sativa*, delta-9-tetrahydrocannabinol (THC) and CBD are the major compounds.^{4,5,8–12} THC is the most abundant psychoactive chemical and is primarily responsible for the well-known hallucinogenic effects of *C sativa*. In contrast, CBD is not psychoactive.^{4,5,8–12}

In the literature, CBD has several proposed therapeutic effects accomplished through multiple mechanisms. Despite low affinity for CB1 and CB2 receptors, CBD has proposed indirect activity on the ECS through its action of inhibiting the inactivation of anandamide—a neurotransmitter within the ECS—which leads to activity on the CB1 receptor.^{4,5,8–12} This mechanism, in conjunction with activity on 5-HT_{1A} receptors, is believed to be a key factor in the reported therapeutic effects of CBD in anxiety.^{4,5,8–12} Available literature suggests a favorable adverse-effect profile of CBD and minimal drug interaction potential when compared with other therapeutic agents; however, it should be noted that there is a dearth of studies examining these parameters.¹³

CBD can be administered through various routes of administration and is currently available and marketed in numerous formulations, such as tinctures administered under the tongue, concentrated oil administered orally or topically, topical compounds such as ointments and creams, vaporized solutions, and infused beverages and food items. In the United States, there is only 1 Food and Drug Administration (FDA)-approved CBD product, Epidiolex, which is approved for treatment of seizures associated with Lennox-Gastaut syndrome and Dravet syndrome.¹⁴ All other cannabis-derived CBD products remain under the purview of the FDA regulation under the 2018 Farm Bill, and determination of the scope of this regulation is evolving.¹⁵ With the dramatic increase in use of CBD products, it is prudent to assess the validity of therapeutic claims as well as the safety profile.¹⁵ This information will be beneficial to clinicians when examining the risks and benefits of using CBD for pharmacologic activity in anxiety.

Objective

The purpose of this systematic review was to evaluate the current evidence on the safety and efficacy of CBD in the management of anxiety and anxiety-related disorders.

Methods

Data sources

This study was a systematic review conducted according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidance statement.¹⁶ A free text search of PubMed (January 1996-June 2019) was conducted. The term “cannabidiol” was combined with either “generalized anxiety disorder,” or “social anxiety disorder,” or “panic disorder,” or “specific phobia,” or “separation anxiety,” or “post-traumatic stress disorder,” or “obsessive compulsive disorder” with the Boolean operator AND. This free text search was duplicated on Google Scholar and International Pharmaceutical Abstracts. In addition, references of relevant articles were also reviewed.

Study selection

Articles were included in the review if they examined CBD treatment in diagnosed anxiety or anxiety-related disorders or if they evaluated the anxiety response in healthy volunteers. Animal studies, articles evaluating the psychosis components of PTSD and OCD, and studies evaluating the role of CBD in managing THC-related anxiety were excluded from review. In addition, editorials, commentaries, and letters to the editor

were excluded. Two reviewers independently executed the search and screened articles for inclusion.

Data extraction

Two reviewers independently extracted the following data from the articles: year of publication; study design; patient characteristics (sex; type of anxiety disorder; use of concomitant anxiolytic therapy); dosing strategy and route of CBD administration; and safety and efficacy outcomes. Efficacy outcomes included scores on assessment scales for anxiety, such as the Screen for Anxiety-Related Disorders (SCARED), Hamilton Anxiety Rating Scale (HAM-A), Visual Analogue Mood Scale (VAMS), State-Trait Anxiety Inventory (STAI), Bodily Symptoms Scale (BSS), and Negative Self-Statements subscale (SSPS-N).

Results

Study characteristics

A total of 233 potentially relevant articles resulted from the search. Eight articles met criteria for full text review: 6 small, randomized controlled trials; 1 case series; and 1 case report (Figure 1). One article evaluating the role of CBD in the anxiety response of healthy volunteers, 1 assessing CBD in GAD, 1

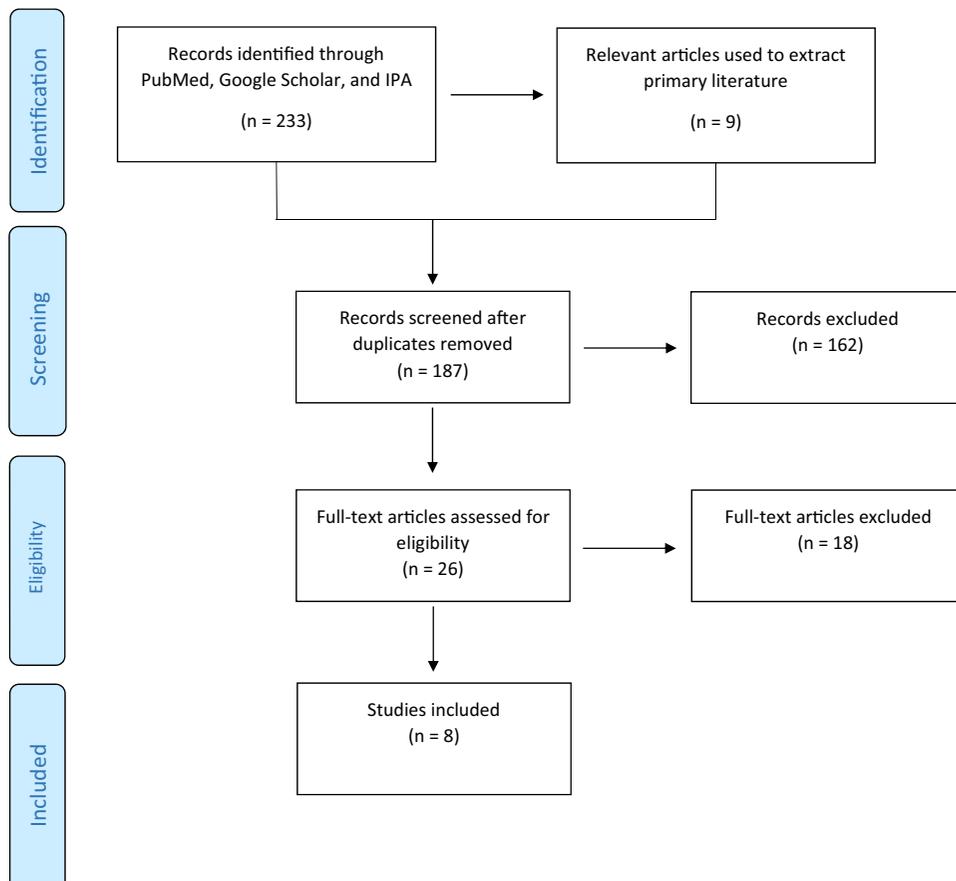

Figure 1. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2009 flow diagram. Abbreviation used: IPA, International Pharmaceutical Abstracts.

evaluating CBD in the anxiety response of PTSD, and 5 articles examining CBD in SAD were identified. No articles on the role of CBD in PD, SP, separation anxiety, or OCD management met the criteria for review. Table 1 summarizes the efficacy and safety outcomes of the studies.

Anxiety response in healthy volunteers: Effects of CBD on regional cerebral blood flow

Crippa et al.¹⁷ conducted a double-blind, crossover study in 10 healthy male patients to evaluate the effect of CBD on neural activity of pathways that normally mediate anxiety, measured through neuroimaging. None of the patients nor their first-degree relatives had a history of psychiatric illness. The participants were separated into 2 groups of 5. Regional cerebral blood flow (rCBF) was measured at rest via single-photon emission computed tomography (SPECT), and each participant was evaluated on 2 occasions separated by 1 week.

At the first session, 1 group received 400 mg of CBD while the other group received placebo, both administered as a gelatin capsule in double-blinded fashion. After 90 minutes, SPECT images were taken. In the second session, the procedure was repeated in a crossover design with those who received placebo being administered CBD and vice versa. VAMS was used to assess subjective feelings of anxiety along with physical sedation, mental sedation, and other attitudes and perceptions. VAMS scores were assessed at 30 minutes before CBD or placebo ingestion, at the time of ingestion, and at 60 and 75 minutes following ingestion. A significant reduction in subjective anxiety, measured through VAMS, was noted following CBD administration at all measurements ($P < 0.001$). In the investigators' comparison of rCBF measurements between CBD and placebo ingestion groups, a significantly ($P < 0.001$) increased uptake of the injected ethyl-cysteinate dimer into the medial temporal cortex along with VAMS findings

Table 2
Considerations for CBD

Potential benefit	Potential risks	
Efficacy	Product variability	Drug interactions
Studies have found CBD to be an effective alternative therapy in the acute treatment of anxiety disorders, specifically:	CBD is considered a dietary supplement, and thus lacks standardization in the following areas:	Potential CYP450 interactions: CBD has been found to be a potent inhibitor of CYP3A4 and CYP2D6, increasing the serum level of the following medications:
<ul style="list-style-type: none"> • GAD • SAD • Anxiety related to PTSD 	<ul style="list-style-type: none"> • Dose-effect response • Dosage strength • Route of administration • Purity • Regulation • Product manufacturing • Labeling 	<ul style="list-style-type: none"> • Warfarin • Macrolides • Calcium channel blockers • Antiretrovirals • Antidepressants • Antipsychotics • Opioids
CBD has shown minimal adverse effects compared with existing pharmacotherapy for acute anxiety.	<ul style="list-style-type: none"> • Patient access • Legal status 	It is important to consider patients with potential genetic polymorphisms of CYP450 enzymes: <ul style="list-style-type: none"> • Decreased CYP2C19 or CYP3A4 have potential risk of CBD accumulation.

Abbreviations used: CBD, cannabidiol; GAD, generalized anxiety disorder; SAD, social anxiety disorder; PTSD, posttraumatic stress disorder.

supported the a priori hypothesis that the limbic and paralimbic areas in the brain are likely mediators of CBD's anxiolytic effect. The study results support findings of another study, which found the role of CBD in GAD to occur owing to effects on the limbic and paralimbic regions of the brain.¹⁸ Crippa et al.¹⁷ noted sedation as an observed adverse effect of CBD in the study but did not expound on the magnitude or frequency of this reported effect.

GAD: CBD in anxiety and sleep

Shannon et al.¹⁹ evaluated the use of open-label CBD therapy on anxiety and sleep levels in a case series of 72 adults seen at a psychiatric outpatient clinic over a 3-month timeframe. Patients were included in the study if they had either a diagnosis of anxiety or a sleep disorder and had at least 1 follow-up visit in the clinic after CBD was prescribed. Patients were excluded if they had a sole or primary diagnosis of schizophrenia, PTSD, or agitated depression. Use of other psychoactive medications and adjunctive counseling services did not preclude participation in this study. Patients' anxiety was assessed through the use of validated HAM-A. On HAM-A, anxiety scores range from 0 to 56, with a score below 17 being indicative of mild anxiety and a score above 25 indicating severe anxiety. Safety was assessed through spontaneous self-report in this study. Patients received CBD in fixed doses, ranging from 25 mg/d to 175 mg/d, with the majority of patients receiving the 25-mg daily dose. All patients completed the 1-month follow-up assessment of HAM-A, whereas 56.9% and 37.5% followed up at the 2- and 3-month timeframes for HAM-A, respectively. At the 1-month assessment, the majority of patients (79.2%) experienced an improvement in anxiety based on HAM-A scores. Of those who followed up at the 2-month assessment, 78.1% demonstrated an improvement in anxiety compared with the prior 1-month visit. There was no appreciable difference in mean HAM-A scores between the 2-month and 3-month follow-up assessments (mean HAM-A scores of 16.35 and 16.36, respectively). A few adverse effects were reported in this study: dry eyes, mild sedation, fatigue, and an increase in sexually inappropriate behaviors. The patients who experienced mild sedation reported

resolution within the first weeks of treatment. Furthermore, a small percentage of patients who experienced fatigue or an increase in sexually inappropriate behavior discontinued therapy. The authors concluded that anxiety scores decreased over the course of the study, and the clinical effect on anxiety was maintained throughout the study duration. CBD was well-tolerated and associated with very few instances of treatment discontinuation.

Anxiety response in PTSD: Effectiveness of CBD oil for pediatric anxiety and insomnia as PTSD

A case report by Shannon et al.²⁰ evaluated the effectiveness of CBD oil in anxiety and sleep disorder secondary to PTSD in a 10-year-old girl. The girl had previously been treated with ineffective pharmacotherapy and had experienced adverse effects from the medication. CBD, administered initially as a capsule and subsequently as a sublingual spray for as-needed dosing, was used for the patient's anxiety and insomnia. The patient was also receiving eicosapentaenoic acid fish oil and diphenhydramine with CBD therapy. The patient was originally initiated on a CBD 25-mg capsule dosed daily, which she took for a duration of 4 months as monotherapy. After 4 months, the patient was prescribed adjunct CBD, administered as an as-needed sublingual spray and dosed at 6–12 mg per spray for breakthrough anxiety symptoms. The patient's anxiety was evaluated using SCARED, with a score above 25 indicating a childhood anxiety disorder. A SCARED score was evaluated before initiation of CBD and then monthly for an additional 5 months, for a total of 6 measurements. From baseline to sixth evaluation, the patient's SCARED score decreased from 34 to 18, a 47.06% reduction. No adverse effects of CBD were reported in this case report. The authors concluded that CBD oil may be an effective option to consider when attempting to reduce anxiety secondary to PTSD.

Healthy volunteer models of SAD: Anxiolytic effect of CBD during public speaking in real life

In this double-blinded study, Zuardi et al.²¹ tested the hypothesis that increasing CBD doses would produce anxiolytic

effects in patients with anxiety. Fifty-nine healthy men and women within the age range of 18–35 years were selected for the study. These patients had no diagnosed anxiety disorder, and no disorders involving alcohol or other substance abuse. However, the study was set up to test anxiety levels in public speaking scenarios as a manifestation of SAD. The volunteers were randomly assigned to 5 groups of 12 participants. Each volunteer received either 1 of 3 doses of CBD capsules (100 mg, 300 mg, or 900 mg), clonazepam 1-mg tablet, or placebo in a double-blinded randomized design. VAMS was used in this study to evaluate anxiety levels as well as the sedative effects of CBD. To assess physiological measurements, systolic blood pressure (BP), diastolic BP, and heart rate were recorded. In the procedure, 1 participant was instructed to speak in front of their group. The other participants who were not speaking at the time were instructed to remain silent with a neutral expression. Each member in the group would take their turn to speak. Each participant's VAMS anxiety and sedation score, BP, and heart rate were recorded at baseline, before the speech, during the middle of the speech, and after the speech. Data were compared at the varying time phases. VAMS scores of subjective anxiety were noted to be significantly decreased when the CBD 300-mg group was compared with the placebo and CBD 100-mg groups during the postspeech phase ($P < 0.05$). Similarly, a significantly greater decrease in VAMS was noted in the comparison of the CBD 300-mg group with the CBD 900-mg group in the speech phase ($P < 0.05$). Higher sedative effects were noted with clonazepam in comparison with the CBD and placebo groups among the phases ($P < 0.05$). The authors concluded that the CBD 300-mg dose had a greater therapeutic effect on anxiety when compared with the 100-mg and 900-mg doses. These results confirmed prior study findings and suggested that CBD induces acute anxiolytic effects with an inverted U-shaped dose-response curve in humans—an effect that, at this time, is not fully understood and should not be considered as an absolute pharmacodynamics principle.^{21,22}

Effects of ipsapirone and CBD on human experimental anxiety

In a double-blinded study, Zuardi et al.²³ used 40 healthy subjects separated into 4 groups of 10 who received either oral CBD 300 mg, diazepam 10 mg, ipsapirone 5 mg, or placebo. The volunteers were subjected to a simulated public speaking test (SPST) to compare the anxiolytic properties of the assigned drug. The effects of these drugs were measured using VAMS, STAI, and BSS, which evaluates somatic symptoms (fatigue, weakness) that would indirectly affect anxiety. After a 15-minute adaptation period, baseline measures were collected before the intervention (drug or placebo) was given. One hour and 20 minutes after the drug was taken, prestress measures were collected. After collection, the subjects watched a video with instructions about the task they would be performing. Each subject had 2 minutes to prepare a 4-minute speech about a topic covered previously in a university course and was told the speech would be recorded and analyzed by a psychologist. Anticipatory anxiety measurements were taken before the subject began speaking. During the middle of the speech, researchers interrupted the subject and subjective anxiety measurements were collected. Fifteen minutes after the speech ended, poststress measurements were collected. The VAMS results of the study demonstrated

that there was a significant increase in subjective anxiety in all groups ($P < 0.001$) during the SPST procedure. Diazepam significantly decreased subjective anxiety throughout the study when compared with placebo ($P = 0.016$). Specifically, diazepam decreased prestress ($P = 0.042$) and poststress ($P = 0.002$) measurements. However, diazepam also significantly increased feelings of physical sedation at the prestress ($P = 0.036$) and anticipatory anxiety ($P = 0.003$) measurements. Ipsapirone significantly decreased performance anxiety ($P = 0.037$) measurements when compared with placebo, while CBD significantly decreased poststress anxiety ($P = 0.017$) measurements. Only diazepam showed significant physical and mental sedative effects, which may limit its therapeutic application in some patients. The authors concluded that acute administration of CBD or ipsapirone may have beneficial alternative anxiolytic effects when used in healthy subjects and may be appropriate alternatives for those experiencing sedative effects from other anxiolytic medications.

CBD presents an inverted U-shaped dose-response curve in a SPST

Linares et al.²⁴ conducted a double-blind, placebo-controlled trial of 57 healthy adult males who were randomized to receive either placebo or CBD dosed at 150 mg, 300 mg, or 600 mg daily before SPST. The SPST was administered according to the Bergamaschi procedures.²⁵ VAMS was used to assess subjective anxiety. In the analysis of variance test of group comparisons, there were no significant findings among groups and phases of the SPST ($P = 0.1$). A post hoc analysis among groups during the phases of SPST indicated that patients in the CBD 300-mg group demonstrated lower anxiety levels in the speech phase than the placebo group ($P = 0.042$). The study investigators inferred an inverted U-shaped dose-response curve based on VAMS results with sequential CBD doses, with the 150-mg and 600-mg doses associated with minimal anxiolytic effects and the intermediate 300-mg dose producing the most clinically significant outcome on anxiety. This result supports findings from previous studies.^{21–23} No safety outcomes were reported in this study.

SAD: CBD reduces the anxiety induced by simulated public speaking in treatment-naïve social phobia patients

In a double-blind, randomized, controlled clinical trial, Bergamaschi et al.²⁵ compared the effects of taking oral CBD 600 mg with those of taking placebo in SPST. A total of 36 patients were included in the study; 24 were treatment-naïve patients with SAD and 12 served as healthy controls (HCs) who did not receive medications. Of the 24 treatment-naïve patients with SAD, 2 separate groups of 12 were formed randomly. One group received CBD while the other received placebo, both packed in identical gelatin capsules. Subjective ratings using VAMS, SSPS-N, and physiological measures such as BP, heart rate, and skin conductance were all measured at 6 different time points during SPST. The time points of evaluation were selected for full evaluation of anxiolytic effects seen with CBD compared with those seen with placebo. In the first stage of the procedure, a single dose of CBD or placebo was administered in a double-blind fashion along with administration of baseline measurements. In the second phase, participants were given instructions to prepare a 2- to 4-minute speech that would be videotaped and analyzed by a

psychologist. Researchers collected anticipatory speech measurements before the public speaking occurred. Interruptions in the speech were made in the middle and speech measurements were again taken. The speech was allowed to continue for another 2 minutes and then concluded, and 2 postspeech measurements were made 15 minutes and 35 minutes after the speech. After analyzing the results from the study, the VAMS scale showed that the placebo group presented with significantly higher anxiety levels with greater cognitive impairment, discomfort, and alertness as compared with the HCs. The pretreated CBD SAD group had significantly reduced anxiety, cognitive impairment, and discomfort during the speech performance compared with the placebo group ($P = 0.009$). An important observation made by the authors was that negative self-evaluation was almost abolished by CBD. There were no significant differences found in vital signs. Overall, the effects of single dose CBD in patients experiencing SAD show a promising impact with a rapid-onset therapeutic effect.

Neural basis of anxiolytic effects of CBD in generalized SAD

In a double-blinded preliminary report, whose purpose was to confirm the hypothesis that CBD may be effective in treating SAD, Crippa et al.²⁶ assessed 10 men with generalized SAD, which was confirmed by the structured clinical interview (SCID) for *DSM-IV*. All the subjects in the study were determined to have a severe social phobia. To analyze the effects of CBD in these patients, researchers evaluated each subject using the VAMS assessment. During the test, subjective ratings on VAMS were made 30 minutes before the ingestion of the drug (prestress), at the time of drug ingestion (adaptation), and at 75 minutes after ingestion (poststress). Functional neuroimaging was used to determine the neurophysiologic effect of CBD in patients with SAD. SPECT imaging was used to compare the effects of CBD and placebo on rCBF. This process was completed in a double-blind, randomized, repeated measures, within-subject crossover design using a dose of 400 mg of CBD given in oral gelatin capsules. In the first session, the men were given CBD 400 mg or placebo. In the second session, this exercise was performed again, but this time the men who had received CBD earlier were administered the placebo and vice versa.

Upon analysis of the VAMS score, the study showed that acute administration of CBD reduced subjective anxiety in patients clinically diagnosed with an anxiety disorder, in this case SAD. Specifically, CBD showed a significantly faster time onset of decreasing anxiety ($P < 0.001$) in the patient compared with placebo. Based on the VAMS score numbers, those taking CBD began with a mean assessment at prestress anxiety of 48.3 and ended poststress anxiety with 30.8, a decrease of 36.23%. Patients in the placebo group began prestress at an anxiety level of 46.9 and ended with a poststress anxiety level of 42.1, a decrease of only 10.23%. The SPECT imaging was able to show that CBD was active in the paralimbic and limbic areas. Overall, the authors concluded that CBD has important advantages in treatment of SAD, such as a minimal adverse-effect profile and early onset of action. However, the authors also concluded that more double-blind, placebo-controlled studies are needed to evaluate the long-term effects of CBD for treatment of anxiety disorders. Last, investigators suggested the need for further research and

definitive conclusions on whether a relationship exists between rCBF and CBD plasma levels, which would potentially provide a less invasive strategy for monitoring CBD's clinical effects.

Discussion

CBD has been studied for use in treating anxiety-like responses for more than a decade.²⁷ Several early studies evaluated the use of CBD in preventing neural responses to fearful faces.^{28,29} Initial studies evaluating the difference in response between CBD and THC showed that while THC use often results in negative behavioral and psychological effects, CBD is safe and well-tolerated with no difference from placebo in regard to increasing unwanted anxiety, sedation, positive psychotic symptoms, and intoxication.^{28,30,31} In addition, CBD may even have utility in minimizing the negative effects of THC.³²

On the basis of the results of currently available published human studies, it is seen that CBD has demonstrated a developing role as an alternative therapy in the indications of anxiety disorders, specifically GAD, SAD, and anxiety related to PTSD. Because the majority of the reviewed studies had small sample sizes, low statistical power posed a notable limitation. Primarily adult, male patients were enrolled in the studies, with only 1 pediatric case report meeting criteria for review. In addition, several studies enrolled healthy volunteers modeling varying anxiety disorders. Very few studies that enrolled patients with an anxiety diagnosis and compared the outcomes of taking CBD with those of taking placebo were identified. Taken together, these overall study characteristics may limit the generalizability of results. Similarly, because wide ranges of CBD doses were implemented among the studies, future evaluations of more intermediate range CBD doses may be warranted to determine optimal dosing definitively. Last, many studies made conclusions related to the dose-response curve of CBD on the basis of the results of neuroimaging findings and subjective scores on anxiety assessments without assessing plasma levels; therefore, these findings should be interpreted with caution.

In the studies reviewed, CBD regularly showed improved clinical outcomes in GAD, SAD, and anxiety related to PTSD, with minimal adverse effects, which differs from other therapeutic agents that are currently used for these indications. These results indicate that CBD could provide a unique therapeutic opportunity to augment or replace existing pharmacotherapy in patients with inadequate relief while causing fewer adverse effects. While CBD did show positive benefits in these patient populations, it can be challenging to translate results across studies owing to the lack of a standardized assessment tool and the variety of dosing schedules and routes of administration that were used. The most regularly used screening tool in CBD studies is VAMS, but its use has not been universal. Further standardized approaches in dosing and outcome measurement will be useful to best determine an effective therapeutic dose of CBD for broader patient populations.

Of note, the increasing amount of human studies evaluating the role of CBD in the treatment of anxiety and anxiety-related disorders are showing potential therapeutic success, specifically when CBD is administered with acute dosing. Fewer studies exist that evaluate the safety and efficacy of long-term

use of CBD in human populations. While clinical evidence supporting the use of CBD in these patient populations now exists, there continue to be considerable challenges in terms of a lack of standardized dosage and route of administration. These challenges also persist in terms of lack of standardization in product manufacturing. Typically, CBD products are labeled not by strength per dose, but by strength of product contained in the entire package. The labeling of these products can lead to confusion for patients attempting to follow a specific dosage schedule based on their clinical indication, suggesting a need for focused patient education and follow-up with patients initiating CBD therapy for a chronic indication.

While CBD has a generally mild adverse-effect profile as demonstrated through human studies, some clinical considerations do exist. Clinical data have demonstrated the potential for CBD to increase plasma levels of warfarin, and suggest that CBD products may potentiate some drug interactions via CYP450 pathways.³³ CBD has the potential to function as a potent inhibitor of CYP3A4 and CYP2D6, which may result in increased serum concentrations of medications such as macrolides, calcium channel blockers, antiretrovirals, antidepressants, antipsychotics, and opioids.^{34,35} In addition, patients with decreased CYP2C19 or CYP3A4 function may be at risk for increased CBD accumulation and exposure, while patients taking a CYP3A4 inducer may see a decrease in CBD exposure.^{33,35} Patients taking anticoagulants or other interacting medications should be counseled about the effects of initiating and discontinuing CBD products. See Table 2 for a list of other CBD considerations.

Another potential challenge surrounding the use of CBD in the general population concerns the persistent issues regarding product purity. Generally, CBD products sold to the public for medical use contain high levels of CBD and low levels of THC, although these levels of THC may range between 0.3% and 5% based on state law.³⁶ Even with the level of THC provided on product labeling, actual content of THC may be higher than what is listed on the label as found in FDA test results of products in 2015 and 2016.^{37,38} For patients where the presence of THC could be problematic because of workplace drug screenings or because the legal status of cannabis products in their state is in question, these factors should be considered before recommendation of CBD products. In addition, because of the lack of product regulation for safety and purity given its status as a dietary supplement, products may also have a variable level of CBD present in them, further increasing difficulty in ensuring that patients receive a desired dose to obtain a specific therapeutic effect. One study in 2015 demonstrated a wide range of product content of CBD, with products sold as medical cannabis products being both over- and underlabeled in regard to CBD content.³⁹ Both regulation and increased quality assurance are needed for CBD products to be routinely recommended for use as a medical product.

Last, patient access to CBD products can vary. While all 50 states have legislation that legalizes CBD products, restrictions vary widely, and CBD products are still considered by the federal government to be in the same restricted access class as marijuana. In similar fashion to their approach to medical marijuana, the federal government generally declines to enforce restrictions on CBD use. The legal status of CBD is evolving, and clinicians should pay careful attention to the laws surrounding CBD sales and usage in their states.

Conclusion

CBD has consistently demonstrated acute reduction in anxiety-related symptoms in patients, specifically within GAD and SAD. Additionally, the use of CBD for these disorders has shown increasingly minimal adverse effects compared with existing pharmacotherapy. Further studies are needed to determine long-term safety and efficacy of CBD products and a more standardized dose-effect response. Clinicians should be mindful of challenges related to product purity, legal status of CBD based on geographic area, and the potential for drug interactions when recommending the use of CBD for anxiety.

ABSTRACT

Cannabis is commonly used recreationally for its euphoric and relaxing effects, while its medical use is permitted in several jurisdictions. With only low-quality evidence suggesting anxiolytic effects of cannabis and strong public sentiment surrounding such purported effects, the purpose of this study was to examine the prevalence of cannabis for medicinal purposes (CMP) use for anxiety symptoms. An online survey was disseminated to CMP users registered with a Canadian licensed producer. Respondents completed demographic and validated self-report questionnaires (GAD-7, PHQ-9, MINI-SPIN, and panic disorder/agoraphobia DSM-5 criteria). Cannabis use behaviors were also discussed. Overall, 2032 completed responses with a verified user number were collected. Of the total sample, 888 (43.7%) reported CMP authorization to treat anxiety symptoms and completed all psychometric screening instruments. Rates of probable disorders were high (Generalized Anxiety Disorder: 45.6%, Social Anxiety Disorder: 42.4%, Major Depressive Disorder: 25.7%, Panic Disorder/Agoraphobia: 25.7%); 63.4% met screening criteria for ≥ 1 disorder. Most (92%) reported that cannabis improved their symptoms, despite continuing to endorse moderate-level severity. Nearly half (49%) reported replacing a non-psychiatric (53.7%) or psychiatric medication (46.3%) prescribed to them by their physician with CMP. Respondents endorsed daily CMP use and severity of anxiety (GAD-7, $p < 0.001$) and depressive (PHQ-9, $p < 0.001$) symptoms were positively associated with the amount of cannabis used/day. The vast majority perceived symptom improvement with CMP use and did not believe CMP use was associated with impairment or an inability to control use. Nevertheless, the possibility of cannabis use disorder cannot be ruled out as well as the possibility that improvements in non-psychiatric conditions were attributed to improvements in anxiety. These results highlight the need to systematically evaluate CMP use for mental illness.

1. Introduction

Cannabis is commonly used recreationally for its euphoric and relaxing effects. The dried plant is typically smoked or vaporized and also consumed in foods or used as a concentrated oil. Although considered an illicit substance in many parts of the world, regulatory bodies in the Netherlands, and several US states have legalized medicinal and/or recreational use, with Canada having legalized recreational use on October 17, 2018. Prior to this, only cannabis for medicinal purposes (CMP) could be legally obtained from licensed producers for a myriad of medical conditions, with appropriate physician authorization. A

recent meta-analysis revealed moderate-quality evidence to support cannabinoid treatment of chronic pain and spasticity, with very low-quality evidence suggesting improvement in anxiety and no effect in depression (Whiting et al., 2015). Only small studies of synthetic cannabinoids (Fabre and McLendon, 1981; Glass et al., 1981; Ilaria et al., 1981; Lee, 2009) or cannabidiol (CBD) (Bergamaschi et al., 2011; Crippa et al., 2011) have been examined in clinically anxious populations. Yet, many Canadians report using cannabis to alleviate self-reported anxiety (Walsh et al., 2013).

Anxiety disorders are chronic conditions with a lifetime prevalence of 31.6% (Kessler et al., 2012). They include social anxiety disorder

(SAD), generalized anxiety disorder (GAD), panic disorder (PD) and specific phobias. These disorders are associated with significant burden for afflicted individuals, their families and society (Katzman et al., 2014). While many established efficacious first-line treatments exist, including antidepressants and cognitive-behavioral therapy, 40–60% of patients continue to have residual, impairing symptoms while others are non-compliant or have difficulty accessing treatments (Katzman et al., 2014). Given such limitations, individuals may seek alternative treatments and public sentiment surrounding cannabis' purported anxiolytic effects suggest cannabis may fulfil this role.

The primary active components in cannabis are Δ^9 -tetrahydrocannabinol (THC) and CBD. While THC is thought to have anxiolytic, antidepressant and hypnotic effects, CBD has demonstrated anti-inflammatory, analgesic, anticonvulsant, and anxiolytic properties, (Walsh et al., 2017). Of the two primary cannabinoids, THC is the psychoactive constituent and at higher doses has been documented to induce panic, paranoia and anxiety, (D'Souza et al., 2004; Fusar-Poli et al., 2009). The ratio of these cannabinoids varies greatly between strains of cannabis and consequently may induce a wide variety of effects. For instance, when CBD is administered with THC, it has demonstrated an ability to “undo” the unwanted and anxiogenic effects of THC by acting as a pharmacological antagonist (Karniol et al., 1974; Zuardi et al., 1982). Given the various cannabinoids and other active compounds in the cannabis plant, it is difficult to discern the specific behavioral effects of cannabis. As such, the existing cannabis literature comprised of studies of pure or synthetic cannabinoids may not be a sufficient proxy to illustrate cannabis' potential anxiolytic effects. Canadians are currently using cannabis for anxiety symptoms (Sexton et al., 2016; Walsh et al., 2013) but whether these individuals are treating state anxiety or symptoms of a clinical disorder remains unclear. With the scientific literature indicating cannabis as a non-evidence-based treatment for anxiety, mood and related disorders (Turna et al., 2017), this study examines the prevalence of CMP use for anxiety, psychiatric symptom severity and CMP use behaviors in a sample of authorized Canadian medicinal cannabis users.

2. Methods

2.1. Study population and design

An online survey was disseminated to all authorized CMP users registered with Tilray (British Columbia, Canada, $n = 16,675$) on January 9, 2017, and was closed 48 h later. Respondents received a \$10 account credit towards future Tilray purchases. Following acknowledgement of a disclosure statement, information regarding demographics and CMP use was collected. Questions were structured in multiple choice, checklist and rating scale format. Individuals were not able to skip question(s) they did not wish to answer, therefore, all completed questionnaires did not contain missing data. Many questions contained “skip logic”, so that if the respondent answered “no”, they did not complete further questions concerning this topic. Study data was collected and managed using Research Electronic Data Capture (REDCap) (Harris et al., 2009), a Health Insurance Portability and Accountability (HIPAA) and Personal Information Protection and Electronic Documents Act (PIPEDA) compliant online survey tool allowing participants to directly enter responses.

2.2. Outcome measures

All respondents answered questions regarding primary illness and symptoms treated with CMP. Those who identified anxiety as one of their primary symptoms treated with CMP in the second question then completed validated self-report symptom severity scales to characterize psychiatric morbidity including: 1) the GAD-7: a 7-item questionnaire used to screen for GAD and anxiety symptom severity, a score ≥ 10 was used to suggest moderate anxiety (Spitzer et al., 2006); 2) The Patient

Health Questionnaire (PHQ-9) is a multipurpose instrument for screening, monitoring and measuring depressive symptom severity with a total score ≥ 15 suggesting moderately severe depression (Kroenke et al., 2001); 3) The MINI Social Phobia Inventory (Mini-SPIN) is a validated 3-item scale in which a total score ≥ 6 indicates significant SAD symptoms (Connor et al., 2001). Given that no brief measure for panic disorder was found in the literature, four screening questions from the Panic Agoraphobia Scale (PAS) (Bandelow, 1995) were included, and a positive screen for potential panic disorder symptoms was coded if respondents identified the presence of panic attacks and reported > 1 panic attack in the past 2 weeks. Respondents were instructed to answer questions based on the past two weeks. Additional questions regarding CMP use and its effect on symptoms were also incorporated. The survey included 25 anxiety-related questions.

2.3. Statistical analysis

Descriptive statistics, including means, standard deviations and percentages were used to describe demographics, perceived efficacy, conditions, etc. Data analysis was performed using R (version 3.3.1, R Core Team). Frequencies were compared using a chi-square test. A one-way ANOVA or *t*-test was used to examine mean differences between groups, where applicable.

2.4. Ethics approval

This study was approved by the Institutional Review Board Services.

3. Results

In total, 3405 responses were received and 2032 responses were paired with a verified user number. Of the total sample, 888 (43.7%, ANX group) identified anxiety as one of the primary symptoms for CMP use from a list of 14 prepopulated medical symptoms. These respondents were asked to complete all symptom severity screening questionnaires.

3.1. Sample demographics

The mean age of the ANX group was 36.3 ± 10.8 years (range: 16–84 years). The sample was primarily male (58.2%), married (36.1%), employed full-time (50.3%), living in an urban area (43.6%) and with a college education (32.2%); additional demographic characteristics can be found in Table 1. This sample was prescribed CMP by 607 different physicians.

3.2. Psychiatric comorbidity

Based on the cut-off for each respective screening tool, rates of probable anxiety and depressive disorders within the ANX were high (Table 2). In this sample 63.4% met screening criteria for ≥ 1 disorder.

The severity of anxiety (GAD-7) and depressive (PHQ-9) scores were positively associated with the amount of cannabis used per day. This was examined using a one-way ANOVA with GAD-7 score as the dependent variable and low (< 1 g/day), moderate (1–2g/day) or high (≥ 3 g/day) CMP use as the independent variables. Post-hoc comparisons revealed that high users had significantly higher GAD-7 (11.5 ± 5.8) and PHQ-9 (11.8 ± 6.9) scores than moderate (GAD-7: 9.1 ± 5.3 ; PHQ-9: 9.5 ± 6.6) or low users (GAD-7: 9.3 ± 5.3 ; PHQ-9: 9.8 ± 6.1) (GAD-7: $F(2,771) = 14.0$, $p < 0.001$; PHQ-9: $F(2,771) = 9.3$, $p < 0.001$). No differences were observed between low and moderate users.

3.3. Psychiatric effects of CMP use

To better understand perceived efficacy of CMP for symptomatic

Table 1
Demographic characteristics of ANX sample.

Characteristic (n = 888)		%	Characteristic (n = 888)		%
Sex	Male	58.2	Employment	Full-time	50.3
	Female	41.5		Part-time	13.0
	Other	0.3		Unemployed (looking for work)	11.1
Marital Status	Married/Common-law	61.1		Unemployed (not looking for work)	5.4
	Single	31.1		Retired	2.5

^a Other: Aboriginal, South Asian, Black, Hispanic and 'Other'.

Table 2
Prevalence of anxiety and depressive disorders in ANX as per self-report screening measures (n = 888).

Disorder	Diagnostic cut-off score	Prevalence (%)	Mean Score
GAD	GAD-7 ≥ 10	45.6%	9.8 ± 5.5
SAD	Mini-SPIN ≥ 6	42.4%	4.9 ± 3.5
MDD	PHQ-9 ≥ 15	25.7%	10.4 ± 6.4
PD/agoraphobia	Modified PAS criteria	25.7%	NA

relief, the ANX group was asked to identify the anxiety and depressive symptoms CMP use improved, using 21 prepopulated choices (allowed to check all that applied). The majority of the ANX group reported that CMP improved their “anxiety, worry, fears” (92.0%), “irritability” (75.5%), “difficulty falling to sleep” (72.4%), “anxiety attacks” (58.8%) and “low mood” (56.9%) (Fig. 1). When asked how effective CMP was at relieving these symptoms on a scale of 1 (not at all effective) to 5 (very effective), 64.9% reported a rating of 4 or more; only 1%

responded “not at all effective”. Respondents using > 3 g cannabis/day reported significantly greater perceived benefit related to cannabis use as compared to individuals using < 3 g/day (p < 0.0001).

Many in the ANX group reported using cannabis to feel relaxed (84.4%). Respondents were also asked which cannabis strains were thought to best improve their anxiety and which strains they found to worsen their anxiety. They could select as many of the 6 prepopulated options available. *Cannabis indica* was more often reported to have a subjective anxiolytic effect (51.5%), while *Cannabis sativa* was the most frequently reported anxiogenic strain (32.3%) (Fig. 2).

3.4. Cannabis use behaviors

A majority of the ANX group used cannabis recreationally (99.5%) prior to medicinal use. However, 85.5% reported trying at least 1 traditional mental health treatment before CMP ($\bar{x} = 2.6 \pm 2.0$ treatments), with 55.5% reporting medication and 20.5% reported cognitive-behavioral therapy. Use of other cannabinoid drugs was relatively

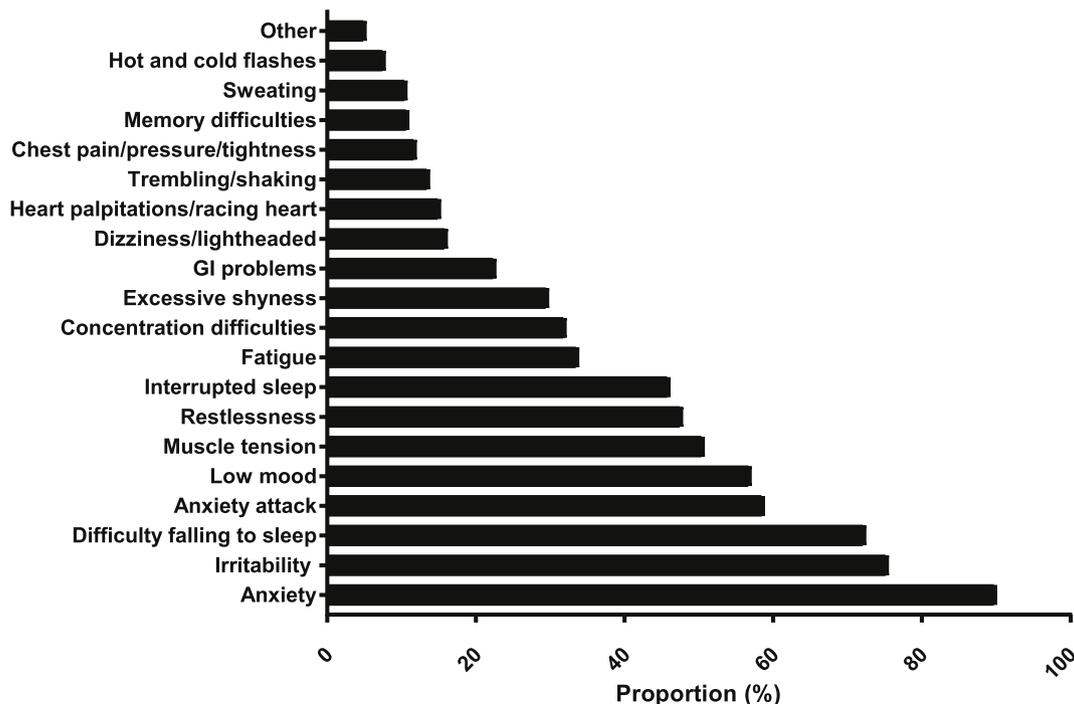

Fig. 1. Symptoms of anxiety and depressive disorders reported to be relieved by CMP use in ANX group (n = 888).

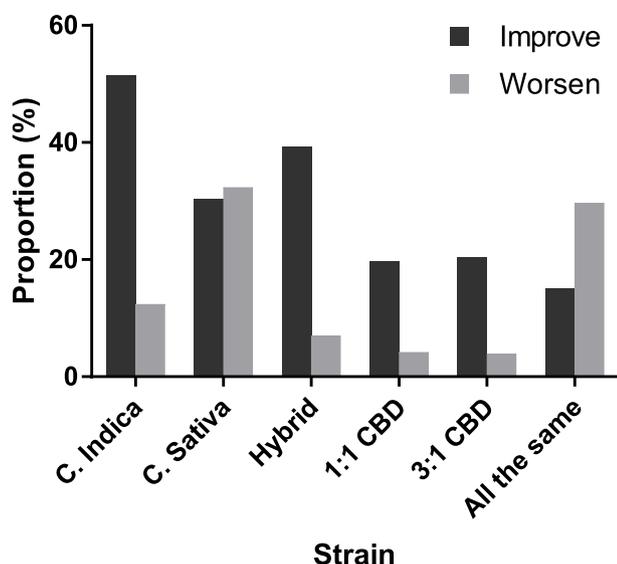

Fig. 2. Subjective reports of anxiogenic versus anxiolytic effects of varying cannabis strains (n = 888).

low (Dronabinol:1.0%, Nabilone:5.9%, Sativex:1.6%, Other Cannabinoids:0.6%). Fifty respondents (6%) endorsed having a primary mental health condition and had no previous treatment prior to their CMP. Although not significant, these individuals tended to be male, have lower levels of education and endorsed that cannabis is safer than prescription medication compared with respondents who had tried at least one traditional treatment. They also reported significantly younger mean age of recreational cannabis use (15.96 vs. 17.48, $t(99.97) = -2.5571, p = 0.01$).

In total, 22.1% of respondents stated that their use of cannabis had increased “a lot” since obtaining access to CMP, with 42% of individuals using 1–2 g of cannabis per day. Thirty-five percent reported using < 1 g/day while 23% of the sample used ≥ 3 g/day. Respondents did not believe they had difficulty controlling CMP use (79.7%) or that their social and leisure activities were impaired by it (84.4%). Most respondents also reported vaporizing (47.6%) as the preferred mode of delivery, followed by oral ingestion (21.4%, includes edibles, oils, etc.), joints (18.5%), etc.

Respondents were also asked which prescription drugs they had replaced with cannabis (up to 3 answers permitted) and at what rate they were substituting the prescription medication with CMP. Nearly half of the ANX sample (49%) reported substituting a prescribed medication with CMP to some degree, of whom 61% indicated that cannabis had completely (100%) replaced a drug prescribed to them by their physician for a given medical condition (Table 3). We also compared the rates of substitution between individuals with and without

Table 3

Proportion of the ANX sample replacing a prescribed medication with medicinal cannabis (n = 888).

Drug Class	%
Antidepressants	23.8
Opioid	19.2
Benzodiazepine	15.8
NSAIDs	6.1
Antiepileptic	5.0
Sedative-Hypnotic	4.2
General Analgesic	3.9
Psychostimulant	3.7
Antipsychotic	3.0
All others	15.3

Table 4

Frequencies of primary condition for which CMP has been authorized by a medical doctor.

Indication	ANX group (n = 888)	All respondents (n = 2032)
Mental Health (Stress, Anxiety, Depression, PTSD, eating disorders)	52.9%	30.6%
Chronic Pain	17.2%	26.7%
Insomnia	8.0%	9.4%
Other	5.0%	8.9%
Arthritis	3.5%	7.7%
All others	13.4%	16.7%

anxiety. No significant differences in medication substitutions or CMP usage patterns were found between those with anxiety and those without.

3.5. Primary condition for CMP

Among all respondents (n = 2032), mental health (30.6%) was most frequently identified as the primary medical condition currently being treated with CMP. Mental health (52.9%) was also the most frequent indication in the ANX group (n = 888) (Table 4). Demographic characteristics and cannabis use behaviours were compared among individuals in the ANX group who were prescribed CMP to treat a mental health condition (52.9%) versus those taking CMP for a non-psychiatric condition (47.1%). Respondents who were prescribed CMP for a non-psychiatric condition appeared to use slightly more cannabis ($\chi^2(6) = 19.339, p = 0.004$) and were more likely to be on disability ($\chi^2(5) = 33.15, p < 0.001$; 24.1% vs. 11.9%) than respondents prescribed CMP to treat a mental health condition. Although not significant, most respondents using CMP for a non-psychiatric condition were male, married, living in a suburban area and have a technical or non-university degree. No significant differences were found between groups in terms of level of income, province of residence, scores on the PHQ-9 or GAD-7 nor in the perceived benefit of cannabis use.

4. Discussion

The primary finding of this study is the high frequency of CMP use for the treatment of self-reported anxiety symptoms (43.7%, ANX). Almost 2/3 of the ANX group met screening criteria for ≥ 1 disorder (63.4%), with GAD and SAD being the most common (Table 2). Similarly, anxiety and depressive scores were also higher in those using more cannabis (using ≥ 3 g/day). Although the majority of participants reported that CMP use improved their anxiety symptoms (Fig. 1), severity measures indicated at least ongoing moderate symptoms (Table 2). This suggests that even if cannabis has been helpful for these individuals, it may not be effectively decreasing symptoms to a clinically significant level. For instance, their symptoms may have previously been more severe and have, with CMP use, decreased to a moderate level. An alternative explanation may be that the improvement noted by CMP users in anxiety may be related to the relief of cannabis-withdrawal associated anxiety symptoms. Or that this improvement may have been confounded by improvements in the non-psychiatric conditions also treated with CMP. Mental health conditions were the leading indication for CMP authorization in both the ANX group and the overall sample (Table 4). Many were also replacing prescribed medications with CMP. The most frequently replaced drugs included psychotropics (antidepressants and benzodiazepines) and pain relievers (Table 3). While most denied social impairment and difficulty controlling use, many would be considered heavy users due to daily use. Cannabis indica, followed by hybrids, were most often rated as anxiolytic (Fig. 2). Interestingly, both strains contain high THC (above

18%) and relatively low CBD (1%). Although THC has been purported to have anxiolytic properties, it has also been associated with the development of panic, paranoia and anxiety, D'Souza et al., 2004; Fusar-Poli et al. (2009). Furthermore, while pre-clinical research suggests that CBD may be anxiolytic (Bergamaschi et al., 2011; Crippa et al., 2011), it is critical to note that the vast biochemical variability of these plants makes it difficult to discern which effects are attributable to which compound. Rather, the notion of an “entourage effect” or synergistic effect between the many cannabinoids, terpenoids and flavonoids (Elzinga et al., 2015) may provide one possible explanation of the reported anxiolytic properties of *Cannabis indica* and hybrids in this sample.

The prevalence of CMP use for anxiety in our sample exceeded what has been previously reported. An older study reported less than 10% of authorized Health Canada CMP users were prescribed cannabis for anxiety, while non-authorized use was significantly higher (Walsh et al., 2013). Canadian regulations surrounding CMP authorization have become more inclusive since this study in 2013, now requiring physician authorization for any condition the physician feels warrants cannabis treatment. This process involves acquiring a medical document which includes the name of the healthcare practitioner and patient, daily CMP quantity prescribed and duration of use; this document is then submitted to the licensed producer (Health Canada, 2017). This change is likely reflected in the considerable increase of authorized users in our sample using cannabis for anxiety. Despite these changes in CMP legislation, the scientific evidence examining cannabis treatment in anxiety disordered clinical populations is still in its infancy. When using the four levels of evidence as defined by the Canadian Network for Mood and Anxiety Treatments (CANMAT) (Kennedy et al., 2016), the existing cannabis literature would be considered Level Three evidence for certain mental health conditions including social anxiety disorder, posttraumatic stress disorder and Tourette's Syndrome (Turna et al., 2017). The increasing number of CMP authorization for mental health issues, reveal that Canadian physicians are being approached for CMP prescriptions to treat these conditions and/or may be willing to prescribe for these symptoms despite a dearth of supporting evidence examining the efficacy and safety of CMP in anxiety.

There is strong public sentiment regarding CMP efficacy for a wide range of medical conditions, including subjective anxiolytic effects (Sexton et al., 2016). However, this is the first study to characterize symptom severity beyond subjective reports of anxiety noted in previous studies (Sexton et al., 2016; Walsh et al., 2013). Validated clinical self-report measures revealed clinically significant psychiatric symptoms in our sample, with 63.4% meeting criteria for at least 1 disorder. Yet, respondents perceived CMP treatment as efficacious for their anxiety symptoms. Given that the symptom severity measures used in this survey have demonstrated sensitivity to change with treatment in clinical trials, these results elude to a possible disconnect between respondent belief regarding CMP efficacy and quantifiable symptom improvement. Furthermore, respondents using > 3g/day also reported greater perceived benefit, yet endorsed higher anxiety and depression symptoms. This finding can be interpreted in several ways: these individuals may be using more cannabis because they are more symptomatic; perhaps cannabis used in this group is not reducing anxiety/depressive symptoms but is providing an improved sense of well-being; or perhaps this a group of patients who have problematic use, as there is some evidence to suggest that higher daily use of cannabis is associated with cannabis use disorder (CUD) (van der Pol et al., 2015). However, we have no way of evaluating CUD within this sample, and the cross-sectional nature of the study limits our ability to derive any conclusions regarding symptomatic change with CMP use. Even though respondents endorsed moderate symptoms we cannot preclude the possibility of improvement in that their symptoms may have been more severe prior to beginning treatment with CMP. Despite many respondents reporting increased cannabis use since receiving CMP authorization and many endorsing daily use, symptoms indicating problematic cannabis use

(social impairment and difficulty controlling use) were minimal. However, data from the National Survey of Drug Use and Health (NSDUH) has suggested that up to 11% of individuals using CMP meet criteria for DSM-IV cannabis abuse/dependence (Lin et al., 2016). Further, daily use is more frequent in medical cannabis users (33%) compared to recreational users (11%) (Lin et al., 2016). We cannot preclude cannabis use disorder (CUD) in our sample as it was not directly examined, however many respondents reported increased use of cannabis since obtaining a prescription. This may suggest the development of tolerance, a hallmark symptom of CUD. The recently published Lower-Risk Cannabis Use Guidelines (LRCUG) (Fischer et al., 2017) suggest frequency or intensity of use to be the strongest and most consistent predictors of severe and/or long-term cannabis-related health problems. However, these guidelines are not specific to medicinal use as there is no existing data to suggest that daily medicinal cannabis use increases risk of CUD. These data highlight the need for additional research to appropriately characterize patients that may benefit from CMP use while protecting those that may be at-risk to possible negative effects.

Of note, many respondents to our survey reported replacing a prescription medication with CMP, primarily antidepressants. A recent US study revealed that 71.8% of their sample of chronic pain medicinal cannabis users decreased use of anti-anxiety medications (benzodiazepines), and to lesser extent antidepressants (37.6%) while using medical cannabis (Piper et al., 2017). Given the high rates of CMP prescription seen for mental health conditions and lack of literature examining the efficacy of CMP in these conditions (NASEM, 2017; Turna et al., 2017), there is an imminent need to begin developing a systematic body of research examining CMP in these conditions. Future studies should examine both the efficacy of cannabis for mental health conditions, as well as its equivalence to current, evidence-based pharmacological treatments. These studies will be critical to inform the development of treatment guidelines so that physicians may prescribe cannabis treatments to patients in an evidence-based and informed manner.

As with any cross-sectional online survey, there are several limitations inherent to the study design. All responses were self-report and retrospective in nature. Although we utilized validated and reliable symptom severity scales to examine prevalence and severity of a given disorder, these do not replace physician confirmation of anxiety and mood disorders. Nevertheless, given that these individuals are physician-authorized CMP users for primarily mental health conditions, it is likely that a medical diagnosis was made by their prescribing physician. We may have a potentially unrepresentative sample as the study was open to self-selection and non-response biases; although the submission of multiple surveys from one participant was prevented, as a verified user number was required. Further participation was incentivized which may have produced additional biases and the number of survey respondents capped. In addition, due to limitations inherent in the cross-sectional design, we were unable to answer several important questions including the impact of potential confounders such as non-psychiatric comorbidity or how many respondents developed anxiety or depression after beginning use of recreational cannabis or CMP. Further, only 25 of 888 respondents in the ANX group endorsed only anxiety and depression and no non-psychiatric condition, limiting the generalizability of these findings. In light of these limitations, the presented findings should be interpreted cautiously and highlight the importance of additional studies to replicate findings in samples of CMP users.

Nevertheless, the results of this study show that patients and physicians are pursuing CMP for a variety of medical conditions including anxiety and a need to inform the significant gaps currently plaguing the existing literature is evident. This research highlights the importance of future studies to clarify the role of cannabis in the treatment landscape. For instance, cannabis is thought to be safe, but it is unclear whether regular use as an anxiolytic treatment poses additional risks. Further, the abuse liability of cannabis is an issue warranting further

consideration, as symptoms of tolerance and withdrawal are not well understood, and psychiatric populations may be particularly vulnerable to this potential consequence. CMP use for mental health conditions requires systematic evaluation to examine efficacy and equivalence using rigorously designed studies including, but not limited to double-blind randomized controlled trials. Research informing CMP prescribers will also be critical given that there is limited information to guide physicians on strains, frequency and dose. This raises a time-sensitive public health concern as legalization of recreational cannabis is forthcoming in Canada which may increase the rate of self-medication with cannabis for mental health purposes. With no information to guide CMP use, it is critical that the scientific literature catch up to policy to better inform patients and physicians respectively.

Disclosures

DESCRIPTORS

Cannabidiol;
Cannabis sativa;
Anxiolytics;
Anxiety disorders.

Abstract

Objectives: To review and describe studies of the non-psychotomimetic constituent of *Cannabis sativa*, cannabidiol (CBD), as an anxiolytic drug and discuss its possible mechanisms of action. **Method:** The articles selected for the review were identified through searches in English, Portuguese, and Spanish in the electronic databases ISI Web of Knowledge, SciELO, PubMed, and PsycINFO, combining the search terms “cannabidiol and anxiolytic”, “cannabidiol and anxiolytic-like”, and “cannabidiol and anxiety”. The reference lists of the publications included, review articles, and book chapters were handsearched for additional references. Experimental animal and human studies were included, with no time restraints. **Results:** Studies using animal models of anxiety and involving healthy volunteers clearly suggest an anxiolytic-like effect of CBD. Moreover, CBD was shown to reduce anxiety in patients with social anxiety disorder. **Conclusion:** Future clinical trials involving patients with different anxiety disorders are warranted, especially of panic disorder, obsessive-compulsive disorder, social anxiety disorder, and post-traumatic stress disorders. The adequate therapeutic window of CBD and the precise mechanisms involved in its anxiolytic action remain to be determined.

Introduction

Cannabis sativa is the most used drug of abuse worldwide and around 20% of youth use it heavily and regularly around the globe.¹ The main psychoactive component of the plant is Δ^9 -tetrahydrocannabinol (Δ^9 -THC), one of the substances responsible for the psychoactive effects of Cannabis.²⁻⁴

Cannabidiol (CBD) is another abundant compound in *Cannabis sativa*, constituting around 40% of the plant's active substances.⁵ The pharmacological effects of CBD are different and often opposite to those of Δ^9 -THC.⁶ The number of publications on CBD has increased remarkably over the last years and support the view that CBD has a vast array of possible therapeutic effects. Among these possibilities, the anxiolytic and antipsychotic properties of CBD stand out.⁷⁻¹⁰ CBD's anxiolytic effects are apparently similar to those of approved drugs to treat anxiety,¹¹ although its effective doses have not been clearly established and the mechanisms underlying these effects are not fully understood. The low affinity of CBD for cannabinoid neuroreceptors^{12,13} and its agonist properties at 5-HT_{1A} receptors^{14,15} have been repeatedly demonstrated.

Most studies on CBD have been conducted with rodents, but studies with human samples have also provided promising results.^{16,17} Therefore, the aim of this paper is to review the scientific literature on the anxiolytic properties of CBD in animal and in humans.

Method

The articles selected for this review were identified by searches in English, Portuguese, and Spanish in the electronic databases ISI Web of Knowledge, SciELO, PubMed, and PsycINFO combining the search terms "cannabidiol and anxiolytic", "cannabidiol and anxiolytic-like", and "cannabidiol and anxiety". In addition, the reference lists of the selected articles and relevant literature reviews and book chapters were handsearched for additional references. We included experimental studies with human and animal samples with no time limits. We sought to exclude studies that used smoked Cannabis, as it is not possible to establish the dose, composition, and proportion of the different cannabinoids in this case, besides the great individual variations in the samples enrolled. Finally, we did not include studies using extracts containing both THC and CBD in oral (Cannador®) or oromucosal spray (Sativex®) forms due to the difficulty to establish the effects of CBD alone (Table 1).

Animal studies

The two first articles about the effects of CBD on experimental anxiety were published in journals that were not indexed in the databases used for this review but were located through handsearch in the reference lists of relevant literature. These two investigations showed contradictory results. In one study, no significant effects of high doses of CBD (100 mg/kg) were seen in rats in the Geller-Seifter conflict test.¹⁸ In the other, a low dose of CBD (10 mg/kg) had anxiolytic effects in rats submitted to the conditioned emotional response test.¹⁹

Later studies using the elevated plus maze (EPM) helped to elucidate this contradiction.⁹ The EPM consists of two opposing open arms (50 x 10 cm) and two closed arms

(50 x 10 x 40 cm) that intersect in their central portion. The arms are made of wood and stand 50 cm above the ground. In this study, mice injected with CBD, diazepam or vehicle (no active substances) were placed in the center of the maze facing the closed arms. The time spent and the numbers of entries in the open and closed arms were measured for 10 minutes. The frequency of entries in the open arms of animals receiving CBD presented an inverted U-shaped curve, with significantly higher rates than those observed in animals treated with vehicle, at the doses of 2.5, 5, and 10 mg/kg. The measures of mice treated with CBD 20 mg/kg did not differ from those of controls, suggesting that anxiolytic effects are only present at low doses, which explains the absence of effects with CBD 100 mg/kg reported in 1981.¹⁸ The same inverted U-shaped dose-response curve was obtained with a wider range of doses of CBD in the EPM (Onaivi et al.).²⁰ Furthermore, the same pattern was observed with the direct infusion of CBD in the periaqueductal gray (PAG) of rats tested in the EPM,^{15,21} confirming that anxiolytic effects should only be expected with low doses of CBD.

The mechanisms through which CBD acts to diminish anxiety have been studied in a number of animal models of anxiety using rodents. One of these studies used Vogel's conflict test,²² in which the animal is water-deprived from and placed in a cage with an electrified grid at the bottom through which the animal receives a shock after licking water for a predetermined number of times. Three substances were tested in rats using the following procedure: CBD (2.5, 5 and 10 mg/kg), diazepam, and flumazenil (an antagonist of benzodiazepine receptors), in addition to vehicle (placebo). The tests showed that CBD produced effects consistent with those of diazepam by increasing the number of licks, even if they resulted in punishment. Flumazenil antagonized the anxiolytic effect of diazepam, but not that of CBD, suggesting that the effects of CBD are not mediated by the activation of benzodiazepine receptors.

There is strong evidence showing that the serotonergic system is involved in the anxiolytic action of CBD. The injection of the 5-HT_{1A} receptor antagonist WAY-100635 (WAY) directly into the dorsolateral portion of the PAG (dIPAG) in rats antagonized the anxiolytic effects of CBD in the EPM and in Vogel's conflict test.¹⁵ The participation of 5-HT_{1A} receptors in the anxiolytic action of CBD was also derived from behavioral and cardiovascular responses to restraint stress in rats.¹¹ In this study, animals were intraperitoneally injected with vehicle or CBD (1, 10 and 20 mg/kg) and, after 30 minutes, they were restrained for 60 minutes. Immobilization increased blood pressure, heart rate, and anxiety responses in the EPM 24 hours later, and these effects were attenuated by CBD. Pretreatment with WAY blocked the anxiolytic action of CBD. The injection of CBD into the intra-dorsal PAG also blocked panic-like responses in the elevated T-maze (ETM) and flight responses to the electrical stimulation of this area.²³ The ETM has three arms with the same dimensions, two open and one closed, and allows the measure of entrance avoidance in the open arms when the animal is placed in the closed arm, as well as of escape when the animal is placed in the open arm. The panic-like response seen with CBD in the two procedures was antagonized by the previous intra-dIPAG administration of WAY.²² Chronic oral administration of CBD also had anti-panic effects in the ETM that were neutralized

Table 1 Studies of the anxiolytic effect of cannabidiol in humans and animals

by intra-dIPAG injection of WAY. However, chronic administration of CBD did not change the extracellular concentration of serotonin in the dIPAG or the expression of 5-HT1A or 5-HT2C, indicating that CBD directly activates 5-HT1A receptors.²⁴ CBD was also found to activate the vanilloid receptor type 1 (TRPV1)²⁵ and there is evidence that this activation could explain the inverted U-shaped dose-response curve of CBD's anxiolytic effect seen in the EPM. TRPV1 receptors regulate the release of glutamate in the dIPAG and the increased activation of this system would result in increased anxiety. Thus, it has been suggested that elevated doses of CBD in the dIPAG could activate local TRPV1 receptors facilitating the glutamatergic neurotransmission and increasing anxiety.

To test this hypothesis, rats pre-treated with the TRPV1 antagonist capsazepine in the dIPAG were injected with CBD (30 and 60 mg/kg) in the same region and tested in the EPM. The dose of 60 mg/kg CBD, which had no anxiolytic action before, was able to reduce anxiety after pre-treatment with capsazepine, suggesting that the activation of TRPV1 receptors by the higher dose of CBD would counterbalance the anxiolytic effect of CBD produced by the activation of 5-HT1A receptors.²¹

Because serotonin has also been implicated in obsessive-compulsive disorder (OCD), the effects of CBD were tested in mice submitted to the marble-burying test (MBT), an animal model of compulsive behavior. CBD induced a significant reduction in the number of buried marbles at different doses (15, 30, and 60 mg/kg) compared to controls in a dose-dependent pattern. The same was found with the administration of the ISRS paroxetine (10 mg/kg) and diazepam (2.5 mg/kg). However, the effects of CBD 30 mg/kg persisted even after seven days of repeated daily administration, whereas the effects of diazepam disappeared. Pre-treatment with WAY (3 mg/kg) counteracted the effects of paroxetine, but did not affect the action of CBD, which was prevented by pre-treatment with the CB1 receptor antagonist AM251 (1 mg/kg).²⁶ This action of CBD in the MBT was recently replicated by another group using a higher dose (120 mg/kg).²⁷

The participation of specific cannabinoid receptors (CB1) in the anxiolytic action of CBD has also been investigated using animal models. In the study with the EPM that reported the antagonism of the anxiolytic effect of intra-dIPAG CBD by WAY, the CB1 receptor antagonist AM251 was unable to avoid this effect.¹⁵ However, this receptor system seems to be involved in another anxiolytic-like action of CBD, according to tests using a procedure known as contextual fear conditioning. In this procedure, animals are pre-conditioned to a hostile environment (foot shocks) and later exposed to the same environment, when they normally present freezing, the duration of which can be monitored as a measure of anxiety. Both CBD and diazepam are successful in attenuating freezing in rats, as well as the increased heart rate and blood pressure induced by re-exposure to the contextually feared environment.¹⁰ This effect of CBD on contextual memory is also produced by the endocannabinoid reuptake inhibitor AM404, which increases the availability of cannabinoids in the synaptic cleft.²⁸ In this study, the two drugs were injected into the ventricles and their effects were counteracted by the CB1 receptor antagonist SR141716A, suggesting the involvement of the endocannabinoid system in the anxiolytic action of CBD in this model. The pre-limbic region of the prefrontal cortex

appears to underlie this effect of CBD, as the reduction in contextual fear produced by systemic administration of CBD (10 mg/kg) is associated with reduced c-Fos expression in this area. In addition, the microinjection of CBD (30 nmol) in the pre-limbic region of the frontal cortex reduced freezing induced by re-exposure to the aversive context.²⁹ The effects of CBD on contextual fear indicate a possible therapeutic action of this cannabinoid in post-traumatic stress disorder.

Another area that is apparently involved in the anxiolytic-like effects of CBD is the bed nucleus of the stria terminalis (BNST). The intra-BNST injection of CBD (15, 30, and 60 nmol) increased the number of punished licks in Vogel's conflict test and the number of open arm entries in the EPM. These effects were blocked in rats pre-treated with WAY.³⁰

CBD was also effective in an ethologic model that investigates behaviors induced by innate fear, the predator-prey paradigm.³¹ This procedure was performed using a semi-transparent plexiglass box in the shape of a quadrangular arena (154x72x64 cm) with walls covered with a light-reflecting film and floor in transparent plexiglass over a board of stainless steel divided in 20 equal rectangles. One of the corners of the arena has a shelter box with black walls and a complex maze inside. Three days prior to the experiment, the mice were placed and kept in this arena, with free access to food and water until the day of the trial. The "no threat" group had its behaviors recorded for five minutes. Animals exposed to the predator (snake) were divided into four groups (n = 12/11 per group) and pre-treated with intraperitoneal injections of CBD (0.3, 3 and 30 mg/kg) or vehicle (control group). The group of animals that were not confronted with the predator presented no defensive behaviors. Animals pre-treated with CBD had significant reductions in explosive flight and defensive immobility, responses related to panic models. Risk assessment and defensive attention were unaltered in animals treated with CBD. These results suggest that CBD can be effective in the control of panic attacks.

Human studies

The first evidence of CBD's anxiolytic effects in humans, documented with assessment scales, was published in 1982 in a study on the interaction between CBD and THC.⁷ The study sample consisted of eight volunteers with a mean age of 27 years, no health problems and who had not used *Cannabis sativa* in the previous 15 days. In a double-blind procedure, the volunteers received CBD, THC, THC + CBD, diazepam, and placebo in different sequences and days. The results showed that the increased anxiety following the administration of THC was significantly attenuated with the simultaneous administration of CBD (THC + CBD).

Based on this preliminary evidence, researchers decided to investigate a possible anxiolytic action of CBD in experimentally induced anxiety in healthy volunteers using the simulated public speaking (SPS) model.³² The procedure consists of asking a subject to speak in front of a video camera for a few minutes, while subjective anxiety is measured with self-rated scales and physiological correlates of anxiety are recorded (heart rate, blood pressure, skin conductance). CBD (300 mg), as well as the anxiolytic drugs diazepam (10 mg) and ipsapirone (5 mg), administered in a double-blind design, significantly attenuated SPS-induced anxiety.

The SPS test may be regarded as a good model of anxiety and has apparent validity for social anxiety disorder (SAD), as the fear of speaking in public is considered a central feature in this condition. Therefore, the anxiolytic effect of CBD in healthy volunteers observed in this test led to the hypothesis that this cannabinoid could be effective to treat SAD. This hypothesis was recently tested in 24 patients with SAD who had their performance in the SPS test compared to that of a group of 12 healthy controls.³³ The patients with SAD were divided into two groups of 12, one of which received CBD 600 mg and the other placebo, in a double-blind procedure. The results showed that the levels of anxiety, somatic symptoms, and negative self-assessment were higher in patients who took placebo than in those of the CBD group who performed similarly to healthy controls in some measures.

In another study that investigated the effects of CBD on regional cerebral blood flow (rCBF) in healthy volunteers using single photon emission computed tomography (SPECT), SPS-induced anxiety was reduced in patients receiving CBD.³⁴ In that study, patients received either CBD (400 mg) or placebo, in a crossed double-blind design, in two experimental sessions with an interval of one week. CBD significantly reduced subjective anxiety as measured by rating scales, while brain activity was increased in the left parahippocampal gyrus and decreased in the left amygdala-hippocampus complex, including the fusiform gyrus. This pattern of SPECT results is compatible with an anxiolytic action.

SPECT was also used later to investigate the neural correlates of CBD's anxiolytic effects in a sample of patients with SAD.¹⁷ A single dose of CBD 400 mg was able to reduce subjective anxiety measures and SPECT showed changes in the same regions previously identified in healthy volunteers.

Functional magnetic resonance imaging (fMRI), which allows the acquisition of larger series of images with better temporal and spatial resolution, was used to investigate the neural correlates of the anxiolytic effects of CBD in 15 healthy volunteers.³⁵ This experiment showed that CBD (600 mg) attenuated fMRI responses during the recognition of fearful facial expressions in the amygdala and the anterior cingulate, and that this attenuation pattern correlated with skin conductance responses to the stimuli. The same group also reported that the anxiolytic action of CBD occurs by altering the subcortical prefrontal connectivity via amygdala and anterior cingulate.¹⁶

Conclusion

Together, the results from laboratory animals, healthy volunteers, and patients with anxiety disorders support the proposition of CBD as a new drug with anxiolytic properties. Because it has no psychoactive effects and does not affect cognition; has an adequate safety profile, good tolerability, positive results in trials with humans, and a broad spectrum of pharmacological actions,³⁶ CBD appears to be the cannabinoid compound that is closer to have its preliminary findings in anxiety translated into clinical practice.³⁷ Future studies should test this possibility in clinical trials involving patients with different anxiety disorders, especially panic disorder, obsessive-compulsive disorder, social anxiety disorder, and post-traumatic stress disorder. In addition, because the actions of CBD are biphasic, the adequate therapeutic window for each anxiety disorder remains to be determined.

Regarding the mechanism underlying the anxiolytic effects of CBD, the most consistent evidence points to the involvement of the serotonergic system, probably through direct action on 5-HT_{1A} receptors, although other systems, as the endocannabinoid system itself, may also be implicated. Further investigation is warranted to clarify these issues, especially if we consider that CBD is a drug with a variety of effects in the nervous system.³⁸⁻⁴⁰

Δ^9 -tetrahydrocannabinol (THC), anandamide, anxiety, 2-arachidonoyl glycerol (2-AG), cannabidiol, cannabinoid receptors, cognition, depression, memory, neurogenesis, reward

Abstract

The psychoactive constituent in cannabis, Δ^9 -tetrahydrocannabinol (THC), was isolated in the mid-1960s, but the cannabinoid receptors, CB1 and CB2, and the major endogenous cannabinoids (anandamide and 2-arachidonoyl glycerol) were identified only 20 to 25 years later. The cannabinoid system affects both central nervous system (CNS) and peripheral processes. In this review, we have tried to summarize research—with an emphasis on recent publications—on the actions of the endocannabinoid system on anxiety, depression, neurogenesis, reward, cognition, learning, and memory. The effects are at times biphasic—lower doses causing effects opposite to those seen at high doses. Recently, numerous endocannabinoid-like compounds have been identified in the brain. Only a few have been investigated for their CNS activity, and future investigations on their action may throw light on a wide spectrum of brain functions.

INTRODUCTION: CANNABIS AND THE BRAIN

Cannabis Use Over Millennia: A Bird’s-Eye View

The Assyrians (about second millennium BC to sixth century BC) used cannabis for its

psychoactive, mind-altering effects as well as for its medical properties. It was named either *ganzi-gun-nu* (“the drug that takes away the mind”) or *azzalu*, which was apparently a drug for “depression of spirits,” for a female ailment (possibly amenorrhea), or even for annulment of witchcraft (Campbell Thomson 1949). The importance of cannabis intoxication seems to have been central in early Zoroastrian shamanic ecstasy (Mechoulam 1986). Its wide use in the Middle East has continued ever since. Indeed, it was a central theme in Arab poetry of the Middle Ages (Rosenthal 1971). In China and India it was known for the dual nature of its effects. In the Chinese classic medical pharmacopeia Ben Ts’ao, originally compiled around the first century AD, cannabis was recommended for numerous maladies, “but when taken in excess it could cause seeing devils” (Mechoulam 1986, p. 9).

In Europe, cannabis was introduced by the Napoleonic soldiers returning from Egypt and by British physicians returning from India. Industrial hemp, which contains negligible amounts of psychoactive material, was of course grown previously, but the psychoactive variety was unknown. The psychological effects caused by cannabis preparations—presumably North African hashish—became known in Europe mostly through the writings of members of the Parisian *Le Club des Hashichins* in the mid-nineteenth century, particularly Baudelaire, Gautier, and Moreau (Mechoulam 1986). Baudelaire, a major literary figure at the time, emphasized the “groundless gaiety” and “the distortion of sounds and colours” following cannabis use. Moreau, a psychiatrist, in his 1845 book, *Hashish and Mental Illness* (Moreau 1973), described in detail numerous psychological phenomenon noted in experimental subjects: feeling of happiness, excitement and dissociation of ideas, errors of time and space, enhancement of the sense of hearing, delusions, fluctuations of emotions, irresistible impulses, and illusions and hallucinations. This diversity of actions—some of them opposite to each other—has confounded cannabis research ever since. Indeed, Moreau reported that some of

his volunteers experienced "...occurrences of delirium or of actual madness". He concluded, "There is not a single, elementary manifestation of mental illness that cannot be found in the mental changes caused by hashish..." (Moreau 1973, p. 18). But today few marijuana users will reach a state of "delirium or of actual madness." In most cases, they will report an increase in relaxation and euphoria and possibly enhancement of their senses, but an impairment of memory. These striking differences are probably due to the well-known biphasic activity of Δ^9 -tetrahydrocannabinol (THC)—the psychoactive constituent—whose effects at low doses may be opposite to those produced by high doses. Moreau's volunteers presumably orally consumed large amounts of hashish, whereas today North Americans and Europeans usually smoke cannabis, and most users adjust their dose to achieve the desired effects.

Surprisingly, research on cannabis advanced slowly. A major reason for the neglect was the lack of knowledge of its basic chemistry. Modern research—namely research over the past 150 years—is based on quantitative data. Unlike morphine and cocaine, which had been isolated and made available in the nineteenth century and thus could be quantitatively investigated *in vitro*, in animals, and in humans, the psychoactive constituent(s) of cannabis were not isolated and their structures were not elucidated until the 1960s; hence quantitative research was not possible before then.

It is conceivable that the material reaching Europe in the past varied widely in its contents; thus its medical use also was not reliable, and research with it was of little value. Indeed, around the beginning of the twentieth century cannabis almost disappeared, both as a medicinal agent and for recreational purposes in Europe and in North America. In addition, the anti-cannabis laws made research on it, particularly in academic institutions, very difficult. Indeed, from the early 1940s until the mid-1960s, research on cannabis was limited to a few scattered groups. This paucity of early research has now been more than compensated for by the avalanche of papers on the plant cannabi-

noids and on the endogenous cannabinoids. Not surprisingly, the burst of recreational marijuana use, in the mid-1960s in the United States and later in Europe, coincided with the new wave of research on cannabis.

Δ^9 -Tetrahydrocannabinol and Cannabidiol

Over nearly a century, numerous attempts were made to isolate in pure form the active marijuana constituent(s) and to elucidate its (or their) structure(s), but these attempts were unsuccessful (Mechoulam & Hanus 2000). Now we can understand the reason for this lack of success. There are more than 60 cannabis constituents, with closely related structures and physical properties, making their separation difficult. With the advance of modern separation techniques, the isolation and the structure elucidation of the active principle, THC, was finally achieved in 1964 (Gaoni & Mechoulam 1964). Shortly thereafter, THC was synthesized (Mechoulam et al. 1967). Thus, THC became widely available for research, and several thousand papers have been published on it. Surprisingly, although most of the plant cannabinoids have now been identified—and their structures are related chemically—the only major mood-altering constituent is THC.

Another major plant cannabinoid is cannabidiol (CBD), which was isolated during the late 1930s, but its structure was elucidated only in 1963 (Mechoulam & Shvo 1963). As it does not parallel THC in its central nervous system (CNS) effects, initially only a limited amount of research was focused on it. However, over the past two decades CBD was found to be a potent anti-inflammatory agent, to attenuate the memory-impairing effects produced by THC, and to cause a plethora of other effects. Hundreds of publications have addressed its various actions (for a review, see Mechoulam et al. 2009). Both THC and CBD are present in the plant mainly as their nonpsychoactive carboxylic precursors (THC-acid and CBD-acid), which slowly lose their acidic function (decarboxylate) in the

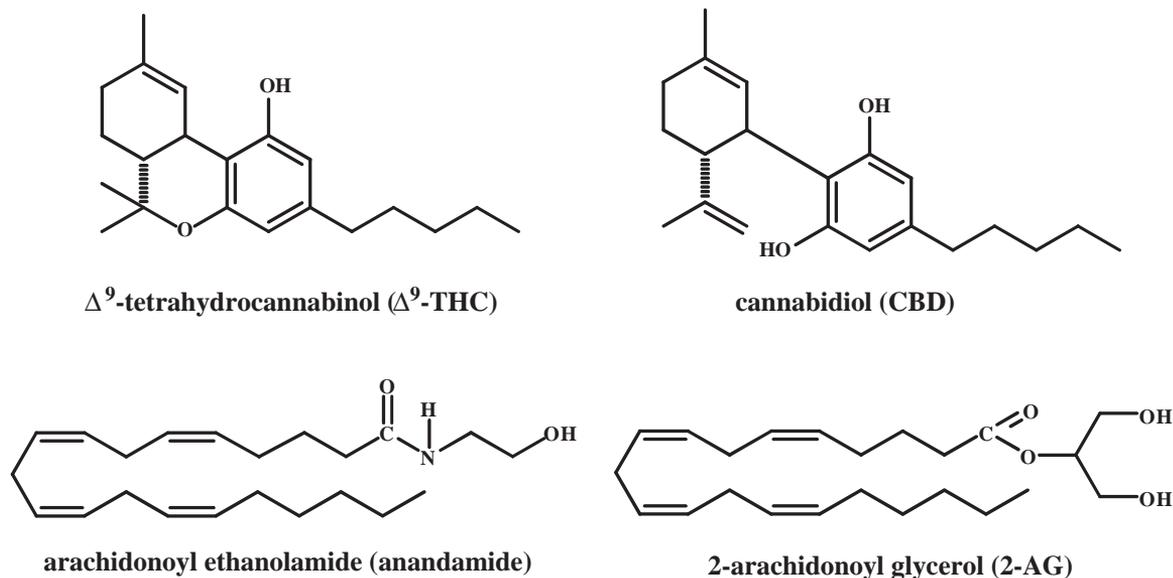

Figure 1

Structures of the plant cannabinoids Δ⁹-tetrahydrocannabinol and cannabidiol and of the endogenous cannabinoids anandamide and 2-arachidonoyl glycerol.

plant on heating. The structures of THC and CBD are presented in **Figure 1**.

The cannabis plant varieties differ tremendously in their contents. In industrial hemp the concentration of THC is less than 0.3%, in hashish in the 1960s it was about 5%, whereas in marijuana it was about 2% to 3%, but nowadays strains have been developed—mostly for illegal use—that contain up to 25%.

The Endocannabinoid Receptors

Originally it was assumed that cannabinoids act through a nonspecific membrane-associated mechanism; however, the very high stereospecificity of the action of some synthetic cannabinoids pointed to a more specific mechanism (Mechoulam et al. 1988). The first data indicating that cannabinoids may act through receptors were published by Howlett, who showed that cannabinoids inhibit adenylate cyclase formation, and the potency of the cannabinoids examined paralleled the level of their pharmacological action (Howlett et al. 1986). The same group shortly thereafter indeed

reported the existence of binding sites in the brain (Devane et al. 1988). Their distribution was found to be consistent with the pharmacological properties of psychotropic cannabinoids (Herkenham et al. 1990), and the receptor was cloned (Matsuda et al. 1990). A second, peripheral receptor, CB₂, was later identified in the spleen (Munro et al. 1993). Both CB₁ and CB₂ receptors belong to the superfamily of G protein-coupled receptors (GPCRs). The two cannabinoid receptors exhibit 48% amino acid sequence identity. Both receptor types are coupled through G proteins to adenylyl cyclase and mitogen-activated protein kinase (for a detailed review on the pharmacology of cannabinoids, see Howlett et al. 2002).

The CB₁ Receptor

It was originally believed that the CB₁ receptor was expressed mainly in the CNS, and hence it was considered a brain cannabinoid receptor. We are now aware that it is present in numerous peripheral organs, although in some of them the receptor levels are low. CB₁ receptors are

among the most abundant GPCRs in the brain. The highest densities of CB1 receptors, in the rodent brain, are noted in the basal ganglia, substantia nigra, globus pallidus, cerebellum, and hippocampus, but not in the brainstem. The high CB1 levels in the sensory and motor regions are consistent with the important role of CB1 receptors in motivation and cognition. CB1 receptors appear to be involved in γ -aminobutyric acid (GABA) and glutamate neurotransmission, as they are found on GABAergic and glutamatergic neurons (Howlett et al. 2002). The CB1 receptor is present and active from the earliest phases of ontogenetic development, including during the embryonal stages, which indicates that it is of importance in neuronal development and newborn suckling (Fride et al. 2009). Surprisingly the CB1 receptor levels in rats are increased on transition from adolescence [postnatal days (PND) 35–37] to adulthood (PND 70–72), a pattern that is opposite to that of other neuroreceptor systems (Verdurand et al. 2012). Also, unexpectedly, ligands that interact similarly with CB1 receptors may have significantly different pharmacological profiles. This may be due to the ability of CB1 receptors to form heteromeric complexes with other GPCRs (Pertwee et al. 2010).

The distribution of CB1 receptors differs in neonatal brain and adult brain. It is abundant in white matter areas at the early age but is much less abundant later (Romero et al. 1997). It is of interest to determine whether this difference has anything to do with the behavioral landmarks associated with different ages.

The CB1 receptors are found primarily on central and peripheral neurons in the presynapse. These locations facilitate their inhibition of neurotransmitter release, which is one of the major functions of the endocannabinoid system. Activation of CB1 receptors leads to a decrease in cyclic adenosine monophosphate (cAMP) accumulation and hence to inhibition of cAMP-dependent protein kinase (PKA). CB1 receptor activation leads to stimulation of mitogen-activated protein (MAP) kinase activity, which is a mechanism by which cannabinoids affect synaptic plasticity,

cell migration, and possibly neuronal growth (Howlett et al. 2002). CB1 receptors are also coupled, again through G proteins, to several types of calcium and potassium channels.

Several types of CB1 receptor gene knock-out mice are available and are widely used (Zimmer et al. 1999). CB1 receptor gene polymorphisms have been observed, and their importance is yet unknown, although susceptibility to addiction and neuropsychiatric conditions has been suggested (Zhang et al. 2004).

The CB2 Receptor

It was originally assumed that CB2 receptors were present only in cells of the immune system; however, they have now been identified throughout the CNS (Ashton et al. 2006, Onaivi et al. 2008a, van Sickle et al. 2005), particularly in microglial cells (Nunez et al. 2004, Stella 2004), though at lower levels than those of the CB1 receptors. Under some pathological conditions, CB2 receptor expression is enhanced in the CNS as well as in other tissues. It seems possible that the CB2 receptor is part of a general protective system (for a review, see Pacher & Mechoulam 2011). In that review, we speculated that “The mammalian body has a highly developed immune system which guards against continuous invading protein attacks and aims at preventing, attenuating or repairing the inflicted damage. It is conceivable that through evolution analogous biological protective systems have evolved against nonprotein attacks. There is emerging evidence that lipid endocannabinoid signaling through CB2 receptors may represent an example/part of such a protective system” (Pacher & Mechoulam 2011, p. 194). In view of the various protective effects associated with the CB2 receptor, several synthetic CB2-specific receptor agonists, which do not bind to the CB1 receptor, have been synthesized. HU-308 was one of the first such compounds reported (Hanus et al. 1999); however, numerous additional ones are now known, and since they do not cause the psychoactive effects associated with CB1 agonists, several pharmaceutical firms are presently active in the field.

CB2 receptor agonists might be expected to become drugs in various fields, including neuropsychiatric, cardiovascular, and liver disease.

Endogenous Cannabinoid Agonists

The discovery of the cannabinoid receptors suggested that endogenous molecules, which may stimulate (or inhibit) the receptors, are presumably present in the mammalian body. The plant constituent THC, which, apparently by a quirk of nature, binds to these receptors, is a lipid compound; hence it was assumed that any possible endogenous cannabinoid molecules (endocannabinoids) would also be lipids. Indeed, we were able to isolate and identify two compounds, one from brain—which we named anandamide, based on the Sanskrit word *ananda* (“supreme joy”)—and a second one [2-arachidonoyl glycerol (2-AG)] from peripheral tissues (Devane et al. 1992, Mechoulam et al. 1995). Their structures are presented in **Figure 1**. These two endogenous cannabinoids have been investigated in great detail (for a review, see Howlett et al. 2002). Additional endogenous molecules that bind to the cannabinoid receptors have been identified, but some of them may be artifacts, and interest in them is negligible.

Unlike most neurotransmitters (e.g., acetylcholine, dopamine, and serotonin), anandamide and 2-AG are not stored in vesicles but rather are synthesized when and where they are needed. Again, unlike most neurotransmitters, their action is not postsynaptic but rather mostly presynaptic, i.e., they serve as fast retrograde synaptic messengers (Howlett et al. 2002). However, whether both endocannabinoids, or only 2-AG, serve as fast retrograde synaptic messengers remains to be established. Thus 2-AG, after its postsynaptic synthesis, crosses the synapse and activates the cannabinoid presynaptic receptor, which makes possible the inhibition of various neurotransmitter systems that are present there. This is a primary activity of the endocannabinoids.

Contrary to THC, which is metabolized over several hours and excreted (or stored as

one of its metabolites), endocannabinoids are rapidly removed by a membrane transport process yet to be fully characterized (Fu et al. 2011). In the cell, anandamide is hydrolyzed to arachidonic acid and ethanolamine by fatty acid amide hydrolase (FAAH). 2-AG is also hydrolyzed enzymatically, both by FAAH and by monoacyl hydrolases. Suppression of these enzymes prolongs the activity of the endocannabinoids (Gaetani et al. 2009).

Although there is solid evidence that the activation of presynaptic CB1 receptors can lead to inhibition of the release of a number of different excitatory or inhibitory neurotransmitters both in the brain and in the peripheral nervous system, there is also in vivo evidence that CB1 receptor agonists can stimulate dopamine (DA) release in the nucleus accumbens (Gardner 2005). This effect apparently stems from a cannabinoid receptor-mediated inhibition of glutamate release. Indeed, many of the actions of cannabinoid receptor agonists (including endocannabinoids) are dose-dependently biphasic (Sulcova et al. 1998). Endocannabinoids also exhibit an “entourage effect”—namely enhancement of their activity by structurally related, biologically inactive, endogenous constituents (Ben-Shabat et al. 1988). The multiple functions of endocannabinoid signaling in the brain have recently been very well reviewed (Katona & Freund 2012).

In the following review of the effects of brain endocannabinoids and related fatty acid amides of amino acids (FAAAs) and closely related compounds on emotions and cognition, we summarize the large number of published observations. It seems that many of the FAAAs in the CNS that have been investigated—and most have not been investigated yet—have significant effects. If we assume that the dozens of compounds of this type present in the brain are not biosynthesized by mistake but rather play some physiological role, it is tempting to speculate that their levels and their interactions may be of importance in the profile of emotions and possibly of individual personalities. This topic is further discussed in the Conclusions section of this review.

THE CANNABINOID SYSTEM IN ANXIETY AND DEPRESSION

Freud considered the problem of anxiety a “nodal point, linking up all kinds of most important questions; a riddle, of which the solution must cast a flood of light upon our whole mental life” (Freud 1920). We have made some progress since Freud’s time, but according to the National Institute of Mental Health, anxiety disorders still affect about 40 million people in the United States alone, and anti-anxiety drugs are among the top prescription drugs.

Cannabis has been used for millennia as a medicinal agent (Mechoulam 1986). In India, *bhangue* (the local name for cannabis at the time) was believed to help the user to be “delivered from all worries and care” (Da Orta 1563), and its extensive present-day use throughout the world is presumably due, in part at least, to the same effects. For recent reviews on cannabis and anxiety, see Gaetani et al. (2009), Moreira & Wotjak (2010), Parolaro et al. (2010), and Zanettini et al. (2012). For general reviews on the endocannabinoid system, including detailed data on anxiety and depression and emerging pharmacotherapy, see Pacher et al. (2006) and Pertwee (2009).

A few years ago the major pharmaceutical firm Sanofi-Aventis developed and initiated marketing for an antagonist (or more precisely an inverse agonist) of the CB1 receptor. Because CB1 agonists enhance appetite, such a drug could become a major weapon against obesity. Many other companies had related compounds in various stages of development. The Sanofi compound, named rimonabant, indeed affected obesity and even blocked the psychoactive effects of THC, including short-term memory and lowered cocaine-seeking responses to suitable cues (in animals). However, although psychiatric disorders were indicated as exclusion criteria, rimonabant-treated patients had enhanced anxiety problems and suicidal tendencies (Christensen et al. 2007), and the drug had to be withdrawn from the market. This rather expensive proof is a further addition to previous

evidence, indicating the importance of the CB1 cannabinoid system in anxiety. Interestingly, Lazary et al. (2011) have recently suggested that as some variants of the CB1 receptor gene contribute more significantly than others to the development of anxiety and depression, by genomic screening—possibly in combination with the gene of the serotonin transporter—high-risk individuals could be identified and excluded from the treatment population and thus CB1 antagonists could still be useful. Such screening and treatment would represent a model for modern personalized medicine.

As mentioned previously, many of the psychological effects of cannabis, as well as of THC, are biphasic, depending principally on the dose level and to a certain extent upon the personality of the user. In normal subjects, THC may cause either euphoria and relaxation or dysphoria and anxiety (D’Souza et al. 2004, Wade et al. 2003). Pure THC may not entirely mimic the effects of cannabis, which contains additional cannabinoid constituents, such as CBD, that modulate the effect of THC. Besides, CB1 receptors rapidly desensitize following the administration of agonists, further diminishing the effect of agonists.

Cannabidiol, which does not bind to either CB1 or CB2, possesses anxiolytic and antipsychotic properties (Mechoulam et al. 2002) both in animals and in humans. It shows anxiolytic-like effects with mice in the elevated plus maze and in the Vogel conflict test (Guimarães et al. 1990, Moreira et al. 2006). In humans it was found to lower anxiety in stressful situations (Bergamaschi et al. 2011). The mode of action of CBD as an anxiolytic molecule is not well understood. Most probably it involves action as a serotonin receptor 1A (5-HT_{1A}) agonist (Campos & Guimaraes 2008), enhancement of adenosine signaling through inhibition of uptake (Carrier et al. 2006), or inhibition of the GPR55 receptor (Sharir & Abood 2010).

Endocannabinoids and Anxiety

There are no direct experimental data on the role of endocannabinoids on anxiety in

humans. To our knowledge neither anandamide nor 2-AG has ever been administered to human subjects. This is an absurd situation, presumably a result of regulatory limitations. By contrast, when insulin was discovered in the 1920s, it became an available drug within a year. We can only assume that, because many of the physiological systems are regulated through checks and balances by a variety of endogenous molecules, the endocannabinoids, which affect neurotransmitter release, apparently exert such an action on anxiety, which is a normal human reaction to a variety of stressful conditions.

Considerable data exist on the direct effects of endocannabinoids on anxiety in animals. Rubino et al. (2008) have shown that methanandamide (a stable analog of anandamide) injected into the prefrontal cortex of rats leads to an anxiolytic response. However, large increases of the dose administered led to an anxiogenic response due to TRPV1 stimulation.

An indirect pathway for enhancement of endocannabinoid levels is by blocking their enzymatic hydrolysis. The Piomelli group (Kathuria et al. 2003) reported a novel class of potent, selective, and systemically active carbamate-based inhibitors of FAAH, the enzyme responsible for the degradation of anandamide. The best inhibitors in this series (URB532 and URB597) had anxiolytic properties in rats in the elevated zero-maze test and suppressed isolation-induced vocalizations due to augmented brain levels of anandamide. These effects could be prevented by blockage of the CB1 receptor. These results indirectly confirmed that anandamide has antianxiety properties. The rationale behind this approach is based on the mechanism of anandamide formation and release, which is known to take place when and where needed. As mentioned above, contrary to the classical neurotransmitters, anandamide is not stored in synaptic vesicles but rather is synthesized and released in the synaptic cleft following neuronal activation. Presumably its levels and those of FAAH in anxiety and depression will be highest in the brain areas involved in the regulation of mood and emotions. Therefore, inhibition of anandamide

metabolism would enhance CB1 activation mainly where anandamide levels are highest. Following the same experimental rationale, Moise et al. (2008) confirmed that URB597 inhibited FAAH activity and led to elevated levels of additional fatty acid amides (N-palmitoyl ethanolamine and N-oleoyl ethanolamine), but not of anandamide itself, in hamster brain. However, Cippitelli et al. (2008) have reported an elevation of anandamide levels in rats with URB597, which was found to reduce anxiety associated with alcohol withdrawal. Blockade of the CB1 receptor with rimonabant induced anxiogenic-like behavior in the elevated plus maze; URB597 induced anxiolytic-like effects in this assay. URB597 did not alter unconditioned or conditioned social defeat or rotarod performance.

Enhancement of 2-AG levels produces similar effects. Sciolino et al. (2011) have shown that enhancement of endocannabinoid signaling with JZL184, an inhibitor of the 2-AG-hydrolyzing enzyme monoacylglycerol lipase (MGL), produces anxiolytic effects under conditions of high environmental aversiveness in rats.

Recently, two parallel publications indicated that the CB2 receptor is also involved in endogenous antianxiolytic activity. García-Gutiérrez & Manzanares (2011) reported that mice overexpressing the CB2 receptor showed lower anxiety-like behaviors in the open field, the light-dark box, and the elevated plus maze tests, indicating that increased expression of the CB2 receptor significantly modifies the response to stress in these tests. Busquets-García et al. (2011), using doses of URB597 and JZL184 that selectively modulated the concentrations of anandamide and 2-AG, respectively, recorded similar anxiolytic-like effects in two behavioral paradigms. However, whereas the anxiolytic-like effects of URB597 were mediated through a CB1-dependent mechanism, the anxiolytic-like effects of JZL184 were CB1 independent. The anxiolytic-like effects of JZL184 were absent in CB2 knockout mice and were prevented by pretreatment with selective CB2 antagonists. These two

publications indicate the crucial role of the CB2 receptor on the modulation of anxiety. As activation of the CB2 receptor does not lead to undesirable psychoactivity, these observations may be of significant clinical importance, and therefore the CB2 receptor represents a novel target to modulate anxiety-like responses. The protective effect of the CB2 receptor is in line with our previous suggestion that this receptor is part of a general protective mechanism (Pacher & Mechoulam 2011).

The molecular mechanism of the effect of endocannabinoids on anxiety is still to be fully clarified. Andó et al. (2012) have confirmed considerable involvement of CB1 receptors in the effect of exo- and endocannabinoids on GABA efflux. However, they also found that CB2-like receptors are likely involved. Hofmann et al. (2011) have described a new form of cannabinoid-mediated modulation of synaptic transmission, so far in the dentate gyrus only. They report that anandamide action under certain conditions is not mediated by CB1 receptors, CB2 receptors, or vanilloid type I receptors, and is still present in CB1^{-/-} animals. It would be of interest to determine whether this new pathway (through a receptor?) is involved in anxiety and depression.

The endocannabinoid system plays a gatekeeper role with regard to activation of the hormonal hypothalamic-pituitary-adrenal (HPA) axis. Tonic endocannabinoid signaling constrains HPA axis activity, ultimately habituating the stress response and restoring homeostasis. Specifically, glucocorticoids produced in response to stress recruit endocannabinoids to increase the excitability of principal neurons in the prelimbic region of the medial prefrontal cortex; the principal neurons initiate inhibitory relays terminating HPA axis activation (Hill et al. 2011). However, following chronic stress, endocannabinoid signaling downregulation is implicated in the overload of hormonal signaling that can result in anxiety and depression in humans. For an excellent review of this literature, see Riebe & Wotjak (2011).

The Endocannabinoid System, Neurogenesis, and Depression

Hill et al. (2008) have summarized the results of the experimental work done on the endocannabinoid system and depression and have concluded that research so far supports the assumption that hypofunctional endocannabinoid signaling contributes to depressive illness and that enhanced endocannabinoid signaling is associated with antidepressant efficacy. However, a hyperfunctional endocannabinoid system contributes to depression. This discrepancy was explained by showing that in the animal model of depression that was used, endocannabinoid signaling was differentially altered in various brain areas. The antidepressive drug imipramine affected some, though not all, of these changes.

In view of the excellent existing summary by Hill et al. (2008), in the present review we discuss mainly the relation between cannabinoids, their two known receptors, and neurogenesis. A leading current hypothesis of depression is that it is linked with neurogenesis. This hypothesis is based on the downregulation of neurogenesis in depressive-like behaviors in animals and on its upregulation by antidepressant treatments.

Over the past few years, considerable data have indicated that the endocannabinoid system plays a central role in neurogenesis (for reviews, see Galve-Roperh et al. 2009, Oudin et al. 2011). It is established that CB1 mRNA is expressed in many regions of the developing brain (Buckley et al. 1998), activation of CB1 is required for the axonal growth response (Williams et al. 2003), the endocannabinoid system drives neural progenitor cell proliferation (Aguado et al. 2006), and cannabinoids actually promote neurogenesis (Berghuis et al. 2007). Reductions in adult neurogenesis were noted in CB1- and CB2-knockout mice (Aguado et al. 2006, Palazuelos et al. 2006). Jin et al. (2004) have reported that both CB1 and VR1 receptors are involved in adult neurogenesis.

Endocannabinoids, particularly 2-AG and diacylglycerol lipases (DAGLs), which are

involved in 2-AG synthesis, play a major role in axonal growth and guidance during development (Oudin et al. 2011). Harkany and colleagues (Keimpema et al. 2010) have shown that the synthesizing enzymes (the DAGLs) alone are not sufficient to account for the growth effect of 2-AG, but both the DAGLs and the degradation enzyme, MGL, play a role. However, MGL is temporally and spatially restricted from the neurite tip, thus enhancing 2-AG activity during axonal growth. The CB2 receptor has recently been shown to promote neural progenitor cell proliferation via mTORC1 signaling (Palazuelos et al. 2012).

Because depression decreases neurogenesis, the findings summarized above are particularly exciting, as they not only help us understand the role of endocannabinoids as endogenous antidepressants but also suggest that synthetic endocannabinoid-like compounds may be developed as a novel type of antidepressive drug.

Onaivi et al. (2008a) and van Sickle et al. (2005) have reported that, contrary to previous reports, CB2 receptors are present in the brain. This unexpected discovery led several groups to investigate the relevance of this receptor in various brain pathological states. Thus, transgenic mice overexpressing the CB2 receptor showed decreased depressive-like behaviors in several relevant assays. Also, contrary to wild-type mice, these transgenic mice showed no changes in BDNF gene and protein expression under stress (García-Gutiérrez et al. 2010). The Onaivi group reported that in Japanese depressed subjects there is high incidence of a certain polymorphism in the CB2 gene (Onaivi et al. 2008b). Hu et al. (2009) compared the antidepressant action of the CB2 agonist GW405833 with the action of desipramine in two antidepressive rodent assays—the time of immobility and a swimming assay. Although both desipramine and GW405833 significantly reduced immobility, contrary to desipramine, GW405833 had no effect in the swimming test. These results indicate that desipramine and cannabinoid drugs have different mechanisms in their antidepressive action.

These results together indicate that as increased CB2 receptor expression reduces depressive-related behaviors, apparently via a mechanism that differs from the mode of action of most antidepressants used at present, the CB2 receptor could be a novel therapeutic target for depression. It will be of interest to establish whether the activity of the CB2 receptor in depression is related to neurogenesis.

CANNABINOIDS AND REWARD SYSTEMS

Although the conditions under which cannabinoid drugs have rewarding effects are more restricted than with other drugs of abuse (such as cocaine and heroin), when they produce reward-related behavior, similar brain structures are involved (for an excellent recent review, see Serrano & Parsons 2011).

Rewarding/Aversive Effects of Cannabinoids

In humans, marijuana produces euphoria, but dysphoria, dizziness, and anxiety are also reported, probably the result of the previously mentioned biphasic effects of THC. Following administration of THC to humans, some studies have shown increased dopamine transmission (Bossong et al. 2009) but others have shown no change in dopamine transmission (Barkus et al. 2011) as measured by positron emission tomography. The endocannabinoid system may play a specific role in appreciation of rewards, as THC pretreatment attenuated the brain response to feedback of monetary rewards as measured by functional magnetic resonance imaging (fMRI) (van Hell et al. 2012).

In animal models, early research suggested that THC was not rewarding to monkeys (Harris et al. 1974) when assessed in the drug self-administration paradigm. In rodents, some investigators have reported that THC (as well as other abused drugs such as cocaine) reduces the threshold for electrical brain stimulation reward (Gardner et al. 1988), but other investigators report that it increases the

threshold (Vlachou et al. 2007). Unlike the self-administration paradigm, the conditioned place preference (CPP) paradigm can be used to assess both the rewarding and the aversive effects of drugs. Conflicting findings were reported in studies using the CPP paradigm with rodents. Early reports revealed that THC produced CPPs (Lepore et al. 1995), but other reports showed conditioned place aversions (e.g., Mallet & Beninger 1998a, Parker & Gillies 1995) due to differing CPP procedures. Indeed, unlike other rewarding drugs, such as cocaine or heroin, low-dose pre-exposure to the effects of THC is necessary to establish a CPP in rodents (Valjent & Maldonado 2000).

More recently, Tanda et al. (2000) have developed a very sensitive and reliable method of establishing self-administration in monkeys, which relies on the use of very low doses of THC but does not require pre-exposure to the drug. In addition, both anandamide (Justinova et al. 2005) and 2-AG (Justinova et al. 2011) are self-administered by monkeys with or without a cannabinoid self-administration history, and both effects are prevented by pretreatment with rimonabant, indicating that the rewarding effect is CB1 receptor mediated. Treatment with the FAAH inhibitor, URB597, shifts the anandamide self-administration dose-response curve to the left, such that anandamide has rewarding effects at lower doses (Justinova et al. 2008). However, URB597 is not self-administered by monkeys (Justinova et al. 2008) and does not produce a CPP in rats (Gobbi et al. 2005), possibly because it neither causes THC-like effects nor increases extracellular mesolimbic DA levels in rats (Justinova et al. 2008, Solinas et al. 2007). In contrast, DA is known to be released in the striatum by THC (Bossong et al. 2009). Cues associated with marijuana use also activate the reward neurocircuitry associated with addiction in humans (Filbey et al. 2009). Indeed, microinjections of THC into the posterior ventral tegmental area (VTA) and into the posterior shell of the nucleus accumbens (NAcc) serve as rewards for both self-administration and CPP in rats (Zangen et al. 2006).

Cannabinoids and Relapse

Treatment of addiction is often hindered by the high rate of relapse following abstinence from the addicting drug. Multiple factors such as exposure to drug-associated stimuli, drug priming, and stress can precipitate drug craving and relapse in humans. In humans, alterations in the CB1 receptor gene and in the FAAH gene have been shown to enhance fMRI activity in reward-related areas of the brain during exposure to marijuana cues (Filbey et al. 2010).

Considerable recent research suggests that CB1 receptor antagonism (or inverse agonism) interferes with drug- and cue-induced relapse in animal models. Relapse is characterized by drug-seeking behavior in extinction triggered by renewed exposure to drug-associated cues or a priming dose of a drug itself (Everitt & Robbins 2005). Such drug-seeking behavior contrasts with actual drug-taking behavior during the self-administration session. Rimonabant prevents drug-associated cues from producing relapse following extinction training in rats and mice (De Vries & Schoffelmeer 2005). Recent evidence suggests that rimonabant is relatively more effective in interfering with drug-seeking behavior than drug-taking behavior (De Vries & Schoffelmeer 2005). In an early report, the CB1 receptor agonist, HU-210, was shown to reinstate cocaine seeking following long-term extinction of cocaine self-administration (De Vries et al. 2001), an effect that was prevented by rimonabant. Of most therapeutic importance, however, was that rimonabant alone blocked drug seeking evoked by the cocaine-paired cues and by a priming injection of cocaine, as well as seeking of heroin (De Vries et al. 2005, Fattore et al. 2003), methamphetamine (Anggadiredja et al. 2004), and nicotine (De Vries et al. 2005) evoked by drug-associated cues and by a priming injection of the drug itself. Therefore, blockade (or inverse agonism) of the CB1 receptor interferes generally with drug-seeking behavior.

Drug-seeking behavior represents the incentive motivational effects of addictive drugs under control of the mesolimbic DA system.

The regulation of the primary rewarding effects of drugs of abuse may be in part controlled by endocannabinoid release in the VTA, which produces inhibition of the release of GABA, thus removing the inhibitory effect of GABA on dopaminergic neurons (Maldonado et al. 2006). In the NAcc, released endocannabinoids act on CB1 receptors on axon terminals of glutamatergic neurons. The resulting reduction in the release of glutamate on GABA neurons that project to the VTA results in disinhibition of the VTA dopamine neurons. Blockade of CB1 receptors attenuates the release of DA in the NAcc in response to rewarding medial forebrain bundle electrical stimulation (Trujillo-Pisanty et al. 2011). The prefrontal cortex and NAcc appear to play a primary role in the prevention of cue-induced reinstatement of heroin (Alvarez-Jaimes et al. 2008) and cocaine (Xi et al. 2006) seeking by CB1 antagonism.

Although blockade of CB1 receptors affects cue- and drug-induced relapse, it does not appear to affect cocaine seeking that is reinstated by exposure to mild footshock stress (De Vries et al. 2001). Indeed, stress-induced relapse to heroin or cocaine seeking is much more sensitive to manipulations of the corticotrophin-releasing factor and noradrenaline systems than the DA system (Shaham et al. 2000). For instance, infusion of noradrenergic antagonists into the bed nucleus of the stria terminalis or the central nucleus of the amygdala prevents footshock-induced but not cocaine-induced reinstatement of cocaine seeking (Leri et al. 2002).

Rimonabant showed great promise as an antirelapse treatment; however, as mentioned above, it was removed from the European market as a treatment for obesity because of the undesirable side effects of anxiety. The generality of the effects of cannabinoids on motivational processes may explain these undesirable side effects. Given that rimonabant not only acts as a CB1 antagonist but is also a CB1 inverse agonist, the relapse-preventing properties, and potentially the adverse side effects, may also be mediated by its inverse cannabimimetic effects that are opposite in direction from those

produced by cannabinoid receptor agonists (Pertwee 2005). Recent evidence suggests that at least some adverse side effects of CB1 receptor antagonists/inverse agonists seen in clinical trials (e.g., nausea) may reflect their inverse agonist properties (Bergman et al. 2008). It will be of interest to evaluate the potential of more newly developed CB1 receptor neutral antagonists, such as AM4113 (Sink et al. 2008), to prevent drug-seeking behavior.

Recently, selective CB2 receptor agonists were shown to inhibit intravenous cocaine self-administration, cocaine-enhanced locomotion, and cocaine-enhanced accumbens extracellular dopamine in wild-type and CB1 receptor knockout mice but not in CB2 knockout mice. This effect was blocked by a selective CB2 receptor antagonist. These findings suggest that brain CB2 receptors also modulate cocaine's effects (Xi et al. 2011). Again, as mentioned above, the CB2 receptor seems to have general protective properties (Pacher & Mechoulam 2011).

Although considerable evidence indicates that antagonism of the CB1 receptor interferes with cue- and drug-induced relapse, there is a growing literature suggesting that FAAH inhibition and cannabidiol also prevent relapse to drug seeking. FAAH inhibition has been selectively evaluated for prevention of nicotine seeking (Forget et al. 2009, Scherma et al. 2008). However, it is not clear if these effects are mediated by the action of anandamide or other fatty acids [oleoylethanolamide (OEA) and palmitoylethanolamide (PEA)], which act on peroxisome proliferator-activated receptor- α (PPAR- α) receptors, because Mascia and colleagues (2011) recently showed that selective PPAR- α agonists also counteract the reinstatement of nicotine seeking in rats and monkeys. Thus, elevations in fatty acids produced by blockade of FAAH may have potential in treating relapse. Most recently, Cippitelli et al. (2011) found that FAAH inhibition reduced anxiety produced by nicotine withdrawal. Cannabidiol, the nonpsychoactive compound in marijuana, also attenuated cue-induced reinstatement of heroin seeking as well as restored disturbances of glutamatergic and endocannabinoid systems

in the accumbens produced by heroin seeking (Ren et al. 2009). Apparently, in addition to the many other ailments that cannabidiol improves (Mechoulam et al. 2002), it may also be a potential treatment for heroin craving and relapse.

CANNABINOIDS AND COGNITION

Cognition involves the ability to acquire, store, and later retrieve new information. Several recent reviews are available on the effects of cannabis on cognition in humans and other animals (Akirav 2011, Marsicano & Lafenetre 2009, Ranganathan & D'Souza 2006, Riedel & Davies 2005). Clearly, the chief psychoactive component in cannabis, THC, produces acute cognitive disturbances in humans and animals, more profoundly affecting short-term than long-term memory.

Effects of Cannabis on Cognition in Humans

When under the influence of THC, humans demonstrate transient impairment in short-term episodic and working memory and consolidation of these short-term memories into long-term memory, but no impairment in retrieval of information once it has been previously encoded into long-term storage (Ranganathan & D'Souza 2006). However, a recent naturalistic study revealed that cannabidiol prevented the memory-impairing effects of acute THC in humans (Morgan et al. 2010). Therefore, the relative THC/cannabidiol ratio in cannabis will profoundly modify the effects of cannabis on memory in human marijuana smokers.

The effect of chronic cannabis exposure on cognitive abilities of abstinent individuals is, however, controversial and fraught with contradictions in the literature. Polydrug abuse and pre-existing cognitive and emotional differences between cannabis users and nonusers make interpretation of the human literature problematical. In a review of the literature, Solowij & Battisti (2008) conclude that chronic exposure to marijuana is associated

with dose-related cognitive impairments, most consistently in attention and working memory functions—not dissimilar to those observed under acute intoxication. On the other hand, several reports indicate that few, if any, cognitive impairments are produced by heavy cannabis use over several years (e.g., Dregan & Gulliford 2012, Lyketso et al. 1999). More recently, a thorough review of the specific versus generalized effects of drugs of abuse on cognition (Fernandez-Serrano et al. 2011) reported that there has been only one study (Fried et al. 2005) of “pure” cannabis users. Fried et al. (2005) conducted a longitudinal examination of young adults using neurocognitive tests that had been administered prior to the first experience with marijuana smoke. Individuals were defined (by urination samples and self-reports) as light (fewer than five times a week) or heavy (greater than five times a week) current or former (abstinent for at least three months) users. Current heavy users performed worse than nonusers in overall IQ, processing speed, and immediate and delayed memory tests. In contrast, former heavy marijuana smokers did not show any cognitive impairment. Fernandez-Serrano et al. (2011) conclude that the acute effects of cannabis on prospective memory are attenuated in long-term abstinence (at least three months).

Drawing conclusions from the human literature is challenging (Ranganathan & D'Souza 2006) because of widely differing methodologies, including different tasks, lack of sufficient controls, participant selection strategies (only experienced cannabis users included in samples), different routes of administration, different doses administered, often small sample sizes, tolerance of and dependence on cannabinoids, and the timing of the test (given the long half-life of THC). In addition, factors such as a predisposition to substance use in general may confer greater vulnerability to cannabis-related cognitive effects. Therefore, experimental investigation of the effects of cannabinoids on various processes involved in learning and memory rely heavily upon animal models. These models provide insights into the critical role of the

endocannabinoid system in the physiology of learning and memory.

Effects of CB1 Agonists on Learning and Memory in Nonhumans

Consistent with the human literature, most reports using animal models suggest that acute administration of CB1 agonists selectively disrupts aspects of short-term or working memory while leaving retrieval of previously learned memory (long-term or reference memory) largely intact. A common behavioral paradigm designed to evaluate these different aspects of memory is the delayed matching (or nonmatching) to sample (DMS) task. Once the animal has learned to perform this operant task (reference memory), it must then indicate (usually by pressing a bar) which test sample matches (or does not match) the original sample stimulus presented several seconds earlier (working memory). CB1 agonists (THC and WIN-55,212) disrupt accuracy of such performance in a delay-dependent manner, consistent with a selective disruption of working memory (Heyser et al. 1993). These effects are blocked by the CB₁ antagonist rimonabant. It is important to note that these effects occur at doses that do not interfere with the acquisition of the original reference memory of the task. A simpler variant of the DMS procedure used in rodents, the spontaneous object recognition task, does not rely upon prior operant training, but instead relies upon a rodent's natural preference to explore novel objects. In this task, a rat or mouse is allowed to spontaneously explore two identical objects, then after a delay is given a choice to explore a novel object or the previously presented sample object. In this measure of short-term memory, CB1 agonists (WIN-55,212 and CP55,940) produced a delay-dependent deficit in discrimination between the novel and familiar objects in the choice task (O'Shea et al. 2004, Schneider & Koch 2002), with the disruptive effect enhanced 21 days after chronic pretreatment in adolescents but not adults (O'Shea et al. 2004).

Spatial memory tasks also rely upon accurate working memory. A demanding spatial

memory task is the 8-arm radial maze, which requires rats to first learn which arms contain food rewards (reference memory) and then to remember which arms have already been visited in a test session (working memory) after an imposed delay. THC increases the number of working memory errors (re-entries) at low doses, and these effects are blocked by rimonabant (Lichtman & Martin 1996). The impairment of working memory by THC (5 mg/kg) in adult rats is enhanced following chronic exposure (once a day for 90 days), but disappears following 30 days of abstinence from the drug (Nakamura et al. 1991). On the other hand, adolescent rats treated with very high escalating doses of THC (2.5–10 mg/kg) chronically for 10 days and left undisturbed for 30 days until their adulthood exhibited greater impairment in spatial working memory on the radial arm maze than did vehicle controls. The working memory deficit was also accompanied by a decrease in hippocampal dendritic spine density and length (Rubino et al. 2009).

The commonly employed spatial memory task, the Morris water maze, requires animals to navigate in a pool of water to locate a hidden platform by learning its location relative to salient visual cues. The water maze task can be used to evaluate the effect of cannabinoid agonists on reference memory (location of the platform remaining fixed across days and on trials within a day) and working memory (location of platform is changed each day, but remains constant across trials within a day). In the water maze task, THC disrupts working memory at much lower doses than those that disrupt reference memory; in fact, doses sufficient to disrupt working memory are below those that produce other effects characteristic of CB1 agonism, including antinociception, hypothermia, catalepsy, or hypomotility (Varvel et al. 2001). Vaporized marijuana smoke produces a similar effect (Niyuhire et al. 2007a).

Although exogenous CB1 agonists consistently suppress working memory in these models, manipulations that elevate endogenous cannabinoids do not consistently produce such an impairment. On the one hand, elevation

of anandamide (by FAAH inhibition), but not 2-AG (by MGL inhibition), interfered with the consolidation of contextual conditioned fear and object recognition memory (Busquets-Garcia et al. 2001); on the other hand, several other studies have reported facilitation of working memory by FAAH inhibition (Campolongo et al. 2009a, Mazzola et al. 2009, Varvel et al. 2007). Likewise, FAAH-deficient mice (with tenfold increases in brain levels of anandamide) also showed improved rather than impaired performance in this task. Therefore, the effects of exogenously administered CB1 agonists are not always consistent with the effects of manipulations that elevate the natural ligands for the receptors. However, FAAH inhibition also elevates several other fatty acids, including OEA and PEA, which are ligands for PPAR- α . Mazzola et al. (2009) recently found that the enhanced acquisition of a passive avoidance task by the FAAH inhibitor, URB597, was not only reversed by a CB1 antagonist, but also by a PPAR- α antagonist (MK 886). The PPAR- α agonist (WAY1463) also enhanced passive avoidance performance, and this effect was blocked by a PPAR- α antagonist (Campolongo et al. 2009a). Therefore, FAAH inhibition may enhance memory not only by increasing anandamide, but also by elevating OEA and PEA. Most recently, Pan et al. (2011) reported that MGL knockout mice, with elevated levels of 2-AG, show improved learning in an object recognition and water maze task. Thus, there is evidence that both anandamide and 2-AG enhance learning and memory under some conditions.

Effects of CB1 Antagonists on Learning and Memory in Nonhumans

The findings that CB1 agonists produce working memory deficits suggest that inhibition of these receptors may lead to enhancement of short-term memory. However, the literature is replete with mixed findings. CB1 antagonist administration produces memory enhancement in mice in an olfactory recognition task (Terranova et al. 1996) and a spatial memory task in an 8-arm radial maze (Lichtman 2000).

In addition, CB1^{-/-} mice are able to retain memory in an object recognition test for at least 48 hours after the first trial, whereas wild-type controls lose their capacity to retain memory after 24 hours (Reibaud et al. 1999). In contrast, studies using other paradigms, such as the DMS, have shown no benefits of rimonabant on learning or memory (e.g., Hampson & Deadwyler 2000, Mallet & Beninger 1998b). One explanation (Varvel et al. 2009) for the mixed findings is that the temporal requirements of the task predict the potential of CB1 antagonism to facilitate or not facilitate performance. Studies showing enhancement of memory generally require memory processes lasting minutes or hours, whereas studies showing that rimonabant is ineffective generally require retention of information lasting for only seconds, suggesting that blockade of CB1 receptors may prolong the duration of a memory rather than facilitate learning. If this is the case, then rimonabant may facilitate retention of memories tested after long intervals but may have no benefits in tasks such as DMS and repeated acquisition that require rapid relearning of new information (for review, see Varvel et al. 2009).

Role of Endocannabinoids in the Hippocampus in Learning and Memory

The decrement in working memory by cannabinoids appears to involve their action at the hippocampus. The hippocampus is one of the areas of the brain with the highest density of CB1 receptors, and large amounts of anandamide are found in the rodent hippocampus. Interestingly, the selective detrimental effect of CB1 agonists on working memory (but not reference memory) resembles the effects of hippocampal lesions on these two forms of memory (Hampson & Deadwyler 2000, Heyser et al. 1993). Furthermore, THC-induced deficits in the DMS paradigm are associated with specific decreases in firing of individual hippocampal neurons during the sample but not the match part of the experiment (Heyser et al. 1993). Intracranial administration of the CB1 agonists

directly into the hippocampus also disrupts working memory performance in an 8-arm radial maze (Lichtman et al. 1995, Wegener et al. 2008), water maze spatial learning (Abush & Akirav 2010), and object recognition memory (Clarke et al. 2008). In contrast, intrahippocampal AM251 also has been shown to disrupt memory consolidation of an inhibitory avoidance task (de Oliveira et al. 2005). Recent work suggests that the cannabinoid and the cholinergic systems in the hippocampus interact during performance of a short-term memory task in the rat (Goonawardena et al. 2010). These effects may be mediated by cannabinoid-induced decreases in acetylcholine release in the hippocampus. Acetylcholine is also implicated in the pathophysiology of Alzheimer's disease and other disorders associated with declined cognitive function.

Overall, the literature implicates changes in hippocampal functioning as the source of working memory deficits produced by THC, although other brain regions are currently being investigated as well (Marsicano & Lafenetre 2009). Cannabinoid receptors localized to different brain regions modulate distinct learning and memory processes, such that the role of endocannabinoids in other regions may be different than their role in the hippocampus. In fact, Campolongo et al. (2009b) showed that infusion of CB1 agonist WIN 55,212,2 into the basolateral amygdala actually enhanced consolidation of inhibitory avoidance learning by enhancing the action of glucocorticoids in this region. Consistently, Tan et al. (2011) found that delivery of a CB1 antagonist to this region interferes with olfactory fear conditioning. The differential effects of CB1 agonists on different brain regions may account for different findings reported between systemic and localized administration of cannabinoid agonists.

Long-term changes in synaptic strength are believed to underlie associative memory formation in the hippocampus and amygdala. The impairments in working memory produced by CB1 agonists may be the result of the suppression of glutamate release in the hippocampus, which is responsible for the establishment of

long-term potentiation, a putative mechanism for synaptic plasticity (Abush & Akirav 2010, Shen et al. 1996). Retrograde signaling by endocannabinoids results in suppression of neurotransmitter release at both excitatory (glutamatergic) and inhibitory (GABAergic) synapses in the hippocampus in a short- and a long-term manner. Endocannabinoid-induced long-term depression (LTD) is one of the best examples of presynaptic forms of long-term plasticity. Recent evidence indicates that presynaptic activity coincident with CB1 receptor activation and NMDA receptor activation is required for some forms of endocannabinoid LTD. The long-lasting effects of LTD appear to be mediated by a CB1 receptor-induced reduction of cAMP/PKA activity in the hippocampus (Heifets & Castillo 2009).

Endocannabinoid Modulation of Extinction of Aversive Memory

Avoidance of aversive stimuli is crucial for survival of all animals and is highly resistant to extinction. Considerable evidence indicates that the endogenous cannabinoid system is specifically involved in extinction learning of aversively motivated learned behaviors (Marsicano et al. 2002, Varvel & Lichtman 2002). A seminal paper by Marsicano et al. (2002) reported that CB1 knockout mice and wild-type mice administered the CB1 antagonist rimonabant showed impaired extinction in classical auditory fear-conditioning tests, with unaffected memory acquisition and consolidation. This effect appeared to be mediated by blockade of elevated anandamide in the basolateral amygdala during extinction (Marsicano et al. 2002). Using the Morris water maze task, Varvel & Lichtman (2002) reported that CB1 knockout mice and wild-type mice exhibited identical acquisition rates in learning to swim to a fixed platform; however, the CB1-deficient mice demonstrated impaired extinction of the originally learned task when the location of the hidden platform was moved to the opposite side of the tank. Because animals deficient in CB1 receptor activity show impairments

in suppressing previously learned behaviors, CB1 agonists would be expected to facilitate extinction of learned behaviors in nondeficient animals. Indeed, WIN-55,212 facilitated extinction of contextual fear memory and spatial memory in rats (Pamplona et al. 2006).

The effect of enhancing the endogenous levels of anandamide by blocking its reuptake or by inhibiting FAAH during extinction learning has also recently been investigated. Chhatwal et al. (2005) reported that the reuptake blocker (and FAAH inhibitor) AM404 selectively facilitated extinction of fear-potentiated startle in rats, an effect that was reversed by rimonabant pretreatment. Varvel et al. (2007) reported that mice deficient in FAAH, either by genetic deletion (FAAH^{-/-}) or by pharmacological inhibition, displayed both faster acquisition and extinction of spatial memory tested in the Morris water maze; rimonabant reversed the effect of FAAH inhibition during both task phases. These effects appear to be specific to extinction of aversively motivated behavior, because neither CB1-deficient mice (Holter et al. 2005) nor wild-type mice treated with rimonabant (Niyuhire et al. 2007b) displayed a deficit in extinction of operant responding reinforced with food. Most recently, Manwell et al. (2009) found that the FAAH inhibitor URB597 promoted extinction of a conditioned place aversion produced by naloxone-precipitated morphine withdrawal but did not promote extinction of a morphine-induced or amphetamine-induced CPP.

It has been well established that extinction is not unlearning, but instead is new inhibitory learning that interferes with the originally learned response (Bouton 2002). The new learning responsible for extinction of aversive learning appears to be facilitated by activation of the endocannabinoid system and prevented by inhibition of the endocannabinoid system. More recent work has suggested that the apparent effects of manipulation of the endocannabinoids on extinction may actually reflect its effects on reconsolidation of the memory that requires reactivation (Lin et al. 2006, Suzuki et al. 2008). That is, every time a consol-

idated memory is recalled it switches to a labile state and is subject to being disrupted. Depending upon the conditions of retrieval and the strength of the original trace, these reactivated memories can undergo two opposing processes: reconsolidation, when the conditions favor the permanence of the trace, or extinction, when the conditions indicate that the memory has no reason to persist. Suzuki et al. (2008) have proposed that the endocannabinoid system is important for the destabilization of reactivated contextual fear memories; that is, reconsolidation or extinction relies on a molecular cascade (protein synthesis and cAMP response element-binding-dependent transcription) that is impeded by prior blockade of the CB1 receptors. Fear memory cannot be altered during restabilization if it was not previously destabilized via activation of the CB1 receptor. Whatever the actual mechanism for facilitated extinction of aversive memories with activation of the endocannabinoid system and inhibited extinction with inhibition of the endocannabinoid system, these results have considerable implications for the treatment of posttraumatic stress disorder. Progress in enhancing endocannabinoid signaling will be of great benefit in the treatment of this distressing disorder.

CONCLUSIONS

Cannabinoid research was originally initiated with the limited aim of understanding the action of an illicit drug. After the chemistry of the plant and the pharmacological and psychological actions of THC were elucidated—or actually only assumed to be elucidated—in the 1960s and early 1970s, research in the field waned. However, over a decade starting from the mid-1980s, two specific receptors and their ligands—the bases of the endocannabinoid system—were found to be involved in a wide spectrum of biological processes. This endocannabinoid system has opened new vistas in the life sciences, particularly in aspects associated with the CNS.

One of the main results of activation of the presynaptic CB1 receptor is inhibition of neurotransmitter release. By this mechanism the

endocannabinoids reduce excitability of presynaptic neurons. CB1 receptors are responsible for the well-known marijuana effects as well as for effects on cognition, reward, and anxiety. In contrast, a major consequence of CB2 receptor activation is immunosuppression, which limits inflammation and associated tissue injury. Enhancement of CB2 receptor expression and/or of endocannabinoid levels has been noted in numerous diseases, including CNS-related ones. Thus, a main result of CB2 receptor activation seems to be a protective effect in a large number of physiological systems.

In the present review we have summarized evidence that cannabinoids modulate anxiety, brain reward function, and cognition by acting at CB1 (and possibly CB2) receptors in distinct brain regions. The effects of cannabis on anxiety appear to relate to the dose of THC and are modulated by the anxiolytic action of cannabidiol (if present in the plant material). A major function of the endocannabinoid system is the homeostatic regulation of the HPA axis in response to stressors. Although THC does not appear to be as rewarding as other drugs of abuse (cocaine, heroin, amphetamine) in animal models of drug abuse, recent work suggests that under optimal conditions, animals do self-administer THC. The rewarding effects of THC are mediated by elevation of DA in the mesolimbic DA system. Blockade of CB1 receptors in this system interferes with the potential of drugs or drug-related cues (but not stress) to produce relapse in animal models.

Both the animal and human literatures suggest that CB1 agonists interfere with short-term working memory and may interfere with consolidation of these memories into long-term memories while leaving previously learned long-term reference memory intact. In cannabis, these effects of THC may be prevented by a sufficiently high dose of cannabidiol. In addition, the memory-impairing effects of THC are usually limited to the acute effects of the drug itself. Recent literature suggests that the endocannabinoid system may play an especially important role in the extinction of aversively motivated learning. Treatments

that amplify the action of endocannabinoids may play a critical role in treating posttraumatic stress disorder in the future. Memory decline in aging may also be protected by the action of the endocannabinoid system. Mice lacking CB1 receptors showed accelerated age-dependent deficits in spatial learning as well as a loss of principal neurons in the hippocampus, which was accomplished by neuroinflammation (Albayram et al. 2011). These exciting findings suggest that CB1 receptors on hippocampal GABAergic neurons protect against age-dependent cognitive declines. In addition, interesting recent work suggests that cannabidiol reduces microglial activity after β -amyloid administration in mice and prevents the subsequent spatial learning impairment (Martin-Moreno et al. 2011), suggesting that this nonpsychoactive compound in marijuana may be useful in treating Alzheimer's disease. Cannabidiol has also been shown to recover memory loss in iron-deficient mice, a model of neurogenerative disorders (Fagherazzi et al. 2012).

A very large number of anandamide-like compounds, namely FAAAs or chemically related entities, have been found in the brain (Tan et al. 2010). The action of very few of them has been evaluated. However, those that have been investigated show a variety of effects. Arachidonoyl serine has vasodilator activity—an important protective property in some brain diseases—and lowers the damage caused by head injury (Cohen-Yeshurun et al. 2011). Surprisingly, this effect is blocked by CB2 antagonists, although this compound does not bind to the CB2 receptor. Apparently, its action is indirectly CB2 related. Oleoyl serine, which is antiosteoporotic, is also found in the brain (Smoum et al. 2010); oleoylethanolamide regulates feeding and body weight (Fu et al. 2005); stearoylethanolamide shows apoptotic activity (Maccarrone et al. 2002); the anti-inflammatory palmitoylethanolamide may also be protective in human stroke (Naccarato et al. 2010); arachidonoyl glycine is antinociceptive (Bradshaw et al. 2009); and arachidonoyl dopamine affects synaptic transmission in dopaminergic neurons

by activating both cannabinoid and vanilloid receptors (Marinelli et al. 2007). Presumably, the additional many dozens of related endogenous molecules found in the brain will also exhibit a wide spectrum of activities. Why does the brain invest so much synthetic endeavor (and energy) to prepare such a large cluster of related molecules rather than just a few of them?

If subtle chemical disparity is one of the causes for the variability in personality—an area in psychology that is yet to be fully understood—we may have to look for a large catalog of compounds in the brain with distinct CNS effects. Is it possible that the

above-described large cluster of chemically related anandamide-type compounds in the brain is related to the chemistry of the human personality and the individual temperamental differences? It is tempting to assume that the huge possible variability of the levels and ratios of substances in such a cluster of compounds may allow an infinite number of individual differences, the raw substance which of course is sculpted by experience. The known variants of CB1 and FAAH genes (Filbey et al. 2010, Lazary et al. 2010) may also play a role in these differences. If this intellectual speculation is shown to have some factual basis, it may lead to major advances in molecular psychology.

Anxiogenic-like effects of chronic cannabidiol administration in rats

Abstract

Rational Several pre-clinical and human-based studies have shown that acutely administered cannabidiol (CBD) can produce anxiolytic-like effects

Objectives The present study investigated the effects of chronic administration of CBD on rat behaviour and on the expression of brain proteins.

Methods Male Lister-hooded rats (150–200 g, $n=8$ per group) received daily injections of CBD (10 mg/kg, i.p.) for 14 days. The rats were subjected to two behavioural tests: locomotor activity and conditioned emotional response (CER). The expression of brain-derived neurotrophic factor (BDNF), its receptor tyrosine kinase B (Trk B), extracellular signal-regulated kinases (ERK1/2) and phospho-ERK1/2 and the transcription factor cyclic AMP response element binding protein activation (CREB) and phospho-CREB were determined in brain regions such as the frontal cortex and hippocampus using Western immunoblotting.

Results CBD significantly increased the time spent freezing in the CER test with no effect on locomotor activity. CBD significantly reduced BDNF expression in the hippocampus and frontal cortex with no change in the striatum. In addition, CBD significantly reduced TrkB expression in the hippocampus with a strong trend

towards reduction in the striatum but had no effect in the frontal cortex. In the hippocampus, CBD had no effect on ERK1/2 or phospho-ERK2, but in the frontal cortex, CBD significantly reduced phospho-ERK1/2 expression without affecting total ERK.

Conclusion Chronic administration of CBD produced an anxiogenic-like effect in clear opposition to the acute anxiolytic profile previously reported. In addition, CBD decreased the expression of proteins that have been shown to be enhanced by chronic treatment with antidepressant/anxiolytic drugs.

Keywords Cannabidiol · Anxiety · BDNF · ERK · CREB · Hippocampus · Cannabinoids

Introduction

The *Cannabis sativa* plant contains at least 66 different cannabinoids, including the main psychoactive component, Δ^9 -tetrahydrocannabinol (Δ^9 -THC) and other non-psychoactive components such as cannabidiol (CBD) (Ashton 2001; Mechoulam and Hanus 2002). Although the relative amounts of phytocannabinoids in cannabis preparations are highly variable, the content of CBD can exceed that of THC, in cannabis resin for example (Potter et al. 2008). CBD represents one of the most promising candidates for clinical utilisation, in a variety of conditions, due to its lack of cognitive and psychoactive actions and its excellent tolerability in humans (Mechoulam and Hanus 2002). Retrospective studies in cannabis users and small clinical trials have shown that moderate recreational or medicinal use of cannabis in humans results in mood elevation with a reduction in stress, anxiety and depressive symptoms (Gruber et al. 1996; Williamson and Evans

2000), and some of these effects have been attributed to CBD. However, the molecular mechanisms underlying these effects are unclear, and several mechanisms of actions have been proposed for CBD, including diffuse targets within the endocannabinoid system (Bisogno et al. 2001), inhibition of serotonin reuptake and increased catecholaminergic activity (Russo and McPartland 2003), activation of serotonergic (5HT_{1A}) receptors (Russo et al. 2005), transient receptor potential type V1 (TRPV1) (Bisogno et al. 2001) and V2 (TRPV2) (Qin et al. 2008) and enhancement of adenosinergic signalling (Carrier et al. 2006). CBD, unlike Δ^9 -THC, has very low affinity for either cannabinoid CB1 or CB2 receptors (Petitet et al. 1998), but it has been shown to block the transport of anandamide, the archetypal endocannabinoid ligand (Bisogno et al. 2001) and to inhibit its enzymatic hydrolysis (Mechoulam and Hanus 2002). Thus, the action of CBD could involve other cannabinoid receptors such as the abnormal cannabidiol receptor, a non-CB1/non-CB2 receptor (Franklin and Stella 2003; Jarai et al. 1999). Actions of CBD at GPR55, an orphan G protein-coupled receptor, either as an agonist or antagonist have also been described (Oka et al. 2007; Ryberg et al. 2007).

Acute anxiolytic properties of CBD have been demonstrated in several preclinical studies that employed various paradigms such as the Vogel conflict test (Moreira et al. 2006), the elevated plus maze (Guimaraes et al. 1990) and fear conditioning (Lemos et al. 2010; Resstel et al. 2006). Recently, antidepressant-like effects have also been reported in mice following acute CBD administration (Zanelati et al. 2010). However, the effects of repeated CBD administration on affective behaviours in pre-clinical tests have not been reported.

The neurotrophin, brain-derived neurotrophic factor (BDNF), has been implicated in a variety of affective disorders including anxiety and depression (Bergami et al. 2009; Martinowich et al. 2007). Multiple classes of antidepressant drugs, as well as electroconvulsive shock treatment, can significantly increase BDNF messenger RNA (mRNA) expression in the hippocampus and prefrontal cortex (Duman and Monteggia 2006; Nibuya et al. 1995). This neurotrophin is thought to enhance neurogenesis (Li et al. 2008) via its receptor, tyrosine kinase B (TrkB), which activates a variety of downstream signalling pathways including extracellular signal-regulated kinases (ERKs) (Patapoutian and Reichardt 2001). Cyclic AMP response element binding protein activation (CREB) is one of the long-term transcriptional modulators that is thought to mediate the effects of antidepressants on BDNF expression (Malberg and Blendy 2005). The effects of repeated CBD administration on the expression and function of these signalling proteins are unknown.

Aim of the work

In order to assess the therapeutic potential of CBD for the treatment of affective disorders, it is necessary to understand the effects of repeated administration. Therefore, the aim of the present study was to test the hypothesis that repeated CBD administration would induce anxiolytic-like effects in aversive conditioned rats and modify the expression of proteins in the brain that have been associated with chronic antidepressant/anxiolytic drug treatments.

Material and methods

Animals

Male Lister-hooded rats (150–200 g, $n=16$) were obtained from the Biomedical Sciences Unit, University of Nottingham (a colony derived from Charles River UK stock). Animals were housed in groups of four and maintained on a 12/12-h light/dark cycle, temperature was maintained at $22\pm 2^\circ\text{C}$ and relative humidity 40–60%. Animals had free access to standard rat laboratory chow and water. All animal procedures were carried out in accordance with the UK Home Office Animals (Scientific Procedures) Act of 1986 and Local Ethical Committee Approval.

Drugs and treatment

Pure crystalline CBD (99.3% by HPLC with no other phytocannabinoids detectable) was a generous gift from GW Pharmaceuticals. It was dissolved in a vehicle of 3:1:16 solution of ethanol/Tween 80/0.9% saline. The rats received daily i.p. injections of either vehicle or CBD (10 mg/kg) for 14 days ($n=8$ per group). The dose of CBD was selected on the basis of other studies that reported effects of the drug in animal models of anxiety (Moreira et al. 2009; Moreira et al. 2006; Oviedo et al. 1993; Resstel et al. 2009; Resstel et al. 2006). Moreover, this dose of CBD (10 mg/kg) was reported to induce an anxiolytic-like effect after acute administration (Moreira et al. 2006; Resstel et al. 2006). CBD and vehicle solutions were prepared immediately before use and injected intraperitoneally (i.p.) in a volume of 1 ml/kg.

Procedures

Physiological measurements

Body weight and food consumption were measured daily throughout the experiment. Each cage housed four rats, and the average amounts of chow consumed per rat per day were determined.

Locomotor activity

Locomotor behaviour was recorded for 20 min on the third and ninth days of the experiment in a sound-isolated room (Fig. 1). The rats were habituated to the activity boxes (40×24×25 cm, clear acrylic) for 1 h on the second day. The activity boxes were cleaned with 20% (v/v) ethanol after removal of rats. Spontaneous locomotor activity, in terms of total distance moved (cm), mean velocity (cm/s) and rearing frequency, was recorded using Ethovision software [Ethovision (version 2.0), Noldus Information Technology, Costerweg, and The Netherlands]. The duration of periods of rearing and grooming was scored manually.

Conditioned emotional response testing

The conditioned emotional response (CER) has been used as a model of conditioned aversion in order to evaluate the anxiolytic effects of several classes of drugs such as selective serotonin reuptake inhibitors (Inoue et al. 1996) and benzodiazepines (Li et al. 2001). A conditioned fear response to a context is produced by exposing the animal to an environment (context) where an aversive or unpleasant stimulus (mild foot shock) is delivered (Rudy et al. 2004). Re-exposure to the same context induces conditioned fear responses, such as freezing behaviour.

The test consisted of two phases: conditioning on the 10th day and testing on the 11th day (Fig. 1). Rats were individually conditioned on the 10th day of the experiment by exposure to inescapable foot shock. Rats were subjected to 0.4 mA of footshock for 1 s every minute for 10 min in a shock chamber with a metal grid floor. This chamber had Perspex walls (26×23×39 cm) with 21 stainless steel rods spaced 1.5 cm apart as the floor, and this was and connected to a shock generator (Campden Instruments, Loughbrough, UK). Twenty-four hours after the last shock session, the rats were again placed in the shock chamber for 10 mins but without shocks, and freezing behaviour was measured. Freezing was defined as the complete absence of movement, except respiration, while the animal assumed a characteristic tense posture. The chamber was cleaned with 20% (v/v) ethanol before and after use (Finn et al. 2004a). The tests were all carried out between 0900 and 1300 hours.

Western immunoblotting

Rats were killed on day 15 of the experiment by a blow to the head followed by decapitation, and their brains were removed rapidly. The meninges were removed and brain regions dissected on ice and stored at −80°C. The expression of various proteins was measured in the hippocampus, frontal cortex and striatum.

Sample preparation A volume of lysis buffer [20 mM Tris, 1 mM EGTA, 320 mM sucrose, 0.1% Triton X100, 1 mM NaF and 10 mM beta-glycerophosphate dissolved in 500 ml distilled water (pH 7.6) containing protease inhibitor cocktail tablets (Sigma, UK)] was added based on the weights of frontal cortical samples to give a final concentration of 100 mg/ml. Samples were kept on ice through the assay all the time. The samples were homogenised by hand and mixed (rotating mixer) in a cold room for 10 min. The samples were centrifuged at 13,000×g for 10 min at 4°C. The supernatant was removed, and the Lowry test (Lowry et al. 1951) was performed to measure the protein concentrations in each sample. Laemmli solubilisation buffer (2×) was added to the samples to give a 1:2 dilution, then the protein concentration was adjusted using volumes of lysis buffer calculated from the protein assay. The samples were assayed immediately or stored at −20°C until needed. For CREB and phospho-CREB assays, the pellets were resuspended in lysis buffer to make a 3:5 dilution.

SDS gel electrophoresis Sodium dodecyl sulphate polyacrylamide electrophoresis gels (SDS-PAGE) were prepared in different concentrations suitable for running different proteins, e.g. 15% SDS-PAGE were used to run BDNF and TrkB immunoblots and 10% SDS-PAGE for CREB, phospho-CREB (p-CREB), ERK1/2 and phospho-ERK1/2 (p-ERK1/2). A layer of 4% gel (stacking gel) was added to the top of the running gel, and the comb was then placed into the gel to prepare ten wells.

Based on preliminary studies, 20–50 µg of protein was loaded onto each lane of the SDS gels. The gels were run in 1× running buffer [Tris (30.3 g), glycine (144 g) and SDS (10 g) dissolved in 1 L distilled water] at 200 V for 45 min using the Bio-Rad apparatus. A standard marker of known molecular weight (Bio-Rad laboratories Ltd, UK) was run alongside.

The proteins were transferred to nitrocellulose paper in the transfer buffer; Tris (30.3 g), glycine (144 g) and were dissolved in distilled water. Methanol (2 L) was added, then made up to 10 L with distilled water using the Bio-Rad apparatus at 100 V for 60 min at 4°C. Protein transfer was checked by adding a few drops of Ponceaus solution (Sigma, UK). The solution can be rapidly removed by washing with Milli-Q water then Tris-buffered saline-Tween (TBST) (25 mM Tris, 125 mM NaCl dissolved in distilled water, pH 7.6). The blots were blocked with 5% fat-free dried milk powder in TBST for 60 min using a platform shaker (Stuart Scientific, UK).

The specific primary antibodies for different proteins were prepared in 5% milk in TBST. The blots were kept in small plastic bags with the antibody overnight in the cold room (4°C) on a platform shaker (Stuart Scientific, UK).

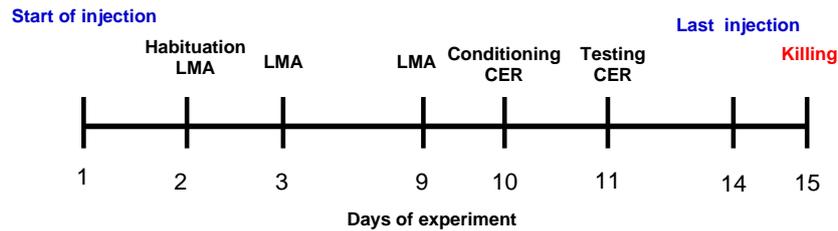

Fig. 1 Timeline showing the experimental protocol employed. Rats received daily intraperitoneal injection of vehicle or CBD (10 mg/kg). *LMA* Locomotor activity, *CER* conditioned emotional response. Note

Next day, the blots were washed three times with TBST buffer, then washed three times for 5 min and three times for 15 min.

The secondary antibody was prepared as 1:2,000 dilutions in 5% milk in TBST and added to the blots for 60 min at room temperature with shaking (Pardon et al. 2005).

In the dark room, the blots were exposed to enhanced chemiluminescence (ECL) reagent (Amersham Biosciences, UK) for 1 min then blotted dry on filter paper and wrapped in Saran wrap cling film. The blots were placed in an X-ray cassette and exposed to Hyperfilm ECL autoradiography film (Amersham Biosciences, UK) for 5–30 min. The films were developed using Kodak GBX developer (Sigma, UK), then fixed using Ilford Hypam rapid fixer (Ilford Imaging Ltd, UK). The developed films were scanned using a GS-710 Imaging Densitometer (Bio-Rad) and analysed using the Quantity One software package for image analysis

Antibodies Anti-BDNF (1:500, Santa Cruz Biotechnology, Inc.), anti-TrkB (1:1,000, upstate cell signalling), anti-CREB (1:1000, Cell Signalling Technology), anti-p-CREB (1:500, Cell Signalling Technology), anti-ERK1/2 (1:1,000, Cell Signalling Technology), anti-pERK (1:1,000, Cell Signalling Technology) and anti- β -actin (1:400,000, Sigma) primary antibodies were used. The secondary antibodies [horse-radish-peroxidase (HRP), DakoCytomation, Denmark] goat anti-rabbit IgG for BDNF, TrkB, ERK1/2, p-ERK1/2, CREB and p-CREB goat anti-mouse IgG for β -actin were prepared as 1:2,000 dilutions in 5% milk in TBST.

Statistical analysis

Data are presented as means \pm standard error of the mean (SEM). Data were analysed by Prism 4 software using unpaired *t* tests (for comparisons between treatment condition and the vehicle control) and the two-way repeated measures ANOVA for changes in body weight and food consumption over time followed by a Bonferroni post hoc test. Results were considered statistically significant if $P < 0.05$.

that the same groups of rats were used for all behavioural tests before killing for brain analysis on day 15

Results

Effect of repeated CBD administration on body weight

Body weight was measured daily between 0900 and 1000 hours. Two-way repeated measures ANOVA revealed significant increases in body weight with time [$F_{(14,196)} = 1041.0$; $P < 0.0001$], but there was no effect of treatment [$F_{(1,196)} = 0.02$; $P = 0.88$]. There were accompanying significant increases in food consumption with time [$F_{(13,26)} = 21.09$; $P < 0.0001$], but there was no effect of CBD treatment on the weight of food consumed [$F_{(1,26)} = 0.01$; $P = 0.93$] (data not shown).

Behavioural effects of repeated administration of CBD

Locomotor activity

The locomotor activity test was performed twice to detect any changes in locomotor activity over the course of CBD treatment. The first test was on the third day of drug injection, and the second was on the ninth day of treatment. CBD had no effect on total distance moved [$t_{(14)} = 1.4$; $P = 0.18$] or velocity [$t_{(14)} = 1.4$; $P = 0.18$] on the third day. This lack of effect of CBD on total distance [$t_{(14)} = 0.04$; $P = 0.97$] and velocity [$t_{(14)} = 0.04$; $P = 0.97$] continued to the ninth day.

Rearing and grooming behaviour were examined as markers of anxiety-related behaviour. CBD had no effect on rearing frequency [$t_{(10)} = 0.18$; $P = 0.86$], rearing duration [$t_{(13)} = 0.36$; $P = 0.72$] or grooming duration [$t_{(14)} = 0.30$; $P = 0.77$] on the third day or on the ninth day; on rearing frequency [$t_{(14)} = 0.11$; $P = 0.92$], rearing duration [$t_{(14)} = 0.38$; $P = 0.71$] or grooming duration [$t_{(14)} = 0.49$; $P = 0.63$].

Conditioned emotional response

The freezing behaviour of the rats was scored on the CER testing day (day 11). Freezing was expressed as a percentage of the total cage exposure time (10 min). Repeated administration of CBD significantly increased the time spent in freezing behaviour on the testing day of the CER procedure [$t_{(14)} = 2.76$; $P = 0.02$] (Fig. 2).

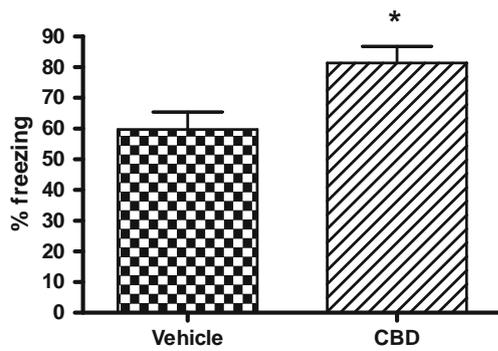

Fig. 2 Effects of chronic administration of CBD on percentage of time spent in freezing behaviour in the CER test on the test day (day 11 of the experiment). Columns represent the mean and bars represent the SEM. CBD significantly increased freezing compared to the vehicle-treated group; $n=8$ per group ($*P<0.05$)

Effect of chronic (14 days) CBD administration on protein expression

BDNF and TrkB

Western blots showed clear bands at the expected molecular weights for BDNF (13 kDa), TrkB (145 kDa) and β -actin (45 kDa) were used as a reference protein for equal loading (Fig. 3), and there were no differences in β -actin expression verifying equal gel loading of samples. The protein levels are presented as percentage changes compared with vehicle-treated control rats designated as 100%. CBD significantly reduced BDNF expression in the hippocampus [$t_{(14)}=3.31$; $P=0.005$] and frontal cortex [$t_{(14)}=2.47$; $P=0.027$], but there was no effect of CBD on BDNF expression in the striatum [$t_{(14)}=0.69$; $P=0.50$] (Fig. 4).

Moreover, CBD significantly reduced TrkB expression in the hippocampus [$t_{(14)}=3.36$; $P=0.005$] with a trend

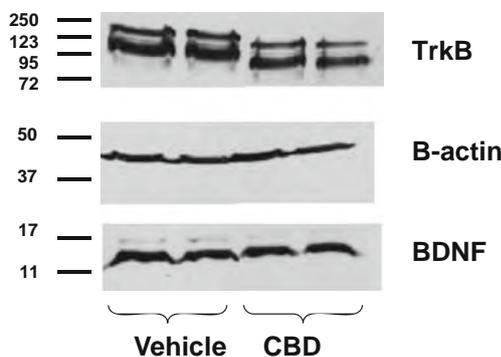

Fig. 3 Example of TrkB, β -actin and BDNF Western blots in the hippocampus. Western blots showed clear bands at the expected molecular weights for BDNF (13 kDa), TrkB (145 kDa) and β -actin (45 kDa). CBD reduced BDNF and Trk B expression in the hippocampus with equal loading

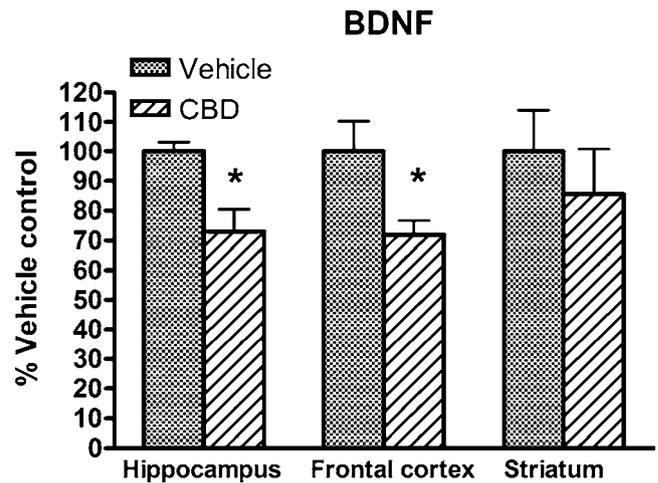

Fig. 4 Effect of chronic administration of CBD on BDNF expression. Data are expressed as percentage changes compared with the vehicle-treated group (designated as 100%) and presented as mean \pm SEM. Paired t tests were performed with Prism 4.0 software. $*P<0.05$ compared with vehicle, $n=8$ per group. CBD (10 mg/kg for 14 days) significantly reduced BDNF expression in the hippocampus and frontal cortex

towards a reduction expression in the striatum [$t_{(14)}=1.84$; $P=0.087$]. There was no effect of CBD on TrkB expression in the frontal cortex [$t_{(14)}=1.20$; $P=0.22$] (Fig. 5).

ERK1/2 and p-ERK 1/2 expression

Using Western immunoblotting, protein bands representing ERK 1/2 and p-ERK 1/2 were detected at 44 and 42 kDa in frontal cortex, although the p-ERK1

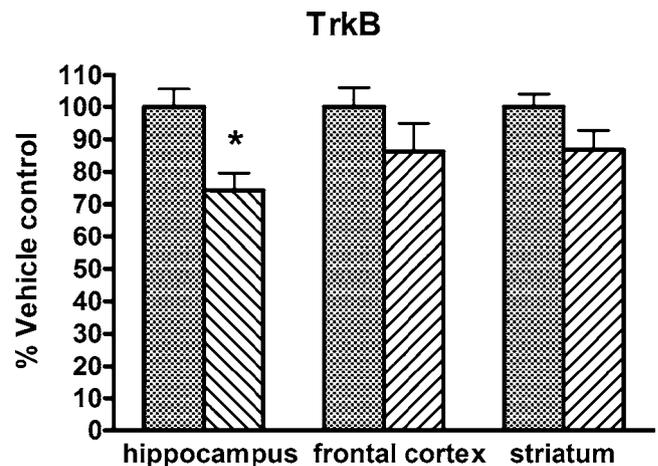

Fig. 5 Effect of chronic administration of CBD on TrkB expression. Data are expressed as percentage changes compared with the vehicle-treated group (designated as 100%) and presented as mean \pm SEM. Paired t tests were performed with Prism 4.0 software. $*P<0.05$ compared with vehicle, $n=8$ per group. CBD (10 mg/kg for 14 days) significantly reduced Trk B expression in the hippocampus

expression in the hippocampus was too low to detect. It should be noted that, although ERK1 and ERK2 were found at similar levels in the different brain areas, the signal was always much stronger for p-ERK2 than for p-ERK1, which was below the detection thresholds in some experiments (Fig. 6).

In the hippocampus, CBD had no effect on ERK1 [$t_{(14)}=0.89$; $P=0.39$], ERK2 [$t_{(14)}=0.67$; $P=0.51$] or p-ERK2 [$t_{(14)}=0.68$; $P=0.51$]. In the frontal cortex, CBD had no effect on ERK1 [$t_{(14)}=0.78$; $P=0.45$] or ERK2 [$t_{(14)}=0.77$; $P=0.45$] but significantly reduced p-ERK1 [$t_{(14)}=2.49$; $P=0.026$] and p-ERK2 [$t_{(14)}=2.46$; $P=0.028$] (Fig. 7).

CREB and p-CREB

Protein bands representing CREB and p-CREB were detected at 43 kDa in the frontal cortex, but p-CREB was undetectable in the hippocampus. CBD had no effect on CREB [$t_{(14)}=0.51$; $P=0.62$] or p-CREB [$t_{(14)}=0.33$; $P=0.75$] expression in the frontal cortex or CREB expression in the hippocampus [$t_{(14)}=1.20$; $P=0.25$].

Discussion

The phytocannabinoid CBD, which is one of the most abundant bioactive components of the cannabis plant, has been reported to have an acute anxiolytic effect in both animals and humans (Crippa et al. 2004; Lemos et al. 2010; Moreira et al. 2006; Zuardi et al. 1982). More recently, CBD has also been shown to have an acute antidepressant-like effect, via the activation of 5-HT_{1A} receptors, in a mouse forced-swimming test (Zanelati et al. 2010) without changing activity in the open field.

In the present study, no change in body weight was detected after administration of CBD for 14 days. On the contrary, Ignatowska-Jankowska et al. (2011) reported that repeated administration of CBD (2.5 and 5 mg kg⁻¹ day⁻¹)

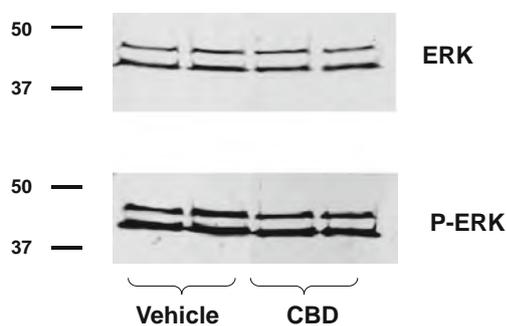

Fig. 6 Example Western blot of ERK and pERK expression in frontal cortex. Protein bands representing ERK 1/2 and p-ERK 1/2 were detected at 44 and 42 kDa in frontal cortex. CBD reduced both p-ERK1 and p-ERK2

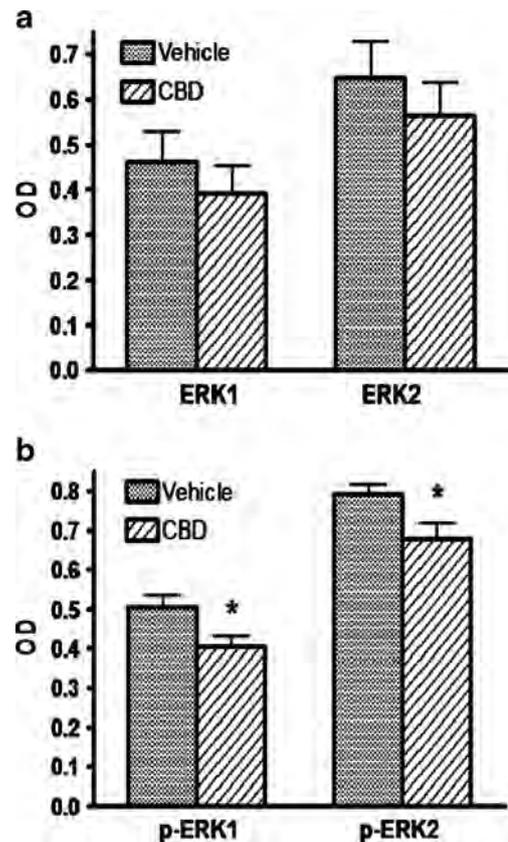

Fig. 7 Effect of chronic administration of CBD on protein expression of **a** ERK 1/2 and **b** p-ERK 1/2 in the frontal cortex. Unpaired *t* tests were performed with Prism 4.0 software. * $P<0.05$, $n=8$ per group. CBD (10 mg/kg for 14 days) significantly reduced p-ERK1/2 expression in the frontal cortex

for 14 days decreased the body weight gain of rats. This variance from the present study's findings may be related to the difference in species or dose of CBD used.

In the present study, the locomotor activity of the rats in a neutral environment was measured to detect any hypoactivity or changes in rearing and grooming hyperactivity associated with CBD treatment that could interfere with the interpretation of behavioural changes in the CER test. The administration of CBD (10 mg/kg, i.p. for 14 days) failed to affect the rats' spontaneous locomotor activity. This result is in agreement with Wiley et al. (2005) and Finn et al. (2004b) who reported that acute administration of CBD had no effect on locomotor activity of mice or rats respectively.

Rearing and grooming were examined as markers of anxiety-related behaviour as increased self-grooming in rats is frequently observed after the application of mild stressors, such as novelty or handling of the animals (van Erp et al. 1994). Anxiolytic drugs attenuate the increase in grooming induced by a novel environment without significantly affecting general locomotor activity,

which dissociates grooming activity from sedation (Dunn et al. 1981; Moody et al. 1988).

In the present study, there were no differences in rearing and grooming between the treatment groups in agreement with Finn et al. (2004b), who found that rearing and grooming were unaltered by acute administration of a lower dose of CBD (5 mg/kg).

In the CER test, however, the rats were exposed to an environment paired previously with inescapable electric foot shock, which results in a well-characterised freezing response. The duration of freezing has been used as an index of induced fear and anxiety (Fanselow 1980), and a number of anxiolytic drugs decrease the duration of freezing (Hashimoto et al. 1996; Inoue et al. 1996).

Resstel et al. (2006) observed that acute injection of CBD (10 mg/kg, i.p.) reduced the freezing time in conditioned rats, and Bitencourt et al. (2008) reported that CBD facilitated conditioned fear extinction in rats, which might contribute to the anti-anxiogenic effect detected in the same study. In the present study, it was hypothesised that CBD would induce an anxiolytic-like effect in the CER test in the form of reduced conditioned freezing. However, on the contrary, repeated CBD administration significantly *increased* the time spent in freezing behaviour indicating an anxiogenic-like effect after chronic administration.

There were some differences in methodology between the present study and those previously reporting anxiolytic effects. For example, rats were individually housed in the study of Resstel et al. (2006), while they were group housed in the present study. There were also differences the conditioning protocols in that the rats received six 2.5 mA foot shocks in the study of Resstel et al. (2006) and ten 0.4 mA shocks in the present study. Nevertheless, it seems unlikely that the qualitative differences in behavioural outcomes between acute and chronic administration of CBD could be explained by relatively minor variations in methodology. It is noteworthy that the anxiolytic effect of CBD in humans has only been reported after acute administration (Zuardi et al. 2006).

Long et al. (2009), however, demonstrated that chronic daily administration of CBD to male adult C57BL/6JArc mice for 21 days produced moderate anxiolytic-like effects in the open-field test at 50 mg/kg and in the light–dark test at a low dose (1 mg/kg). This variance from the present study's findings may be related to the species used, the behavioural test employed or the dose and duration of CBD administration. For example, in the study of Magen et al. (2009) the optimal dose of CBD for cognitive enhancement in the bile duct ligation model was 5 mg/kg over a 4-week period, while 1 and 10 mg/kg were ineffective. This indicates a complex dose–response relationship for CBD, at least in this model, which complicates interpretation of inter-study differences. Although the dose of CBD used in

the present study was reported to induce an anxiolytic-like effect after acute administration in previous studies (Moreira et al. 2006; Resstel et al. 2006), a biphasic effect of CBD was reported in other studies (Guimaraes et al. 1990; Kwiatkowska et al. 2004; Malfait et al. 2000; Rock et al. 2008), which emphasises the need for additional long-term multi-dose studies.

The neurotrophic hypothesis of depression (Nestler et al. 2002) suggests that BDNF is reduced in depression and increased by many antidepressant/anxiolytic treatments. We hypothesised that CBD might increase expression of BDNF protein, its receptor (TrkB) or the downstream mitogen-activated protein kinase (MAPK) signalling protein cascade (ERK). This is, of course, relevant to potential anxiolytic actions of CBD since antidepressant drugs are the first line therapy for long-term anxiety (Dell'Osso et al. 2010). We focused on the hippocampus, frontal cortex and striatum as these brain areas may be dysfunctional in affective disorder (Kennedy et al. 1997; Sheline 2000). However, in the present study, Western immunoblotting showed that chronic administration of CBD significantly *decreased* BDNF expression in the hippocampus and frontal cortex while having no effect on BDNF levels in the striatum. Moreover, CBD also significantly reduced TrkB expression in the hippocampus with a strong trend towards a decrease in the striatum but with no effect in the frontal cortex. Magen et al. (2009) reported that chronic administration of CBD (5 mg/kg) for 4 weeks to female Sabra mice had no effect on BDNF mRNA in the hippocampus but normalised the reduced BDNF after bile duct ligation, a model of hepatic encephalopathy. Zanelati et al. (2010) reported that acute administration of CBD (30 mg/kg) did not affect BDNF expression in the mouse hippocampus, although it showed an antidepressant-like effect in the forced swim test.

Previous studies have demonstrated that chronic antidepressant treatment increases the expression of CREB in limbic regions of rat brain (Nibuya et al. 1996). CREB in its phosphorylated form is a transcription factor that mediates the actions of intracellular messengers on gene expression. The function of CREB is regulated largely by phosphorylation at Ser¹³³, which results in activation of gene transcription (Thome et al. 2000). CREB activation could alter the expression of specific gene products involved in the modulation of anxiety, such as BDNF and could, thereby, underlie some of the effects of antidepressant treatment on long-term anxiety. Since the phosphorylation of CREB may be mediated by the MAPK pathway through the phosphorylation of ERK and TrkB signals, at least partly, through MAPK activation, we focused our attention on the effects of CBD on p-CREB and p-ERK induction.

In the present study, CBD had no effect on CREB expression in the frontal cortex and hippocampus or p-

CREB expression in the frontal cortex, while in the hippocampus, p-CREB was undetectable. With respect to ERK and p-ERK, CBD significantly reduced p-ERK1/2 in the frontal cortex without affecting total ERK1/2 expression, and there was no apparent change in ERK1/2 or p-ERK2 expression in the hippocampus.

Given the pleiotropic effects of cannabidiol, it is difficult to propose a straightforward molecular mechanism to explain the effects of the drug on the expression of these proteins, but, although no direct assessments of neurogenesis were made in these animals, the combined negative effects of cannabidiol on BDNF and BDNF-related signalling proteins would certainly not be consistent with the enhanced neurogenesis reported for clinically effective antidepressants/antxiolytics and would probably predict the opposite.

Conclusion

The data presented indicate an anxiogenic-like profile of behaviour in normal healthy rats following repeated CBD administration. This was accompanied by reductions in the expression of the neurotrophin BDNF and related signalling proteins, and, overall, the results are not consistent with the potential clinical anxiolytic properties suggested by acute experiments with CBD. This emphasises the need for additional long-term multi-dose studies of the drug in models of affective disease.

Acknowledgements We would like to thank GW Pharmaceuticals for kindly supplying the CBD.

Effects of Cannabidiol (CBD) on Regional Cerebral Blood Flow

José Alexandre de Souza Crippa^{*1,4}, Antonio Waldo Zuardi¹, Griselda EJ Garrido², Lauro Wichert-Ana¹, Ricardo Guarnieri¹, Lucas Ferrari³, Paulo M Azevedo-Marques³, Jaime Eduardo Cecílio Hallak¹, Philip K McGuire⁴ and Geraldo Filho Busatto⁵

Animal and human studies have suggested that cannabidiol (CBD) may possess anxiolytic properties, but how these effects are mediated centrally is unknown. The aim of the present study was to investigate this using functional neuroimaging. Regional cerebral blood flow (rCBF) was measured at rest using ^{99m}Tc-ECD SPECT in 10 healthy male volunteers, randomly divided into two groups of five subjects. Each subject was studied on two occasions, 1 week apart. In the first session, subjects were given an oral dose of CBD (400 mg) or placebo, in a double-blind procedure. SPECT images were acquired 90 min after drug ingestion. The Visual Analogue Mood Scale was applied to assess subjective states. In the second session, the same procedure was performed using the drug that had not been administered in the previous session. Within-subject between-condition rCBF comparisons were performed using statistical parametric mapping (SPM). CBD significantly decreased subjective anxiety and increased mental sedation, while placebo did not induce significant changes. Assessment of brain regions where anxiolytic effects of CBD were predicted *a priori* revealed two voxel clusters of significantly decreased ECD uptake in the CBD relative to the placebo condition ($p < 0.001$, uncorrected for multiple comparisons). These included a medial temporal cluster encompassing the left amygdala–hippocampal complex, extending into the hypothalamus, and a second cluster in the left posterior cingulate gyrus. There was also a cluster of greater activity with CBD than placebo in the left parahippocampal gyrus ($p < 0.001$). These results suggest that CBD has anxiolytic properties, and that these effects are mediated by an action on limbic and paralimbic brain areas.

Keywords: cannabidiol; anxiety; regional cerebral blood flow; SPECT; neuroimaging

INTRODUCTION

Cannabidiol (CBD) constitutes up to 40% of *Cannabis sativa* (Grille, 1976) and has quite different psychological effects to the plant's best known constituent, Δ^9 -tetrahydrocannabinol (Δ^9 -THC) (Perez-Reyes *et al*, 1973; Zuardi *et al*, 1982). In particular, in animal studies CBD has effects similar to anxiolytic drugs in conditioned emotional paradigms (Zuardi and Karniol, 1983), the Vogel conflict

test (Musty *et al*, 1984), and the elevated plus maze test (Guimaraes *et al*, 1990; Onaivi *et al*, 1990). Using the latter test, anxiolytic effects were also reported for three derivatives of CBD, HU-219, HU-252, and HU-291 (Guimaraes *et al*, 1994). In humans, oral administration of CBD in healthy volunteers attenuates the anxiogenic effect of Δ^9 -tetrahydrocannabinol (Δ^9 -THC) (Zuardi *et al*, 1982). This effect does not seem to involve any pharmacokinetic interactions (Aguirell *et al*, 1981; Zuardi *et al*, 1982), and CBD does not bind to the central known cannabinoid receptor, CB₁, (Bisogno *et al*, 2001; Mechoulam *et al*, 2002) and hence cannot be a competitive antagonist (Howlett *et al*, 1992). CBD may thus possess inherent anxiolytic properties unrelated to THC-type activity. This is consistent with its anxiolytic effect on anxiety elicited by simulated public speaking (Zuardi *et al*, 1993a).

As the receptors that mediate the psychological effects of CBD are unknown, its mechanism of action on the brain is unclear. The aim of the present study was to use functional

neuroimaging to investigate this. In view of its anxiolytic effect, we tested the hypothesis that CBD would affect neural activity in areas that normally mediate anxiety. We compared the effects of CBD and placebo on resting cerebral regional blood flow (rCBF) in healthy volunteers in a double-blind, cross-over design. Based on previous functional imaging studies of anxiety (Maddock and Buonocore, 1997; Fischer *et al*, 1996; Liotti *et al*, 2000; Ketter *et al*, 1996), we predicted that, relative to placebo, CBD would modulate rCBF in limbic and paralimbic areas: the orbitofrontal, cingulate and medial temporal cortex, and the insula.

MATERIALS AND METHODS

Subjects

A total of 10 healthy male postgraduate students were studied. None had undergone rCBF SPECT examinations or other nuclear medicine procedures before. All were right-handed as assessed by the Edinburgh Handedness Inventory (Oldfield, 1971), and were nonsmokers (of tobacco). Their mean age was 29.8 years (range 25–42 years, SD = 5.1), their mean weight was 74.1 kg (67–85 kg, SD = 6.05), and their body mass index ranged between 21 and 25 kg/m². The subjects had not taken any medicines for at least 3 months before the study (Mathew *et al*, 1992). No subject had a history of head trauma, neurological, or major medical illnesses, based on a semistandardized medical questionnaire and physical examination. Neither the subjects (based on the Structured Clinical Interview for DSM-IV, First *et al*, 1997) nor their first-degree relatives (based on subjects' report) had a history of psychiatric illness. No subject had used marijuana more than five times in their lives (nor in the last year), and none had used any other illegal drug. The experiment was conducted with the understanding and consent of each subject, following approval by the local ethical committee.

Cannabidiol

CBD in powder, approximately 99.9% pure (supplied by THC-Pharm, Frankfurt, Germany), was dissolved in corn oil (Zuardi *et al*, 1993a, 1995). The same amount of corn oil was used as a placebo. The drug and placebo were packed inside identical gelatin capsules.

Self-Rating Scale

Subjective states were evaluated by means of the Visual Analogue Mood Scale (VAMS) of Norris (1971), translated into Portuguese by Zuardi and Karniol (1981b). It consists of 16 analogue scales to measure drug effects, which were arbitrarily divided by Norris into four factors: anxiety, physical sedation, mental sedation, and other feelings and attitudes. A factor analysis with the Portuguese version of this scale (Zuardi *et al*, 1993a) extracted four factors that can be identified with those of the Norris proposal. Prior to the experiment, each volunteer had performed a training session completing this scale.

Procedure

Subjects were told not to consume any alcohol for 24 h and caffeine for at least 4 h before each visit to the laboratory (Mathew *et al*, 1999). Subjects who reported having less than 6 h of sleep the previous night were excluded. After at least 8 h of fasting, subjects were instructed to have a light, standardized breakfast 2 h before the experiment. They were randomly divided into two groups of five subjects. Each subject was evaluated on two different occasions, 1 week apart. In the first session, after a 30-min period of adaptation, subjects were given a single dose of oral CBD (400 mg) or placebo, in a double-blind procedure. The sessions were held in the morning (between 0800 and 1200) to minimize the effects of circadian variation. SPECT image acquisition was performed 110 min after drug ingestion. Subjective ratings on the VAMS were made 30 min before drug ingestion, at the time of drug ingestion, and at 60 min and at 75 min afterwards. In the second session, an identical procedure was followed except that the other drug was administered (ie those given CBD in the first session received placebo in the second; and *vice versa*). Subjects were informed that they would receive CBD and placebo, but they were not told in which order. The investigators were also blind to the content of the capsules.

SPECT

Subjects had a venous cannula inserted into their right arm, and rested supine with minimal environmental sensory stimulation. They were instructed to keep their eyes closed under eye pads and to relax for 15 min without falling asleep. Their ears were unplugged. VAMS ratings were made just before and 15 min after insertion of the venous cannula. At 30 min after insertion of the venous cannula, 740 MBq (20 mCi) of ethyl-cisteinate-dimer (ECD) labeled with technetium-99m (^{99m}Tc-ECD) was injected. Subjects rested for an additional period of 5 min postinjection, after which the venous cannula was removed.

Image acquisition started 20 min after the ^{99m}Tc-ECD injection, using a double-detector SOPHA[®] DST system (Sophy Medical Vision, Twinsburg, USA). High-resolution low-energy collimators were used, with 128 views acquired on a 128 × 128 matrix (30 s per view), with a total acquisition time of 30 min, and approximately 75 000 counts/frame/head. Raw images were prefiltered with a Butterworth filter (order number 4, cutoff frequency 0.16), and reconstructed by filtered back-projection as transaxial slices parallel to the long axis of the temporal lobe. Attenuation correction was performed considering a pixel size of 2.55 mm and using the first-order algorithm of Chang (coefficient 0.12/cm).

Image Processing and Analysis

Images were analyzed using Statistical Parametric Mapping software (SPM99) (Friston *et al*, 1995). Reconstructed transaxial datasets were transferred to a PC (Pentium IV, 2.2 GHz, 512 Mb RAM), converted to Analyze format and reoriented to neurological convention (ie left = left).

Placebo images were realigned to CBD images using sinc interpolation. Linear (translations and rotations) and non-linear ($7 \times 8 \times 7$ nonlinear basis functions) deformations were used to register images to the SPM SPECT template, which is based on the Montreal Neurological Institute (MNI) template (Mazziotta et al, 1995). Finally, an isotropic Gaussian filter of 12 mm was applied to diminish inter-individual differences, and to conform data to the theory of Gaussian Random Fields (Friston et al, 1995), in order to allow the subsequent application of parametric statistical tests.

Between-condition (CBD vs placebo) comparisons of regional tracer uptake were performed on a voxel-by-voxel basis using paired *t*-tests. Before statistical testing, the regional ECD uptake of every voxel in each subject was standardized to the mean global uptake of the image in that subject, using proportional scaling. Only voxels with signal intensities above a threshold of 0.8 of the global mean (calculated using the standardized values) entered the statistical analysis. The resulting statistics at each voxel were transformed to *Z*-scores, thresholded at $Z=2.33$ (corresponding to $p<0.01$, one-tailed), and displayed as 3-D statistical parametric maps (SPM). These maps were first inspected for the presence of voxel clusters of significant difference in the regions where effects of CBD had been predicted *a priori* (medial temporal, cingulate, orbitofrontal, and insular cortices). Clusters in these regions were considered as significant if they included voxels with *Z*-scores of 3.09 or greater (corresponding to one-tailed $p<0.001$), and contained more than 20 voxels. Levels of $p<0.001$, uncorrected for multiple comparisons, have been frequently used in previous SPM analyses of positron emission tomography (PET) (Dougherty et al, 1999; Bremner et al, 1999b) and SPECT (Blackwood et al, 1999; Busatto et al, 2000) data, and are considered to provide good protection against false-

positive results when there are clear hypotheses as to the location of findings. The SPMs were also inspected for differences in other, unpredicted regions. These areas were reported as significant if they survived a correction for multiple comparisons based on Gaussian random field theory ($p<0.05$) (Friston et al, 1995).

For each voxel cluster showing significant between-condition differences, estimates were calculated for the mean, median, and maximal percentages of ECD count rate change (and their variances) (Table 1). These indices were obtained by partitioning the Student's *t*-test value of each voxel into its main components, with the numerator of the *t* statistic used as an approximation of the magnitude of the signal change for each contrast (placebo > CBD or CBD > placebo), and the denominator (the standard error) used to calculate the variances. The MNI coordinates for the voxels of maximal statistical significance for each anatomical brain region included in a given cluster were converted to the Talairach and Tournoux (1988) system using the method described by Brett et al (2002).

The four VAMS factors were submitted to an ANOVA for repeated measures in both CBD and placebo sessions. The differences between CBD and placebo in each phase of the experimental session (-30, 0, 1'00, 1'15) were analyzed by *t*-tests. Correlations between the regional tracer uptake and each of the VAMS factors scores were also investigated with SPM99, at the same statistical significance levels as described above for the between-condition rCBF comparisons. The last point in which the VAMS was applied (75' after drug intake) was chosen for these correlations due to its proximity to the injection of the SPECT tracer. Moreover, this is the point where CBD is expected to have its maximum anxiolytic effect among all the time points chosen for assessment during the experimental session (Zuardi et al, 1993a). The choice for

this time point was also based on previous studies, which have shown that the plasma peak of an oral dose of CBD usually occurs between 1 and 2 h after ingestion (Agurell et al, 1981).

RESULTS

Visual Analogue Mood Scale

The administration of CBD was associated with significantly decreased subjective anxiety ($F(3,27) = 18.56$, $p < 0.001$) and increased mental sedation ($F(3,27) = 42.85$, $p < 0.001$), while placebo was not ($F(3,27) = 1.86$, $p = 0.16$ and $F(3,27) = 2.24$, $p = 0.11$, respectively) (Figure 1). In addition, an analysis at each time point indicated the following: (i) CBD was associated with significantly decreased anxiety at cannula insertion (60' after drug intake, $t = 2.95$, $p = 0.009$) and resting phases (75' after drug intake, $t = 5.50$, $p < 0.001$) as compared to placebo; (ii) CBD was associated with significantly increased feelings of mental sedation at cannula insertion (60' after drug intake, $t = -3.91$, $p = 0.001$) and resting phases (75' after drug intake, $t = -3.67$, $p = 0.002$) as compared to placebo.

Between-Condition rCBF Comparisons

The SPM showing increases in ECD uptake in the CBD relative to placebo condition revealed only one cluster (> 20 voxels) that surpassed the initial $Z = 2.33$ statistical cutoff (Figure 2). This cluster, which achieved statistical significance at the $p < 0.001$ level (uncorrected for multiple comparisons), was located in the medial temporal cortex, where the effects of CBD had been predicted *a priori*, and involved the left parahippocampal gyrus,

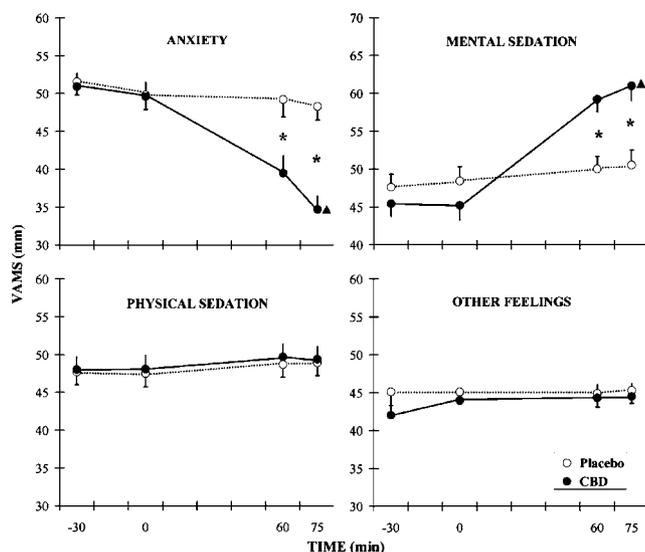

Figure 1 Effect of CBD and placebo (PLCB) on the four factors of the VAMS. Points are means (\pm SEM) of 10 healthy subjects in the following phases of the experiment: predrug (-30), drug intake (0), prestress (60), and adaptation (75). Asterisk (*) indicates significant difference from placebo in each phase. Triangle (\blacktriangle) indicates ANOVA significant changes.

extending inferiorly to encompass the left fusiform gyrus (Table 1).

Significantly decreased ($p < 0.001$, uncorrected for multiple comparisons), ECD uptake in the CBD relative to the placebo condition was evident in two regions where effects of CBD had been predicted *a priori* (Table 1). One cluster included the medial portion of the left amygdala-hippocampal complex and uncus, as well as the hypothalamus. The other was located in the superior portion of the left posterior cingulate gyrus (Brodmann area—BA31),

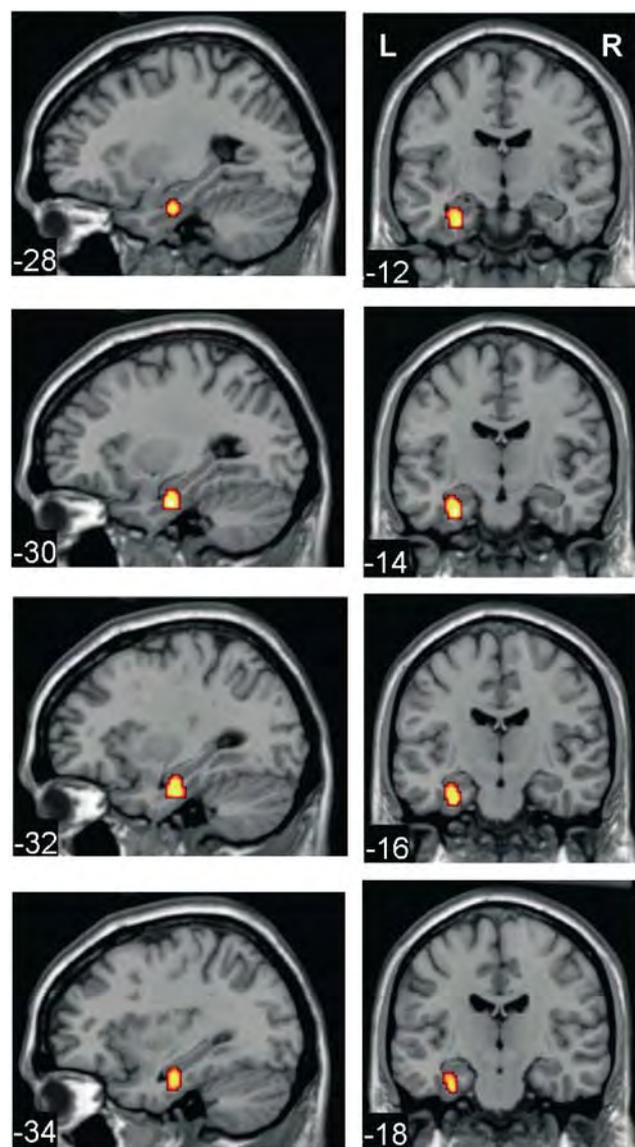

Figure 2 The brain region where there was significantly increased rCBF in healthy volunteers ($n = 10$) during CBD vs placebo has been overlaid on coronal sections (-18, -16, -14, -12) and sagittal sections (-28, -30, -32, -34) of a reference brain, imaged with structural MRI and spatially normalized into an approximation to the Talairach and Tournoux (1988) stereotactic atlas. The results are displayed in neurological convention (ie left = left). The numbers associated with each frame represent the standard coordinate in the y - (for the coronal frames) and x -axis (for the sagittal frames). The voxel cluster shown was located in the left parahippocampal gyrus extending inferiorly to encompass the left fusiform gyrus (peak Z -score = 3.69, coordinates $_{xyz} = -30, -14, -30$; $p < 0.0001$ uncorrected for multiple comparisons; 114 voxels).

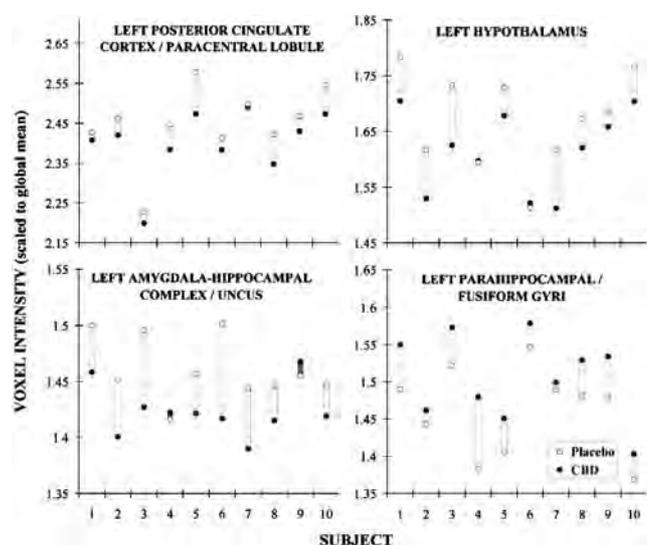

Figure 3 Tracer uptake values during the CBD (filled circle) and PLCB (hollowed circle) conditions are plotted for the 10 subjects, using the voxel of maximal significant difference of each of the four regions reported in Table 1. From left to right and top to bottom: $-4, -27, 47$ (left posterior cingulate cortex/paracentral lobule), $-6, -6, -8$ (left hypothalamus), $-16, -11, -21$ (left amygdala-hippocampal complex), and $-30, -15, -24$ (left parahippocampal/fusiform gyri). Individual values were normalized to the global ECD uptake for each subject and condition. The graphs show that the large majority of individual subjects showed lower ECD activity in the CBD condition relative to the placebo condition in the left amygdala-hippocampus complex, hypothalamus, and posterior cingulate cortex/paracentral lobule, while all subjects had greater ECD uptake in the CBD condition relative to the placebo condition in the left parahippocampal/fusiform gyri.

extending towards the paracentral lobule (BA5/6). At the $p < 0.001$ uncorrected level of significance, this SPM showed additional, unpredicted foci of decreased rCBF in the ECD relative to the placebo condition (> 20 voxels) in the right cerebellum, medial occipital cortex, left inferior temporal, and posterior lateral frontal cortex, but none of these retained significance after correction for multiple comparisons.

Figure 3 displays, for each subject, the magnitude of tracer uptake changes between the CBD and placebo conditions at the voxel of maximal statistical significance in the regions where ECD uptake differences were observed (as summarized in Table 1). All 10 subjects showed greater ECD uptake values in the CBD condition relative to the placebo condition in the left parahippocampal/fusiform gyri. Of the 10 subjects, eight showed lower ECD activity in the CBD condition relative to the placebo condition in the left amygdala-hippocampal complex; eight in the left hypothalamus; and nine in the left posterior cingulate cortex/paracentral lobule (Figure 2). Similar patterns across individual subjects were observed when we used the mean tracer uptake values of all voxels included in the clusters of significant difference between the CBD and placebo conditions (data not shown).

Correlations with Subjective Status Ratings

No correlations were observed between subjective anxiety ratings and ECD uptake in the brain areas where the effects

of CBD had been predicted *a priori* ($p < 0.001$, uncorrected), or in other unpredicted areas after correction for multiple comparisons.

DISCUSSION

When undergoing neuroimaging procedures, such as PET or SPECT, subjects often report increased anxiety before scanning, which is greater than that during or after image acquisition (Grey *et al*, 2000; Gur *et al*, 1987; Giordani *et al*, 1990; Malizia, 1999). The results of the present study showed that a single dose of CBD induced significant decreases in state anxiety before SPECT scanning. Our data thus suggest that this compound has anxiolytic properties, consistent with the results from previous studies in both laboratory animals (Zuardi and Karniol, 1983; Musty *et al*, 1984; Guimaraes *et al*, 1990; Onaivi *et al*, 1990) and humans (Zuardi *et al*, 1982, 1993a).

The anxiolytic effects found in the present study were detected before the anxiety-evoking situation (the tracer injection and scanning procedure), indicating that CBD can affect anticipatory anxiety. In a previous study (Zuardi *et al*, 1993a), the anxiolytic effect of CBD was evident after the stress of public speaking. These antianxiety effects are in contrast to the anxiogenic effects of high doses of Δ^9 -THC (Malit *et al*, 1975; Zuardi *et al*, 1982; Mathew *et al*, 1999), and may help to reconcile apparently conflicting findings obtained with *Cannabis sativa* in relation to anxiety (Johns, 2001; Tournier *et al*, 2003).

Consistent with an anxiolytic effect, we found that CBD significantly modulated resting activity predominantly in limbic and paralimbic cortical areas, which are usually implicated in the pathophysiology of anxiety (Gray, 1982; Graeff, 1994). Thus, between-condition activity differences were detected in a left medial temporal cluster, which included portions of the amygdala and the hippocampus, as well as the hypothalamus, the left posterior cingulate gyrus, and the left parahippocampal gyrus.

The only brain region that showed significantly increased activity in the CBD relative to the placebo condition was the left parahippocampal gyrus. Deactivation of the parahippocampal region in healthy volunteers has been reported after panic attacks induced by lactate (Reiman *et al*, 1989) and CCK-4 (Javanmard *et al*, 1999), and with anxiety induced by presentation of combat-related images (Bremner *et al*, 1999b) and autobiographical memory scripts (Liotti *et al*, 2000). In addition, the abnormal asymmetry of resting activity in the parahippocampal gyri has been associated with panic disorder and with vulnerability to lactate-induced panic (Reiman *et al*, 1984, 1986; Nordahl *et al*, 1990, 1998; Bisaga *et al*, 1998; De Cristofaro *et al*, 1993). These studies suggest that anxiety can be associated with reduced parahippocampal activity, consistent with an anxiolytic effect of CBD and the increased activity in this region that we observed.

In contrast, activity in the left amygdala-hippocampal complex, hypothalamus, and posterior cingulate cortex decreased with CBD relative to placebo. The amygdala is thought to play a key role in mediating fear and anxiety (Deakin and Graeff, 1991; LeDoux, 1998; Gorman *et al*, 2000), being activated during fear conditioning (Furmark

et al, 1997; Morris et al, 1998; LaBar et al, 1998; Buchel et al, 1998), while processing anxious faces (Breiter et al, 1996; Morris et al, 1996; Whalen et al, 1998; Hariri et al, 2002) and during pharmacologically induced anxiety (Ketter et al, 1996; Benkelfat et al, 1995; Servan-Schreiber et al, 1998). Functional and structural changes in the amygdala have also been reported in PTSD (Pitman et al, 2001; Rauch et al, 1996; Shin et al, 1997; Rauch et al, 2000; Liberzon et al, 1999), panic disorder (Uchida et al, 2003; Bystritsky et al, 2001), generalized anxiety disorder (Thomas et al, 2001; De Bellis et al, 2000), and in social (Birbaumer et al, 1998; Tillfors et al, 2001; Furmark et al, 2002) and simple phobias (Wik et al, 1997). The reduction in amygdala activity that we observed with CBD is thus consistent with the anxiolytic effect that it had in our subjects. The hippocampus has also been implicated in the processing of anxiety. Functional neuroimaging studies have shown increased activity in the hippocampus in association with anxiety in OCD (McGuire et al, 1994), panic disorder (Bisaga et al, 1998; Bystritsky et al, 2001; Boshuisen et al, 2002), PTSD (Osuch et al, 2001), and in social phobia (Schneider et al, 1999). However, other studies have reported either decreased or no difference in activity in the hippocampus in association with normal anxiety or anxiety disorders (Schuff et al, 2001; Schneider et al, 1999; Bremner et al, 1997; Fredrikson et al, 1997; Fischer et al, 1996; Paradiso et al, 1997; Liotti et al, 2000).

The hypothalamus is a major component of the central autonomic nervous system, and is often involved in mediating the effects of stress and anxiety (Afifi and Bergman, 1998). Functional imaging studies during fear and anxiety induction in healthy subjects (Fredrikson et al, 1995b; Javanmard et al, 1999) and in panic disorder patients (Boshuisen et al, 2002) have reported increases in the activity of the hypothalamic region, and hypothalamic–pituitary–adrenal axis abnormalities have been commonly reported in anxiety disorders (Hageman et al, 2001). The reduced hypothalamic activity that we observed is thus consistent with the anxiolytic effect of CBD.

The posterior cingulate cortex is strongly linked to temporolimbic structures (Vogt et al, 1992; Maddock, 1999; Afifi and Bergman, 1998), and is thought to play a central role in emotion and anxiety (MacLean, 1993; Maddock, 1999). Increased activity in the posterior cingulate gyrus has been associated with watching anxiety-provoking videos (Fischer et al, 1996; Fredrikson et al, 1995a), and with experimentally provoked obsessions and anxiety in patients with obsessive–compulsive disorder (OCD) (McGuire et al, 1994). Untreated patients with OCD show increased metabolism in the posterior cingulate (Perani et al, 1995) that decreases with treatment, with the change in posterior cingulate rCBF correlated with symptomatic improvement (Rauch et al, 2001, 2002). There have also been reports of increased posterior cingulate activation during symptom provocation in post-traumatic stress disorder (Bremner et al, 1999a) and panic disorder (Bystritsky et al, 2001). However, anxiety induction in phobic patients has been associated with deactivation in the posterior cingulate region (Wik et al, 1993) and Busatto et al (2000) reported a negative correlation between rCBF in the left posterior cingulate cortex and severity of symptoms in OCD.

We did not observe a correlation between the severity of anxiety and rCBF in the areas where activity was modulated by CBD, but this may have been difficult to detect because there was a 15-min gap between the points when the ratings were made and the SPECT tracer was injected.

While the areas where we found modulatory effects of CBD are thus implicated in mediating anxiety, and have also been associated with the anxiolytic effects of diazepam (Di Piero et al, 2001), citalopram (Van der Linden et al, 2000; Furmark et al, 2002), sertraline, and desipramine (Hoehn-Saric et al, 2001), these effects of CBD could be related to an effect other than on anxiety. For instance, we also observed sedative effects of CBD, confirming former findings in animals (Pickens, 1981; Monti, 1977; Colasanti et al, 1984; Zuardi et al, 1981a, 1991) and humans (Carlini et al, 1979; Zuardi et al, 1982, 1993b). This effect has been reported to be dose-related (Pickens, 1981) and CBD has also been shown to decrease wakefulness (Monti, 1977) and to cause longer sleep duration in insomniacs (Carlini and Cunha, 1981). Thus, the reduced hypothalamic activity observed after CBD use in our study could equally be related to sedative effects of CBD, as suggested to occur with other sedative compounds (Tung et al, 2001).

Other pharmacological effects of CBD have been reported in studies in laboratory animals and humans, such as anti-inflammatory (Malfait et al, 2000), anticonvulsant (Carlini et al, 1973; Izquierdo et al, 1973; Cunha et al, 1980), neuroprotective (Hampson et al, 1998), and hormonal effects (Zuardi et al, 1984, 1993a). In addition, the pharmacological profile of CBD is similar to that of clozapine, an ‘atypical’ antipsychotic drug (Zuardi et al, 1991, 1995), and both CBD and clozapine induce *c-fos* expression in the prefrontal cortex and lateral septal nucleus in rats (Zuardi et al, 2001). The mechanism(s) of action whereby CBD produces all these effects remains obscure. This is largely in contrast with the effects of Δ^9 -THC, which mimics the endogenous cannabinoids in many of its actions. CBD does not act through the known cannabinoid receptors, but the stereospecificity previously observed may indicate that CBD binds to another type of receptor in the brain (Mechoulam et al, 2002).

In conclusion, our results suggest that CBD has anxiolytic effects that are mediated through an action on limbic and paralimbic areas of the brain. However, the findings need to be seen as preliminary, given the limitations of the study. Firstly, it would have been desirable to measure plasma levels of CBD and relate them to the magnitude of change in rCBF. Without a dose–response curve, uncertainty about the regional cerebral effects of CBD remains. Nevertheless, it should be pointed out that it is not clear whether there is a relation between plasma levels of cannabinoids—especially CBD—and their clinical effects (Agurell et al, 1986). In addition, the subject sample was modest and the use of SPECT limited the study’s statistical power. Finally, given the limited spatial resolution of the SPECT technique and the smoothing procedure, the interpretation of large foci of tracer uptake changes as involving different brain structures of small size (such as the amygdala, hippocampus, and hypothalamus) should be made with caution. These limitations could be overcome by examining a larger sample and using functional magnetic resonance imaging, which would permit the acquisition of

greater numbers of images with a better spatial and temporal resolution.

ACKNOWLEDGEMENTS

JASC and AWZ are recipients of Conselho Nacional de Desenvolvimento Científico e Tecnológico fellowships (Grants 200984/01-2 and 303770/85-6, respectively). This research was supported in part by the Fundação de Amparo à Pesquisa do Estado de São Paulo fellowship (Grants 02/13197-2, 01/00189-9, 99/12205-7, 99/09547-3, and 95/06195-8). We are grateful to Professor Dr José Antonio Marin Neto (Department of Medical Clinic, University of São Paulo, Ribeirão Preto, Brazil), for technical and logistic assistance. We also thank Professor Dr Frederico G Graeff (Department of Neuropsychiatry and Medical Psychology, University of São Paulo, Ribeirão Preto, Brazil) for comments and suggestions on the manuscript.

Cannabidiol (CBD) is a major phytocannabinoid present in the *Cannabis sativa* plant. It lacks the psychotomimetic and other psychotropic effects that the main plant compound Δ^9 -tetrahydrocannabinol (THC) being able, on the contrary, to antagonize these effects. This property, together with its safety profile, was an initial stimulus for the investigation of CBD pharmacological properties. It is now clear that CBD has therapeutic potential over a wide range of non-psychiatric and psychiatric disorders such as anxiety, depression and psychosis. Although the pharmacological effects of CBD in different biological systems have been extensively investigated by *in vitro* studies, the mechanisms responsible for its therapeutic potential are still not clear. Here, we review recent *in vivo* studies indicating that these mechanisms are not unitary but rather depend on the behavioural response being measured. Acute anxiolytic and antidepressant-like effects seem to rely mainly on facilitation of 5-HT_{1A}-mediated neurotransmission in key brain areas related to defensive responses, including the dorsal periaqueductal grey, bed nucleus of the stria terminalis and medial prefrontal cortex. Other effects, such as anti-compulsive, increased extinction and impaired reconsolidation of aversive memories, and facilitation of adult hippocampal neurogenesis could depend on potentiation of anandamide-mediated neurotransmission. Finally, activation of TRPV1 channels may help us to explain the antipsychotic effect and the bell-shaped dose-response curves commonly observed with CBD. Considering its safety profile and wide range of therapeutic potential, however, further studies are needed to investigate the involvement of other possible mechanisms (e.g. inhibition of adenosine uptake, inverse agonism at CB₂ receptor, CB₁ receptor antagonism, GPR55 antagonism, PPAR γ receptors agonism, intracellular (Ca²⁺) increase, etc.), on CBD behavioural effects.

1. HISTORY

Cannabidiol (CBD) is the main non-psychotropic phytocannabinoid present in the *Cannabis sativa* plant, constituting up to 40 per cent of its extract. The chemical characterization of the main cannabinoids present in this plant by Mechoulam's group in the 1960s [1] originated the first wave of scientific interest in this compound. With the discovery of the endocannabinoid (eCB) system in the early 1990s

and the rise, in the words of Bill Devane [2], of the new dawn of cannabinoid pharmacology, there was a renewed interest in CBD, with the number of related published studies growing exponentially since then.

Recent comprehensive reviews suggest that this compound is one of the most promising candidates for a therapeutic tool in a wide range of disorders [3,4]. In the present paper, we will review the evidence that supports its use in psychiatric disorders and the proposal mechanisms that try to explain it.

2. CANNABIDIOL AND ANXIETY

Early reports describing the effects of CBD in animal models of anxiety were inconsistent. Silveira Filho &

Tufik [5] did not find any effect of CBD (100 mg kg⁻¹) in rats tested in the classical Geller-Seifter conflict model of anxiety, whereas Zuardi & Karniol [6] described that a much lower CBD dose (10 mg kg⁻¹) attenuated conditioned emotional responses. These apparent contradictory results were subsequently explained by Guimarães *et al.* [7]. Using an ethologically based model of anxiety, the elevated plus maze, they showed that CBD promotes anxiolytic-like effects with an inverted U-shaped dose-response curve, higher doses (more than 20 mg kg⁻¹ in rats) being ineffective (table 1).

The anti-anxiety properties of CBD in rats were later confirmed in different species (mice) and animal models, including the Vogel conflict test and contextual fear conditioning [8–10]. More recently, CBD was shown to decrease defensive behaviours evoked by predator exposure, a proposed model of panic attacks and posttraumatic stress disorder (PTSD) [11,13]. CBD also reduces marble burying behaviour in mice, suggesting that this compound could be effective in obsessive-compulsive disorder (OCD) [14]. Moreover, CBD can interfere in learning and/or memory of aversive events, processes that have

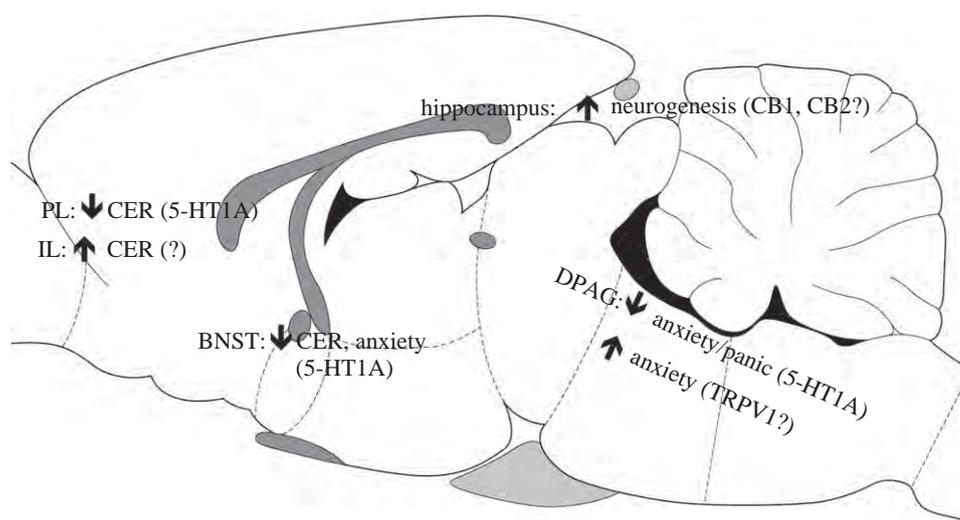

Figure 1. Possible brain sites and mechanisms of CBD effects on anxiety. BNST, bed nucleus of the stria terminalis; CeA, central nucleus of the amygdala; CER, conditioned emotional response; DPAG, dorsal periaqueductal grey; IL, infralimbic prefrontal cortex; PL, prelimbic prefrontal cortex.

been associated with PTSD pathophysiology [30]. Intracerebroventricular administration of CBD facilitates extinction in a contextual aversive conditioning model [15]. In this same paradigm, it can also impair reconsolidation, resulting in the attenuation of the aversive memory trace. In this study, the impairment of contextual fear memory did not show reinstatement and was long-lasting (22 days) [23]. Contrasting with these results, Elbatsh *et al.* [22] have recently reported that repeated (14 days) administration of CBD increases freezing in a contextual fear conditioning test. The reasons for this difference is unknown, but may involve the distinct conditioning protocols and drug administration regime (chronic versus acute) used compared with other studies that investigated the effects of CBD in this model [15,21,23]. Moreover, in this study, it is also possible that CBD could have interfered in learning/memory mechanisms, because the animals were conditioned under the drug effect [22].

(a) *Clinical anxiolytic effects of cannabidiol*

In agreement with the results obtained in animal models, clinical studies confirmed that CBD has anxiolytic properties (table 1). Following the initial report that it blocks the anxiogenic effects of high doses of the main psychoactive compound present in the *Cannabis sativa* plant, Δ^9 -tetrahydrocannabinol (THC) [31], it was demonstrated that CBD can also reduce anxiety in healthy volunteers during a neuroimaging study or after a simulated public-speaking procedure [24,25]. More recently, using the latter procedure, Bergamaschi *et al.* [29] showed that CBD (600 mg p.o.) decreases anxiety in treatment-naïve social phobic patients.

(b) *Brain sites of cannabidiol anxiolytic effects*

Neuroimaging studies show that CBD changes the activity of brain regions related to the control of emotional process [25,27]. It attenuates blood oxygenation in the amygdala and the anterior and posterior cingulate cortex in subjects exposed to fearful faces

[27], impairs the connectivity between the pre-frontal and subcortical regions [27] and decreases the activation of left-amygdala–hippocampal complex and left posterior cingulate gyrus [25].

These clinical findings were complemented by studies in rodents, using direct administration into brain sites related to anxiety- or panic-like responses (figure 1). Microinjection of CBD into the dorsal portions of the periaqueductal grey (DPAG) promoted anxiolytic-like effects in the elevated plus maze, elevated T maze and Vogel conflict tests. It also decreased escape latency in a model of panic attacks, electrical stimulation of the DPAG [16,18]. Anxiolytic effects were also found after CBD injection into the bed nucleus of the *stria terminalis* (BNST) in rats tested in the elevated plus maze, Vogel conflict test and contextual fear conditioning [19,20]. This latter effect corroborates results showing that the effects of CBD in a contextual fear conditioning model is associated with decreased neuronal activation (measure by cFos expression) in this area [21]. This same treatment attenuated the activation of the pre- and infra-limbic cortical regions. In these two brain areas, however, CBD produced opposite effects, decreasing and facilitating, respectively, conditioned emotional responses [10]. Recently, Hsiao *et al.* [26] showed anxiolytic effects of CBD injection into the central nucleus of the amygdala. Other possible brain sites of CBD anxiolytic effect have not yet been investigated (e.g. the hippocampus).

(c) *Mechanisms of the anxiolytic effects of cannabidiol*

CBD can produce multiple pharmacological actions over a wide range of drug concentrations (table 2) [3,4]. CBD is proposed to activate or modify the function of several receptors in the central nervous system (CNS), including CB1, CB2, GPR55, TRPV1 and 5-HT1A receptors (table 2) [32,33,35,42]. Moreover, it could inhibit the anandamide hydrolysing enzyme (fatty acid amide hydrolase, FAAH) and the adenosine

^aCBD was able to antagonize the effects of the CB1 agonist CP55940-induced stimulation of [³⁵S]GTP γ S binding to mouse brain membranes at a much lower concentration ($K_B = 79$ nM) than the K_i for displacement of the CB1 ligand.

^bCBD acts as an inverse agonist with a lower concentration ($K_B = 65$ nM) than the K_i for displacement of the CB2 ligand.

transporter [33,43,50], indirectly increasing the levels of these neurotransmitters.

Some of CBD effects involve intracellular pathways that play fundamental roles in neuronal physiology. For example, in hippocampal neurons, CBD increases intracellular calcium concentrations via mitochondrial uptake and release and/or activation of type-L voltage-gated calcium channels [38,39]. CBD has also a potent action in inhibiting oxidative and nitrosative stress, a mechanism that has been related to its neuroprotective effects with implications for the treatment of Alzheimer's, Huntington's and Parkinson's

diseases. It decreases the neuronal damage promoted by β -amyloid protein deposit [47,51] and attenuates the depletion of tyrosine hydroxylase, dopamine and GABA levels by modulating the expression of the inducible nitric oxide synthase and reducing the production of reactive oxygen species (ROS)-generating NADPH oxidases [47,52–54]. Moreover, CBD pretreatment attenuated high-glucose-induced mitochondrial superoxide generation and NF- κ B activation, along with the expression of adhesion molecules ICAM-1 and VCAM-1 [48]. Together, these results suggest that CBD can exert CB1- and

CB2-independent neuroprotective/antioxidant/anti-inflammatory effects [48].

The large majority of these possible mechanisms have been unveiled by *in vitro* studies. Their association to the behaviour effects of CBD is still not clear, a topic that is further complicated by the common bell-shaped dose-response curves produced by this compound in distinct biological systems [4].

In the last decade, however, several *in vivo* studies have helped us to understand the mechanisms of CBD central effects.

(d) *In vivo mechanisms of cannabidiol anxiolytic effects: 5-HT1A receptors*

Russo *et al.* [35] were the first to suggest that CBD could act as a 5HT1A receptor agonist. They observed that, at μM range, this drug displaces 8-OH-DPAT, a 5-HT1A receptor agonist, from cloned human 5-HT1A receptors expressed in cultured cells obtained from Chinese hamster ovary. *In vivo* experiments gave further support to the involvement of 5-HT1A receptors in the effects of CBD [18–20,55]. For instance, the neuroprotective effects of CBD in hepatic encephalopathy or cerebral infarction are mediated by these receptors [55,56]. Regarding the behavioural studies, the effects of CBD in a PTSD model (predator exposure) were prevented by WAY100635, a 5HT1A receptor antagonist [11]. This same antagonist prevented the anxiolytic- and panicolytic-like effects of CBD after injections into the DPAG [16,18], bed nucleus of the stria terminalis [19,20] and prefrontal cortex (M. V. Fogaça & F. S. Guimarães 2012, unpublished data; figure 1). In humans, although no study so far has investigated the involvement of 5-HT1A mechanisms in CBD effects, the anxiolytic profile of this drug in the public speaking model was remarkably similar to the positive control ipsapirone, a 5HT1A receptor partial agonist [24].

Other CBD effects also involve 5-HT1A receptors. It decreases nausea and vomiting probably by an indirect agonism at these receptors. Although the mechanism of this indirect action is unclear, it may involve interactions with allosteric sites or changes in different systems that would result in a facilitation of 5-HT1A-mediated responses [57]. Adding to the evidence that the interaction of CBD with 5-HT1A receptors could be complex, it was recently shown that this compound antagonizes food intake induced by 8-OH-DPAT [58]. Therefore, additional research is clearly needed to clarify how CBD facilitates 5-HT1A-mediated neurotransmission.

(e) *In vivo mechanisms of cannabidiol effects: the endocannabinoid system*

CBD could facilitate eCB-mediated neurotransmission by blocking the metabolism and uptake of anandamide [33]. However, AM251, a CB1 receptor antagonist, failed to prevent the anxiolytic effects of CBD injected into the DPAG observed in the elevated plus maze at the same dose that antagonized the anxiolytic effects of anandamide [18,59].

On the other hand, CB1, but not 5-HT1A, receptor antagonism was able to prevent CBD effects on both

extinction and reconsolidation, indicating that its interference on aversive memories involves eCB-mediated mechanisms [15,23]. These results agree with the well-described facilitation of extinction by endogenous cannabinoids [60], suggesting that CBD interferes with aversive memories by facilitating the effects of eCBs [45].

Finally, AM251 blocked CBD effects in the marble burying model [14], whereas 5-HT1A-receptor antagonism was ineffective. This result corroborates the proposal that anxiety and OCD models engage distinct brain mechanisms, with the marble burying behaviour being related to repetitive behaviours instead of anxiety [61].

How facilitation of eCB-mediated neurotransmission decreases repetitive behaviour is unknown, but may involve attenuation of glutamate-mediated neurotransmission. eCBs can reduce the release of several neurotransmitters, including glutamate [62], a major neurotransmitter of the cortico-striato-thalamo-cortical circuitry that has been implicated in the pathophysiology of OCD [63]. Anti-glutamatergic drugs such as riluzole and memantine decrease marble burying behaviour [64,65] and are proposed to be clinically useful for OCD treatment [66,67].

An indirect anti-glutamatergic action via increased eCB neurotransmission may also be involved in other central effects of CBD such as anticonvulsant [3], an effect that could also be related to indirect CB1-mediated inhibition of glutamate release. Corroborating this proposal, anticonvulsant effects of other inhibitors of anandamide metabolism/uptake have recently been described [3]. Moreover, epileptic patients present a significant reduction in the fraction of CB1-positive glutamatergic, but not GABAergic, axon terminals, probably resulting in increased neural excitability [68].

(f) *In vivo mechanisms of cannabidiol effects: adult hippocampal neurogenesis*

Impairment in adult hippocampal neurogenesis has been associated with the pathogenesis of anxiety disorders and depression [69] and at least some of the behavioural effects of prototype antidepressant drugs depend on facilitation of this process [70]. CBD can also increase adult hippocampal neurogenesis, as first demonstrated by Wolf *et al.* [71]. They also showed that the proneurogenic effect of CBD was absent in CB1-knockout mice [71]. Because CBD is not a CB1-receptor agonist, this result suggested that CBD effect was mediated by an indirect activation of these receptors, possibly by inhibition of anandamide metabolism/uptake [33]. Corroborating this latter possibility, recent results from our group showed that CBD increases proliferation of hippocampal progenitor cells in culture, an effect mimicked by CB₁ or CB₂ receptor agonists and prevented by antagonists of these receptors [72]. Moreover, CBD effects were also inhibited by overexpression of the FAAH, reinforcing the proposal of anandamide involvement. These results agree with those previously reported by Jiang *et al.* [73] showing that a synthetic CB1 agonist is able to promote embryonic and adult hippocampus neurogenesis, an effect associated with the anxiolytic

and antidepressant properties of the drug. Similar to prototype antidepressants, the anxiolytic effect of repeated administered CBD (30 mg/daily for 14 days) in mice submitted to a chronic unpredictable stress model disappeared when hippocampal neurogenesis was inhibited [72], suggesting a causal link between its proneurogenic and anxiolytic effect after repeated administration (figure 1).

Other mechanisms could also be involved in CBD effects on adult hippocampal neurogenesis—for example, activation of peroxisome proliferator-activated receptors. This particular mechanism seems to be important during neuroinflammation and neurodegenerative process related to β -amyloid protein deposits in CNS [51]. Although the pro-neurogenic effect of CBD has not yet been studied in rats, it could help us to explain the recent report that repeated CBD treatment enhances contextual fear conditioning [22]. Immature newborn neurons are selectively activated by this task [74], and neurogenesis suppression impairs contextual fear memory [75]. Considering the important role proposed for hippocampal neurogenesis in several brain functions [76,77], the effects and mechanisms of CBD on this process is another important research venue to be pursued.

(g) *Cannabidiol and the vanilloid system*

CBD can activate transient receptor potential (TRP) channels [33]. These channels comprise a family of over 50 members and are present in different species, including yeast, worms, insects, fish and mammals [78]. The vanilloid receptor 1 or TRPV1 is one of the first identified members of the family, being a non-selective cation channel with a preference for calcium. It is activated by noxious stimuli, heat, protons ($\text{pH} < 5.9$) and various, mostly noxious, natural products such as capsaicin [79]. TRPV1 receptors are present in the brain, where anandamide has been proposed to act as an endogenous agonist or an endovanilloid [80]. These receptors can facilitate the release of glutamate [81], a neurotransmitter that induces defensive responses in brain areas such as the DPAG [82]. On the basis of these pieces of evidence, we hypothesized that TRPV1 activation could be at least partially responsible for the inverted U-shaped dose-response curves commonly observed with CBD. Accordingly, using intra-DPAG injections, we showed that local pretreatment with an ineffective dose of the TRPV1 antagonist capsazepine turned a higher, ineffective dose (60 nmol) of CBD into an anxiolytic one [83]. TRPV1 receptors are also involved in the bell-shaped dose responses curves of anandamide analogues [84,85].

In addition to TRPV1, CBD could also interfere with other members of the TRP family, activating TRPV2 and ankyrin type 1 (TRPA1) channels and antagonizing melastatin type 8 (TRPM8) channels [45,46]. The role played by these mechanisms on CBD behavioural effects, however, is unknown at the moment.

3. CANNABIDIOL AND PSYCHOSIS

Initial studies with laboratory animals suggested that CBD prevents some of the effects produced by THC [86]. Similar antagonism was also found in humans,

where CBD attenuated the impairment of time production tasks and the euphoria induced by THC in healthy volunteers [87,88]. Confirming and extending these results, Zuardi *et al.* [31] demonstrated that CBD inhibits THC-induced anxiety and psychotic-like symptoms such as disconnected thoughts, perceptual disturbance, depersonalization and resistance to communication. In the same year, it was observed that patients admitted to a psychiatric hospital in South Africa after the use of a variety of *Cannabis* virtually devoid of CBD showed a much higher frequency of acute psychotic episodes than in other countries [89], suggesting that the presence of CBD in *Cannabis* samples protects users against the occurrence of THC-induced acute psychotic episodes. Because experimental evidence indicates that the antagonistic effect of CBD did not result from a pharmacokinetic interaction between the two cannabinoids [90], these initial observations led to the hypothesis that CBD could possess antipsychotic properties.

An initial study in rats investigated whether this compound could attenuate stereotypies induced by the dopaminergic agonist apomorphine. CBD effects were compared with those of haloperidol [91]. Both drugs reduced apomorphine-induced stereotyped behaviour in a dose-related manner. Even though they increased plasma levels of prolactin, CBD had much lower potency, with significant increases only seen after the doses of 120 and 240 mg kg⁻¹. Moreover, contrary to haloperidol, CBD did not induce catalepsy, even at doses as high as 480 mg kg⁻¹. These results suggest that CBD exhibits a profile similar to atypical antipsychotic drugs. In another study, CBD was compared with haloperidol and clozapine, an atypical antipsychotic drug. The drug inhibited the hyperlocomotion induced by amphetamine and ketamine, an NMDA receptor antagonist, in mice [92]. As expected, while both haloperidol and clozapine inhibited hyperlocomotion, only haloperidol induced catalepsy. These results extend CBD antipsychotic-like effects to a glutamate-based model. In agreement with these results, CBD, similar to clozapine, reversed the disruption of prepulse inhibition (PPI) in mice and the hyperactivity and reduction of social interaction in rats caused by MK-801, another NMDA receptor antagonist [93,94]. Typical antipsychotics, on the other hand, are usually unable to restore the deficits in PPI and social interaction induced by NMDA receptor antagonists [95,96].

Extending findings from studies using single drug administration, chronic treatment with CBD attenuated amphetamine-induced hyperlocomotion [97]. Preliminary results from our group indicate that this treatment regime is also able to decrease the impairments in PPI and object recognition induced by repeated administration of MK-801 (F. V. Gomes, E. A. Del Bel & F. S. Guimarães, unpublished data). Despite these findings, there are also negative results regarding the possible antipsychotic effects of CBD. Chronic treatment with this drug failed to change behavioural changes such as locomotor hyperactivity and PPI deficits observed in transmembrane domain neuregulin 1 mutant (Nrg1) mice, a proposed model for a schizophrenia susceptibility gene [98]. A summary of

the studies investigating the antipsychotic-like effects of CBD in animal models can be seen in table 3.

(a) *Cannabidiol and psychosis: clinical studies*

The antipsychotic-effects of CBD have also been demonstrated in humans (table 3). In healthy volunteers, Leweke *et al.* [100] observed that the decrease of the perception of illusory image induced by nabilone, a synthetic cannabinoid drug with THC-like properties,

was reduced by CBD. Another model used to evaluate antipsychotic-like activity of drugs in humans is the administration of sub-anaesthetic doses of ketamine. This drug induces psychotic symptoms that mimic both positive and negative symptoms of schizophrenia. An initial investigation in healthy subjects showed that CBD induced a non-significant trend to reduce ketamine-induced dissociative effects, but, at the same time, augmented the activating effects of ketamine

[102]. Because only a single dose of CBD was used, additional studies are needed to characterize the effects of CBD in this model [102].

The therapeutic use of CBD in psychotic patients was tested for the first time in 1995. In an open, case-report study, a 19-year-old black schizophrenic female patient, who presented serious side effects after treatment with conventional antipsychotics, received increasing oral doses of CBD (up to 1500 mg d⁻¹) for four weeks [103]. A significant improvement with no side effects was observed in all items of the standard brief psychiatric rating scale (BPRS) during CBD treatment, with an efficacy similar to that of haloperidol. Symptom worsening was observed when the administration was interrupted. In another case study, CBD was administered to three 22- or 23-year-old male schizophrenic patients who had not responded to typical antipsychotic drugs for 30 days [104]. The dose of CBD was increased from 40 up to 1280 mg d⁻¹. One patient showed mild improvement, but only slight or no change was observed in the other two, suggesting that CBD may not be effective for the treatment of resistant schizophrenia. Moreover, CBD had no beneficial effects on the performance of schizophrenic patients in the Stroop colour word test, which can be used to assess attentional processes frequently impaired in schizophrenia [106]. It is still unknown whether chronic administration of CBD could improve the cognitive deficits in the disorder. No significant side effects were observed during CBD treatment in these clinical studies, suggesting that CBD is safe and well tolerated in schizophrenic patients.

In an open-label study evaluating CBD effects on psychotic symptoms associated with L-dopa use in Parkinson's patients [105], the drug decreased scores of a questionnaire developed to assess psychotic symptoms in Parkinson's disease (Parkinson psychosis questionnaire), improved total BPRS scores as well as scores specifically related to positive and negative symptoms. Confirming the lack of motor effects observed in animal studies, CBD did not affect motor function. On the contrary, it decreased the total scores of the unified Parkinson's disease rating scale, suggesting an improvement of this function.

Overall, therefore, even if there are negative results, most clinical studies with normal subjects or schizophrenic patients suggest that CBD has antipsychotic properties. Corroborating this possibility, a four-week double-blind controlled clinical trial in 42 acute schizophrenic and schizophreniform psychosis patients comparing the effects of CBD with those of amisulpride, an atypical antipsychotic, showed that both treatments were equally effective in reducing acute psychotic symptoms after two and four weeks of treatment [34]. Moreover, compared with amisulpride, CBD caused a lower incidence of extrapyramidal symptoms and increases in prolactin and weight gain.

The presence of antipsychotic properties in CBD is also supported by convergent evidence linking the habitual use of *Cannabis* to the risk of developing schizophrenia or schizophrenia-like psychosis, especially in vulnerable subjects [107]. This effect has been attributed to THC. In agreement with the initial reports showing antagonism of THC-induced psychotomimetic

effects [31,87,88], the presence of CBD in *Cannabis* strains has been shown to be protective against the occurrence of psychotic-like reactions and cognitive impairment [108–110]. In this context, Di Forti *et al.* [111] found that the use of *Cannabis* containing high THC- and low CBD concentration was associated with a higher risk of a first psychotic episode. Furthermore, the presence of CBD protects from *Cannabis*-associated decrease in hippocampal volume [112]. This neuroprotective effect of CBD has also been reported in the human basal ganglia, where there was a strong positive correlation between *N*-acetylaspartate/total creatine ratio and the amount of CBD (as measured by its presence in hair samples) in the putamen/globus pallidum of recreational *Cannabis* users. This finding could reflect a CBD-induced enhancement of neuronal and axonal integrity in these regions [113]. More recently, Bhattacharyya *et al.* [114], investigating the effects of THC and CBD during attentional salience processing, have also showed that these two cannabinoids produce opposite effects on prefrontal, striatal and hippocampal functions.

(b) Brain sites and mechanisms of cannabidiol antipsychotic effects

Few studies in laboratory animals have investigated the possible brain sites and mechanisms of CBD antipsychotic effects. Consistent with the behavioural data described earlier, both CBD and clozapine, but not haloperidol, increased neuronal activation (measured by cFos-protein expression) in the prefrontal cortex. Probably reflecting its motor side effects, only haloperidol increased cFos in the dorsal striatum. CBD, and, in addition, increased cFos in the nucleus accumbens [115], an effect shared by typical and atypical antipsychotic drugs [116]. Intracerebroventricular administration of CBD (10 µg) also enhanced cFos expression in waking-related brain areas such as hypothalamus and dorsal raphe nucleus [117], but the relation between this finding and its antipsychotic properties is unclear.

A number of neuroimaging studies in healthy volunteers have compared the effects of CBD and high doses of THC. Consistent with the behavioural findings in humans and rodents, these drugs caused opposite effects on brain activity in the striatum, anterior cingulate, prefrontal cortex, parahippocampal gyrus, amygdala, right posterior superior temporal gyrus, middle occipital gyrus and cerebellum [27, 101,114,118–120]. Behavioural measurements in these studies indicated that some of these changes (decreased activation of ventral and dorsal striatum, anterior cingulate gyrus, right temporal lobe) are associated with the psychotic-like effects of THC, suggesting that these regions could be possible brain sites of CBD action [121]. No study using direct injections into key brain regions associated with the pathophysiology of schizophrenia, such as the prefrontal cortex and nucleus accumbens, has been performed so far to investigate CBD antipsychotic properties.

Regarding the pharmacological mechanisms, intracerebroventricular administration of CBD enhanced extracellular levels of dopamine in the nucleus accumbens [122]. A similar finding was found after

Table 4. Antidepressant-like effects of CBD. Studies with laboratory animals. FST, forced swimming test; TST, tail suspension test.

model	species	effective doses	CBD effects	references
restraint stress	rat	10–20 mg kg ⁻¹	↓ cardiovascular and behavioural effects of stress	[17]
FST	mouse	200 mg kg ⁻¹	↓ immobility	[127]
TST	mouse	20–200 mg kg ⁻¹	no effect	[127]
FST	mouse	30 mg kg ⁻¹	↓ immobility	[128]
chronic unpredictable stress	mouse	30 mg kg ⁻¹ (daily, chronic treatment)	↓ the behavioural consequences of stress through enhancement of hippocampal neurogenesis	[72]

microdialysis perfusion of CBD (30, 60 or 90 nM) into the rat lateral hypothalamus [117], a procedure that also enhanced alertness. It is unclear how this effect would relate to the antipsychotic properties of CBD because usual antipsychotic drugs act by antagonizing dopamine-2 receptors [123]. Moreover, studies with animal models that involve dopaminergic stimulation suggest that the antipsychotic-like doses of CBD (60–120 mg kg⁻¹) are higher than those needed to induce anxiolytic-like effects [7,91,92] and reverse behavioural deficits induced by the NMDA receptor antagonist MK-801 [93,94,99]. These findings indicate that the mechanisms of CBD effects on glutamate- or dopamine-based models could be at least partially distinct. This possibility needs to be further explored.

Recently, Leweke *et al.* [34] showed that schizophrenic patients treated with CBD present higher anandamide serum levels compared with those receiving the antipsychotic amisulpride. Moreover, in the CBD group, there was a significant association between anandamide levels and improvement of psychotic symptoms. In the same study, they confirmed, *in vitro*, that CBD inhibits FAAH activity in a concentration (10 μ M) that does not interact with receptors (dopamine, GABA, serotonin and glutamate) commonly associated with schizophrenia. However, by indirectly activating CB1 receptors via increased levels of anandamide, CBD could potentially modulate neurotransmitters systems related to these receptors [121, 124]. Moreover, as previously discussed, facilitation of CB1-mediated neurotransmission by CBD also increases adult hippocampal neurogenesis, a mechanism that could be related to the cognitive deficits found in schizophrenic patients [124].

As discussed already, CBD and anandamide can also activate TRPV1 channels. This mechanism, probably by facilitating the pre-synaptic release of glutamate [80], is involved in the ability of CBD to reverse the disruption of PPI induced by the NMDA receptor antagonist MK-801 [93].

Other mechanisms that could also help us to explain CBD anti-psychotic effects are facilitation of 5-HT_{1A}-mediated neurotransmission, an effect shared by the atypical anti-psychotic aripiprazole, which acts as a partial agonist at these receptors, and anti-inflammatory/neuroprotective action [124].

4. CANNABIDIOL AND DEPRESSION

Cannabis sativa exerts significant effects upon humour, which include euphoria and mood elevation [125].

THC may account for most of these effects through activation of CB1 receptors. Considering these observations, as well as the effects of synthetic cannabinoids and drugs that increase eCB levels, a putative role for the eCB system in mood disorders has been proposed [126]. The effects of CBD, however, have been scarcely investigated (table 4). The fact that this compound, in addition to facilitating eCB activity [33], may facilitate the activation of 5-HT_{1A} receptors [35] suggests that it might also have antidepressant-like properties. 5HT_{1A} receptors modulate responses to stressful stimuli and are proposed to mediate the effects of antidepressant drugs [129].

Stress exposure is a key aetiological factor in depression [130] and animal models used to study antidepressant-like effects are generally based on acute responses to inescapable aversive stimuli, which are prevented by antidepressants [131]. Alternatively, considering the nature of depression as a chronic psychiatric disorder, some models investigate drug effects upon the diverse consequences of chronic stress, including anhedonia and changes in exploratory activity [132].

One of the first studies that indicate the presence of antidepressant-like properties in CBD focused on its ability to prevent the autonomic and behavioural consequences of inescapable stress [17]. Rats were submitted to restraint stress during 60 min, which increases heart rate and blood pressure and caused anxiogenic-like responses in rats exposed to the elevated plus maze 24 h later. CBD was injected 30 min before the stress at the doses of 1, 10 or 20 mg kg⁻¹. The doses of 10 and 20 mg kg⁻¹ attenuated the changes in autonomic parameters, whereas at 10 mg kg⁻¹ CBD also prevented the late anxiogenic-like effect of stress. There were no changes in motor activity or basal cardiovascular parameters, discarding any possible confounding factor [17]. Similar effects were observed after intra-cisterna magna administration of CBD [12], thus suggesting that these effects are centrally mediated.

Another behavioural model widely used to assess antidepressant-like effects, mainly due to its pharmacological predictability, is the forced swim test. In this assay, rats or mice exposed to inescapable swimming assume a posture of immobility, which is reversed by antidepressants [131]. We tested in mice the effects of CBD (3–100 mg kg⁻¹) injected 30 min prior to the test [128]. The drug produced an inverted U-shaped dose-response curve. At the dose of 30 mg kg⁻¹, it reduced immobility similar to the tricyclic antidepressant imipramine (30 mg kg⁻¹). Our behavioural

findings in the forced swimming test were confirmed by another study, published in the same year. CBD was tested at the doses of 20, 100 and 200 mg kg⁻¹ [127], with the higher dose being effective. The drug had no effect, however, in the mouse tail suspension test. One drawback common to all these studies is that the animals received only acute injections. Depression, however, is a chronic disorder that requires long-lasting drug treatment [130]. CBD has been recently tested against the consequences of chronic unpredictable stress, which includes anhedonia and anxiety-like behaviour [130]. Chronic treatment with CBD was able to prevent these behavioural changes, an effect that depends on hippocampal neurogenesis, similar to antidepressant drugs [72]. This observation further strengthens the notion that this natural cannabinoid should be considered as a potential approach for the treatment of mood disorders.

Despite this body of evidence, no clinical study has investigated whether CBD can decrease depressive symptoms in patients. This compound has been tested, however, in patients suffering from bipolar disorders, a subtype of mood disorder, in whom it was not effective in treating manic episodes [133]. Actually, this is in line with animal models, in which CBD failed to prevent hyperactivity in rodents [134].

To summarize, although the data are scarce, preclinical studies so far do provide evidence that this compound could induce antidepressant-like effects. Clinical studies are important to confirm this possibility.

(a) Mechanisms of cannabidiol antidepressant effects

Similar to findings with animal models of anxiety, the attenuation of the behavioural consequences of restraint stress and the antidepressant-like effects of CBD in the forced swimming test were attenuated by a 5-HT_{1A} receptor antagonist [17,128]. In the latter model, despite the association between increased expression of neurotrophic factors and antidepressant activity [130], CBD failed to modify brain-derived neurotrophic factor hippocampal levels [128].

As discussed earlier, CBD can also facilitate hippocampal neurogenesis, probably by facilitation of eCB neurotransmission [72]. The involvement of this mechanism on its antidepressant-like properties after repeated administration remains to be investigated.

5. CONCLUSIONS

CBD is a safe compound with a wide range of therapeutic applications, including the treatment of psychiatric disorders [3,4]. These findings make this drug an attractive candidate for future clinical use. Its therapeutic use, however, has some limiting factors. In addition to its low and variable oral bioavailability in humans [135], it causes bell-shaped dose-response curves and, judging from the studies with laboratory animals, possesses a narrow therapeutic dose range. A clear target of future research, therefore, is to try to develop compounds with similar safety and clinical profile but with larger effective dose ranges. To this aim, a better understanding of the mechanisms responsible for the unique properties of CBD is essential.

The behaviour studies reviewed here clearly indicate that more than one mechanism is involved, depending on the effects being measured (anxiolytic, anti-compulsive, antidepressant or antipsychotic-like) and the drug regime (single versus repeated administration). Facilitation of 5-HT_{1A}-mediated neurotransmission in key brain areas related to defensive responses, including the dorsal periaqueductal grey, bed nucleus of the stria terminalis and medial prefrontal cortex, seems responsible for CBD acute anxiolytic-like effects. Other CBD effects, such as anti-compulsive, increased extinction and impaired reconsolidation of aversive memories, facilitation of adult hippocampal neurogenesis and blockade of the anxiogenic consequences of chronic unpredictable stress could depend on potentiation of anandamide-mediated neurotransmission. Finally, activation of TRPV1 channels may help us to explain the antipsychotic effect and the bell-shaped dose-response curves commonly observed with CBD. In addition to these mechanisms, CBD can interfere in several other important biological processes (e.g. inhibition of adenosine uptake, inverse agonism at CB₂ receptor, CB₁ receptor antagonism, GPR55 antagonism, PPAR γ receptors agonism, intracellular (Ca²⁺) increase, etc.). Additional *in vivo* studies are clearly needed to investigate their possible involvement on CBD behavioural effects.

Abstract Cannabidiol (CBD), a *Cannabis sativa* constituent, is a pharmacologically broad-spectrum drug that in recent years has drawn increasing interest as a treatment for a range of neuropsychiatric disorders. The purpose of the current review is to determine CBD's potential as a treatment for anxiety-related disorders, by assessing evidence from preclinical, human experimental, clinical, and epidemiological studies. We found that existing preclinical evidence strongly supports CBD as a treatment for generalized anxiety disorder, panic disorder, social anxiety disorder, obsessive–compulsive disorder, and post-traumatic stress disorder when administered acutely; however, few studies have investigated chronic CBD dosing. Likewise, evidence from human studies supports an anxiolytic role of CBD, but is currently limited to acute dosing, also with few studies in clinical populations. Overall, current evidence indicates CBD has considerable potential as a treatment for multiple anxiety disorders, with need for further study of chronic and therapeutic effects in relevant clinical populations.

Introduction

Fear and anxiety are adaptive responses essential to coping with threats to survival. Yet excessive or persistent fear may be maladaptive, leading to disability. Symptoms arising from excessive fear and anxiety occur in a number of neuropsychiatric disorders, including generalized anxiety disorder (GAD), panic disorder (PD), post-traumatic stress disorder (PTSD), social anxiety disorder (SAD), and obsessive–compulsive disorder (OCD). Notably, PTSD and OCD are no longer classified as anxiety disorders in the recent revision of the Diagnostic and Statistical Manual of Mental Disorders-5; however, excessive anxiety is central to the symptomatology of both disorders. These anxiety-related disorders are associated with a diminished sense of well-being, elevated rates of unemployment and relationship breakdown, and elevated suicide risk [1–3]. Together, they have a lifetime prevalence in the USA of 29 % [4], the highest of any mental disorder, and constitute an immense social and economic burden [5, 6].

Currently available pharmacological treatments include serotonin reuptake inhibitors, serotonin–norepinephrine reuptake inhibitors, benzodiazepines, monoamine oxidase inhibitors, tricyclic antidepressant drugs, and partial 5-hydroxytryptamine (5-HT)_{1A} receptor agonists. Anticonvulsants and atypical antipsychotics are also used to treat PTSD. These medications are associated with limited response rates and residual symptoms, particularly in PTSD, and adverse effects may also limit tolerability and adherence [7–10]. The substantial burden of anxiety-related disorders and the limitations of current treatments place a high priority on developing novel pharmaceutical treatments.

Cannabidiol (CBD) is a phytocannabinoid constituent of *Cannabis sativa* that lacks the psychoactive effects of Δ^9 -tetrahydrocannabinol (THC). CBD has broad therapeutic properties across a range of neuropsychiatric disorders, stemming from diverse central nervous system actions [11, 12]. In recent

years, CBD has attracted increasing interest as a potential anxiolytic treatment [13–15]. The purpose of this review is to assess evidence from current preclinical, clinical, and epidemiological studies pertaining to the potential risks and benefits of CBD as a treatment for anxiety disorders.

Methods

A search of MEDLINE (PubMed), PsycINFO, Web of Science Scopus, and the Cochrane Library databases was conducted for English-language papers published up to 1 January 2015, using the search terms “cannabidiol” and “anxiety” or “fear” or “stress” or “anxiety disorder” or “generalized anxiety disorder” or “social anxiety disorder” or “social phobia” or “post-traumatic stress disorder” or “panic disorder” or “obsessive compulsive disorder”. In total, 49 primary preclinical, clinical, or epidemiological studies were included. Neuroimaging studies that documented results from anxiety-related tasks, or resting neural activity, were included. Epidemiological or clinical studies that assessed CBD’s effects on anxiety symptoms, or the potential protective effects of CBD on anxiety symptoms induced by cannabis use (where the CBD content of cannabis is inferred via a higher CBD:THC ratio), were included.

CBD Pharmacology Relevant to Anxiety

General Pharmacology and Therapeutic Profile

Cannabis sativa, a species of the *Cannabis* genus of flowering plants, is one of the most frequently used illicit recreational substances in Western culture. The 2 major phyto-cannabinoid constituents with central nervous system activity are THC, responsible for the euphoric and mind-altering effects, and CBD, which lacks these psychoactive effects. Preclinical and clinical studies show CBD possesses a wide range of therapeutic properties, including antipsychotic, analgesic, neuroprotective, anti-convulsant, antiemetic, antioxidant, anti-inflammatory, antiarthritic, and antineoplastic properties (see [11, 12, 16–19] for reviews). A review of potential side effects in humans found that CBD was well tolerated across a wide dose range, up to 1500 mg/day (orally), with no reported psychomotor slowing, negative mood effects, or vital sign abnormalities noted [20].

CBD has a broad pharmacological profile, including interactions with several receptors known to regulate fear and anxiety-related behaviors, specifically the cannabinoid type 1 receptor (CB₁R), the serotonin 5-HT_{1A} receptor, and the transient receptor potential (TRP) vanilloid type 1 (TRPV1) receptor [11, 12, 19, 21]. In addition, CBD may also regulate, directly or indirectly, the peroxisome proliferator-activated receptor- γ , the orphan G-protein-coupled receptor 55, the equilibrative nucleoside transporter, the adenosine transporter,

additional TRP channels, and glycine receptors [11, 12, 19, 21]. In the current review of primary studies, the following receptor-specific actions were found to have been investigated as potential mediators of CBD’s anxiolytic action: CB₁R, TRPV1 receptors, and 5-HT_{1A} receptors. Pharmacology relevant to these actions is detailed below.

The Endocannabinoid System

Following cloning of the endogenous receptor for THC, namely the CB₁R, endogenous CB₁R ligands, or “endocannabinoids” (eCBs) were discovered, namely anandamide (AEA) and 2-arachidonoylglycerol (reviewed in [22]). The CB₁R is an inhibitory G_{i/o} protein-coupled receptor that is mainly localized to nerve terminals, and is expressed on both γ -aminobutyric acid-ergic and glutamatergic neurons. eCBs are fatty acid derivatives that are synthesized on demand in response to neuronal depolarization and Ca²⁺ influx, via cleavage of membrane phospholipids. The primary mechanism by which eCBs regulate synaptic function is retrograde signaling, wherein eCBs produced by depolarization of the postsynaptic neuron activate presynaptic CB₁Rs, leading to inhibition of neurotransmitter release [23]. The “eCB system” includes AEA and 2-arachidonoylglycerol; their respective degradative enzymes fatty acid amide hydroxylase (FAAH) and monoacylglycerol lipase; the CB₁R and related CB₂ receptor (the latter expressed mainly in the periphery); as well as several other receptors activated by eCBs, including the TRPV1 receptor, peroxisome proliferator-activated receptor- γ , and G protein-coupled 55 receptor, which functionally interact with CB₁R signaling (reviewed in [21, 24]). Interactions with the TRPV1 receptor, in particular, appear to be critical in regulating the extent to which eCB release leads to inhibition or facilitation of presynaptic neurotransmitter release [25]. The TRPV1 receptor is a postsynaptic cation channel that underlies sensation of noxious heat in the periphery, with capsaicin (hot chili) as an exogenous ligand. TRPV1 receptors are also expressed in the brain, including the amygdala, periaqueductal grey, hippocampus, and other areas [26, 27].

The eCB system regulates diverse physiological functions, including caloric energy balance and immune function [28]. The eCB system is also integral to regulation of emotional behavior, being essential to forms of synaptic plasticity that determine learning and response to emotionally salient, particularly highly aversive events [29, 30]. Activation of CB₁Rs produces anxiolytic effects in various models of unconditioned fear, relevant to multiple anxiety disorder symptom domains (reviewed in [30–33]). Regarding conditioned fear, the effect of CB₁R activation is complex: CB₁R activation may enhance or reduce fear expression, depending on brain locus and the eCB ligand [34]; however, CB₁R activation potentially enhances fear extinction [35], and can prevent fear reconsolidation. Genetic manipulations that impede

CB₁R activation are anxiogenic [35], and individuals with eCB system gene polymorphisms that reduce eCB tone—for example, FAAH gene polymorphisms—exhibit physiological, psychological, and neuroimaging features consistent with impaired fear regulation [36]. Reduction of AEA–CB₁R signaling in the amygdala mediates the anxiogenic effects of corticotropin-releasing hormone [37], and CB₁R activation is essential to negative feedback of the neuroendocrine stress response, and protects against the adverse effects of chronic stress [38, 39]. Finally, chronic stress impairs eCB signaling in the hippocampus and amygdala, leading to anxiety [40, 41], and people with PTSD show elevated CB₁R availability and reduced peripheral AEA, suggestive of reduced eCB tone [42].

Accordingly, CB₁R activation has been suggested as a target for anxiolytic drug development [15, 43, 44]. Proposed agents for enhancing CB₁R activation include THC, which is a potent and direct agonist; synthetic CB₁R agonists; FAAH inhibitors and other agents that increase eCB availability, as well as nonpsychoactive cannabis phytocannabinoids, including CBD. While CBD has low affinity for the CB₁R, it functions as an indirect agonist, potentially via augmentation of CB₁R constitutional activity, or via increasing AEA through FAAH inhibition (reviewed in [21]).

Several complexities of the eCB system may impact upon the potential of CBD and other CB₁R-activating agents to serve as anxiolytic drugs. First, CB₁R agonists, including THC and AEA, have a biphasic effect: low doses are anxiolytic, but higher doses are ineffective or anxiogenic, in both preclinical models in and humans (reviewed in [33, 45]). This biphasic profile may stem from the capacity of CB₁R agonists to also activate TRPV1 receptors when administered at a high, but not low dose, as demonstrated for AEA [46]. Activation of TRPV1 receptors is predominantly anxiogenic, and thus a critical balance of eCB levels, determining CB₁ *versus* TRPV1 activation, is proposed to govern emotional behavior [27, 47]. CBD acts as a TRPV1 agonist at high concentrations, potentially by interfering with AEA inactivation [48]. In addition to dose-dependent activation of TRPV1 channels, the anxiogenic *versus* anxiolytic balance of CB₁R agonists also depends on dynamic factors, including environmental stressors [33, 49].

5-HT_{1A} Receptors

The 5-HT_{1A} receptor (5-HT_{1A}R) is an established anxiolytic target. Buspirone and other 5-HT_{1A}R agonists are approved for the treatment of GAD, with fair response rates [50]. In preclinical studies, 5-HT_{1A}R agonists are anxiolytic in animal models of general anxiety [51], prevent the adverse effects of stress [52], and enhance fear extinction [53]. Both pre- and postsynaptic 5-HT_{1A}Rs are coupled to various members of the G_{i/o} protein family. They are expressed on serotonergic neurons in the raphe, where they exert autoinhibitory function, and

various other brain areas involved in fear and anxiety [54, 55]. Mechanisms underlying the anxiolytic effects of 5-HT_{1A}R activation are complex, varying between both brain region, and pre- *versus* postsynaptic locus, and are not fully established [56]. While in vitro studies suggest CBD acts as a direct 5-HT_{1A}R agonist [57], in vivo studies are more consistent with CBD acting as an allosteric modulator, or facilitator of 5-HT_{1A} signaling [58].

Preclinical Evaluations

Generalized Anxiety Models

Relevant studies in animal models are summarized in chronological order in Table 1. CBD has been studied in a wide range of animal models of general anxiety, including the elevated plus maze (EPM), the Vogel-conflict test (VCT), and the elevated T maze (ETM). See Table 1 for the anxiolytic effect specific to each paradigm. Initial studies of CBD in these models showed conflicting results: high (100 mg/kg) doses were ineffective, while low (10 mg/kg) doses were anxiolytic [59, 60]. When tested over a wide range of doses in further studies, the anxiolytic effects of CBD presented a bell-shaped dose–response curve, with anxiolytic effects observed at moderate but not higher doses [61, 90]. All further studies of acute systemic CBD without prior stress showed anxiolytic effects or no effect [62, 65], the latter study involving intracerebroventricular rather than the intraperitoneal route. No anxiogenic effects of acute systemic CBD dosing in models of general anxiety have yet been reported. As yet, few studies have examined chronic dosing effects of CBD in models of generalized anxiety. Campos et al. [66] showed that in rat, CBD treatment for 21 days attenuated inhibitory avoidance acquisition [83]. Long et al. [69] showed that, in mouse, CBD produced moderate anxiolytic effects in some paradigms, with no effects in others.

Anxiolytic effects of CBD in models of generalized anxiety have been linked to specific receptor mechanisms and brain regions. The midbrain dorsal periaqueductal gray (DPAG) is integral to anxiety, orchestrating autonomic and behavioral responses to threat [91], and DPAG stimulation in humans produces feelings of intense distress and dread [92]. Microinjection of CBD into the DPAG produced anxiolytic effects in the EPM, VGC, and ETM that were partially mediated by activation of 5-HT_{1A}Rs but not by CB₁Rs [65, 68]. The bed nucleus of the stria terminalis (BNST) serves as a principal output structure of the amygdaloid complex to coordinate sustained fear responses, relevant to anxiety [93]. Anxiolytic effects of CBD in the EPM and VCT occurred upon microinjection into the BNST, where they depended on 5-HT_{1A}R

Table 1 Preclinical studies

Study	Animal	Route	Dose	Model	Effect	Receptor Involvement

Effective doses are in bold

Receptor specific agents: AM251 = cannabinoid receptor type 1 (CB₁R) inverse agonist; WAY100635 = 5-hydroxytryptamine 1A antagonist; SR141716A = CB₁R antagonist; rimonabant = CB₁R antagonist; capsazepine = transient receptor potential vanilloid type 1 antagonist; naloxone = opioid antagonist; flumazenil = GABA_A receptor antagonist

Anxiolytic effects in models used: CER = reduced fear response; CFC = reduced conditioned freezing; CFC extinction = reduced freezing following extinction training; EPM = reduced % time in open arm; ETM = decreased inhibitory avoidance; L-DT = increased % time in light; VCT = increased licks indicating reduced conflict; NSF = reduced latency to feed; OF = increased % time in center; SI = increased social interaction

Anticompulsive effects: MBT = reduced burying

Panicolytic effects: ETM = decreased escape; GABA_A blockade in dISC = defensive immobility, and explosive escape; PAG-E-Stim = increased threshold for escape; PS = reduced explosive escape
WR = Wistar rats; SM = Swiss mice; L-E HR = Long-Evans hooded rats; i.p. = intraperitoneal; dIPAG = dorsolateral periaqueductal gray; i.c.v. = intracerebroventricular; PL = prelimbic; IL = infralimbic; BNST = bed nucleus of the stria terminalis; CeA = amygdala central nucleus; SNpr = substantia nigra pars reticularis; CUS = chronic unpredictable stress; GSCT = Geller-Seifter conflict test; CER = conditioned emotional response; EPM = elevated plus maze; VCT = Vogel conflict test; CFC = contextual fear conditioning; RS = restraint stress; ETM = elevated T maze; PAG E-stim = electrical stimulation of the dIPAG; L-DT = light-dark test; SI = social interaction; OF = open field; MBT = marble-burying test; PS = predator stress; NSF = novel suppressed feeding test; GABA_A = γ-aminobutyric acid receptor A; dISC = deep layers superior colliculus; REM = rapid eye movement; NA = not applicable

activation [79], and also upon microinjection into the central nucleus of the amygdala [78]. In the prelimbic cortex, which drives expression of fear responses via connections with the amygdala [94], CBD had more complex effects: in unstressed rats, CBD was anxiogenic in the EPM, partially via 5-HT_{1A}R receptor activation; however, following acute restraint stress, CBD was anxiolytic [87]. Finally, the anxiolytic effects of systemic CBD partially depended on GABA_A receptor activation in the EPM model but not in the VCT model [61, 62].

As noted, CBD has been found to have a bell-shaped response curve, with higher doses being ineffective. This may reflect activation of TRPV1 receptors at higher dose, as blockade of TRPV1 receptors in the DPAG rendered a previously ineffective high dose of CBD as anxiolytic in the EPM [66]. Given TRPV1 receptors have anxiogenic effects, this may indicate that at higher doses, CBD's interaction with TRPV1 receptors to some extent impedes anxiolytic actions, although was notably not sufficient to produce anxiogenic effects.

Stress-induced Anxiety Models

Stress is an important contributor to anxiety disorders, and traumatic stress exposure is essential to the development of PTSD. Systemically administered CBD reduced acute increases in heart rate and blood pressure induced by restraint stress, as well as the delayed (24 h) anxiogenic effects of stress in the EPM, partially by 5-HT_{1A}R activation [67, 73]. However intra-BNST microinjection of CBD *augmented* stress-induced heart rate increase, also partially via 5-HT_{1A}R activation [85]. In a subchronic study, CBD administered daily 1 h after predator stress (a proposed model of PTSD) reduced the long-lasting anxiogenic effects of chronic predator stress, partially via 5-HT_{1A}R activation [77]. In a chronic study, systemic CBD prevented increased anxiety produced by chronic unpredictable stress, in addition to increasing hippocampal AEA; these anxiolytic effects depended upon CB₁R activation and hippocampal neurogenesis, as demonstrated by genetic ablation techniques [81]. Prior stress also appears to *modulate* CBD's anxiogenic effects: microinjection of CBD into the prelimbic cortex of unstressed animals was anxiogenic in the EPM but following restraint stress was found to be anxiolytic [87]. Likewise, systemic CBD was anxiolytic in the EPM following but not prior to stress [65].

PD and Compulsive Behavior Models

CBD inhibited escape responses in the ETM and increased DPAG escape electrical threshold [68], both proposed models of panic attacks [95]. These effects partially depended on 5-HT_{1A}R activation but were not affected by CB₁R blockade. CBD was also panicolytic in the predator–prey model, which

assesses explosive escape and defensive immobility in response to a boa constrictor snake, also partially via 5-HT_{1A}R activation; however, more consistent with an anxiogenic effect, CBD was also noted to decrease time spent outside the burrow and increase defensive attention (not shown in Table 1) [75, 86]. Finally, CBD, partially via CB₁Rs, decreased defensive immobility and explosive escape caused by bicuculline-induced neuronal activation in the superior colliculus [89]. Anticompulsive effects of CBD were investigated in marble-burying behavior, conceptualized to model OCD [96]. Acute systemic CBD reduced marble-burying behavior for up to 7 days, with no attenuation in effect up to high (120 mg/kg) doses, and effect shown to depend on CB₁Rs but not 5-HT_{1A}Rs [71, 74, 88].

Contextual Fear Conditioning, Fear Extinction, and Reconsolidation Blockade

Several studies assessed CBD using contextual fear conditioning. Briefly, this paradigm involves pairing a neutral context, the conditioned stimulus (CS), with an aversive unconditioned stimulus (US), a mild foot shock. After repeated pairings, the subject learns that the CS predicts the US, and subsequent CS presentation elicits freezing and other physiological responses. Systemic administration of CBD prior to CS re-exposure reduced conditioned cardiovascular responses [63], an effect reproduced by microinjection of CBD into the BNST, and partially mediated by 5-HT_{1A}R activation [79]. Similarly, CBD in the prelimbic cortex reduced conditioned freezing [70], an effect prevented by 5-HT_{1A}R blockade [87]. By contrast, CBD microinjection in the infralimbic cortex *enhanced* conditioned freezing [70]. Finally, El Batsh et al. [80] reported that repeated CBD doses over 21 days, that is chronic as opposed to acute treatment, *facilitated* conditioned freezing. In this study, CBD was administered prior to conditioning rather than prior to re-exposure as in acute studies, thus further directly comparable studies are required.

CBD has also been shown to enhance extinction of contextually conditioned fear responses. Extinction training involves repeated CS exposure in the absence of the US, leading to the formation of a new memory that inhibits fear responses and a decline in freezing over subsequent training sessions. Systemic CBD administration immediately before training markedly enhanced extinction, and this effect depended on CB₁R activation, without involvement of TRPV1 receptors [65]. Further studies showed CB₁Rs in the infralimbic cortex may be involved in this effect [82].

CBD also blocked reconsolidation of aversive memories in rat [76]. Briefly, fear memories, when reactivated by re-exposure (retrieval), enter into a labile state in

which the memory trace may either be reconsolidated or extinguished [97], and this process may be pharmacologically modulated to achieve reconsolidation blockade or extinction. When administered immediately following retrieval, CBD prevented freezing to the conditioned context upon further re-exposure, and no reinstatement or spontaneous recovery was observed over 3 weeks, consistent with reconsolidation blockade rather than extinction [76]. This effect depended on CB₁R activation but not 5-HT_{1A}R activation [76].

Summary and Clinical Relevance

Overall, existing preclinical evidence strongly supports the potential of CBD as a treatment for anxiety disorders. CBD exhibits a broad range of actions, relevant to multiple symptom domains, including anxiolytic, panicolytic, and anticomulsive actions, as well as a decrease in autonomic arousal, a decrease in conditioned fear expression, enhancement of fear extinction, reconsolidation blockade, and prevention of the long-term anxiogenic effects of stress. Activation of 5-HT_{1A}Rs appears to mediate anxiolytic and panicolytic effects, in addition to reducing conditioned fear expression, although CB₁R activation may play a limited role. By contrast, CB₁R activation appears to mediate CBD's anticomulsive effects, enhancement of fear extinction, reconsolidation blockade, and capacity to prevent the long-term anxiogenic consequences of stress, with involvement of hippocampal neurogenesis.

While CBD predominantly has acute anxiolytic effects, some species discrepancies are apparent. In addition, effects may be contingent on prior stress and vary according to brain region. A notable contrast between CBD and other agents that target the eCB system, including THC, direct CB₁R agonists and FAAH inhibitors, is a lack of anxiogenic effects at a higher dose. Further receptor-specific studies may elucidate the receptor specific basis of this distinct dose response profile. Further studies are also required to establish the efficacy of CBD when administered in chronic dosing, as relatively few relevant studies exist, with mixed results, including both anxiolytic and anxiogenic outcomes.

Overall, preclinical evidence supports systemic CBD as an acute treatment of GAD, SAD, PD, OCD, and PTSD, and suggests that CBD has the advantage of not producing anxiogenic effects at higher dose, as distinct from other agents that enhance CB₁R activation. In particular, results show potential for the treatment of multiple PTSD symptom domains, including reducing arousal and avoidance, preventing the long-term adverse effects of stress, as well as enhancing the extinction and blocking the reconsolidation of persistent fear memories.

Human Experimental and Clinical Studies

Evidence from Acute Psychological Studies

Relevant studies are summarized in Table 2. The anxiolytic effects of CBD in humans were first demonstrated in the context of reversing the anxiogenic effects of THC. CBD reduced THC-induced anxiety when administered simultaneously with this agent, but had no effect on baseline anxiety when administered alone [99, 100]. Further studies using higher doses supported a lack of anxiolytic effects at baseline [101, 107]. By contrast, CBD potently reduces experimentally induced anxiety or fear. CBD reduced anxiety associated with a simulated public speaking test in healthy subjects, and in subjects with SAD, showing a comparable efficacy to ipsapirone (a 5-HT_{1A}R agonist) or diazepam [98, 105]. CBD also reduced the presumed anticipatory anxiety associated with undergoing a single-photon emission computed tomography (SPECT) imaging procedure, in both healthy and SAD subjects [102, 104]. Finally, CBD enhanced extinction of fear memories in healthy volunteers: specifically, inhaled CBD administered prior to or after extinction training in a contextual fear conditioning paradigm led to a trend-level enhancement in the reduction of skin conductance response during reinstatement, and a significant reduction in expectancy (of shock) ratings during reinstatement [106].

Evidence from Neuroimaging Studies

Relevant studies are summarized in Table 3. In a SPECT study of resting cerebral blood flow (rCBF) in normal subjects, CBD reduced rCBF in left medial temporal areas, including the amygdala and hippocampus, as well as the hypothalamus and left posterior cingulate gyrus, but increased rCBF in the left parahippocampal gyrus. These rCBF changes were not correlated with anxiolytic effects [102]. In a SPECT study, by the same authors, in patients with SAD, CBD reduced rCBF in overlapping, but distinct, limbic and paralimbic areas; again, with no correlations to anxiolytic effects [104].

In a series of placebo-controlled studies involving 15 healthy volunteers, Fusar-Poli et al. investigated the effects of CBD and THC on task-related blood-oxygen-level dependent functional magnetic resonance imaging activation, specifically the go/no-go and fearful faces tasks [109, 110]. The go/no-go task measures response inhibition, and is associated with activation of medial prefrontal, dorsolateral prefrontal, and parietal areas [111]. Response activation is diminished in PTSD and other anxiety disorders, and increased activation predicts response to treatment [112]. CBD produced no changes in predicted areas (relative to placebo) but reduced activation in the left insula, superior temporal gyrus, and transverse temporal gyrus. The fearful faces task activates the amygdala, and other medial temporal areas involved in

Table 2 Human psychological studies

Study	Subjects, design	CBD route, dose	Measure	Effect
Karniol et al. [99]	HV, DBP	Oral, 15, 30, 60 mg, alone or with THC, acute, at 55, 95, 155, and 185 min	Anxiety and pulse rate after THC and at baseline	↓ THC-induced increases in subjective anxiety and pulse rate No effect at baseline
Zuardi et al., [100]	HV, DBP	Oral 1 mg/kg alone or with THC, acute, 80 min	STAI score after THC	↓ THC-induced increases in STAI scores
Zuardi et al. [98]	HV, DBP	Oral 300 mg, acute, 80 min	VAMS, STAI and BP following SPST	↓ STAI scores ↓ VAMS scores ↓ BP
Martin-Santos et al. [101]	HV, DBP	Oral 600 mg, acute, 1, 2, 3 h	Baseline anxiety and pulse rate	No effect
Crippa et al. [102]	10 HV, DBP	Oral 400 mg, acute, 60 and 75 min	VAMS before SPECT	↓ VAMS scores
Bhattacharyya et al. [103]	15 HV, DBP	Oral 600 mg, acute, 1, 2, 3 h	STAI scores VAMS scores	↓ STAI scores ↓ VAMS scores
Crippa et al. [104]	SAD and HC, DBP	Oral 400 mg, acute, 75 and 140 min	VAMS before SPECT	↓ VAMS scores
Bergamaschi et al. [105]	SAD and HC, DBP	Oral 600 mg, acute, 1, 2, 3 h	VAMS, SSPS-N, cognitive impairment, SCR, HR after SPST	↓ VAMS, SSPS-N and cognitive impairment, no effect on SCR or HR
Das et al. [106]	HV, DBP	Inhaled, 32 mg, acute, immediately following, before, after extinction	SCR and shock expectancy following extinction	CBD after extinction training produced trend level reduction in SCR and decreased shock expectancy
Hindocha et al. [107]	Varying in schizotypy and cannabis use, DBP	Inhaled, 16 mg, acute	Baseline VAS anxiety	No significant effect of CBD

HV = healthy volunteers; DBP = double-blind placebo; SAD = social anxiety disorder; HC = healthy controls; THC = Δ^9 -tetrahydrocannabinol; STAI = Spielberger's state trait anxiety inventory; VAMS = visual analog mood scale; BP = blood pressure; SPST = simulated public speaking test; SCR = skin conductance response; SPECT = single-photon emission computed tomography; SSPS-N = negative self-evaluation subscale; HR = heart rate; VAS = visual analog scale, CBD = cannabidiol

Table 3 Neuroimaging studies

Study	Subjects, design	CBD route, dose, timing	Measure	Effect of CBD
Crippa et al. [102]	10 HV, DBP	Oral 400 mg, acute, 60 and 75 min	SPECT, resting (rCBF)	↓ rCBF in left medial temporal cluster, including amygdala and HPC, also ↓ rCBF in the HYP and posterior cingulate gyrus ↑ rCBF in left PHG
Borgwardt et al. [108]	15 HV, DBP	Oral 600 mg, acute, 1–2 h	fMRI during oddball and go/no-go task	↓ Activation in left insula, STG and MTG
Fusar-Poli et al. [109]	15 HV, DBP	Oral 600 mg, acute, 1–2 h	fMRI activation during fearful faces task	↓ Activation in left medial temporal region, including amygdala and anterior PHG, and in right ACC and PCC
Fusar-Poli et al. [110]	15 HV, DBP	Oral 600 mg, acute, 1–2 h	fMRI functional connectivity during fearful faces task	↓ Functional connectivity between L) AMY and ACC
Crippa et al. [104]	SAD and HC, DBP	Oral 400 mg, acute, 75 and 140 min	SPECT, resting (rCBF)	↓ rCBF in the left PHG, HPC and ITG. ↑ rCBF in the right posterior cingulate gyrus

CBD = cannabidiol; HV = healthy controls; DBP = double-blind placebo; SAD = social anxiety disorder; HC = healthy controls; SPECT = single-photon emission computed tomography; rCBF = regional cerebral blood flow; fMRI = functional magnetic resonance imaging; HPC = hippocampus; HYP = hypothalamus; PHG = parahippocampal gyrus; STG = superior temporal gyrus; MTG = medial temporal gyrus; ACC = anterior cingulate cortex; PCC = posterior cingulate cortex

emotion processing, and heightened amygdala response activation has been reported in anxiety disorders, including GAD and PTSD [113, 114]. CBD attenuated blood-oxygen-level dependent activation in the left amygdala, and the anterior and posterior cingulate cortex in response to intensely fearful faces, and also reduced amplitude in skin conductance fluctuation, which was highly correlated with amygdala activation [109]. Dynamic causal modeling analysis in this data set further showed CBD reduced forward functional connectivity between the amygdala and anterior cingulate cortex [110].

Evidence from Epidemiological and Chronic Studies

Epidemiological studies of various neuropsychiatric disorders indicate that a higher CBD content in chronically consumed cannabis may protect against adverse effects of THC, including psychotic symptoms, drug cravings, memory loss, and hippocampal gray matter loss [115–118] (reviewed in [119]). As THC acutely induces anxiety, this pattern may also be evident for chronic anxiety symptoms. Two studies were identified, including an uncontrolled retrospective study in civilian patients with PTSD patients [120], and a case study in a patient with severe sexual abuse-related PTSD [121], which showed that chronic cannabis use significantly reduces PTSD symptoms; however, these studies did not include data on the THC:CBD ratio. Thus, overall, no outcome data are currently available regarding the chronic effects of CBD in the treatment of anxiety symptoms, nor do any data exist regarding the potential protective effects of CBD on anxiety potentially induced by chronic THC use.

Summary and Clinical Relevance

Evidence from human studies strongly supports the potential for CBD as a treatment for anxiety disorders: at oral doses ranging from 300 to 600 mg, CBD reduces experimentally induced anxiety in healthy controls, without affecting baseline anxiety levels, and reduces anxiety in patients with SAD. Limited results in healthy subjects also support the efficacy of CBD in acutely enhancing fear extinction, suggesting potential for the treatment of PTSD, or for enhancing cognitive behavioral therapy. Neuroimaging findings provide evidence of neurobiological targets that may underlie CBD's anxiolytic effects, including reduced amygdala activation and altered medial prefrontal amygdala connectivity, although current findings are limited by small sample sizes, and a lack of independent replication. Further studies are also required to establish whether chronic, in addition to acute CBD dosing is anxiolytic in human. Also, clinical findings are currently limited to SAD, whereas preclinical evidence suggests CBD's potential to treat multiple symptom domains relevant to GAD, PD, and, particularly, PTSD.

Conclusions

Preclinical evidence conclusively demonstrates CBD's efficacy in reducing anxiety behaviors relevant to multiple disorders, including PTSD, GAD, PD, OCD, and SAD, with a notable lack of anxiogenic effects. CBD's anxiolytic actions appear to depend upon CB₁Rs and 5-HT_{1A}Rs in several brain regions; however, investigation of additional receptor actions may reveal further mechanisms. Human experimental findings support preclinical findings, and also suggest a lack of anxiogenic effects, minimal sedative effects, and an excellent safety profile. Current preclinical and human findings mostly involve acute CBD dosing in healthy subjects, so further studies are required to establish whether chronic dosing of CBD has similar effects in relevant clinical populations. Overall, this review emphasizes the potential value and need for further study of CBD in the treatment of anxiety disorders.

Abstract

*Despite the major benefits of antiretroviral therapy on survival during HIV infection, there is an increasing need to manage symptoms and side effects during long-term drug therapy. Cannabis has been reported anecdotally as being beneficial for a number of common symptoms and complications in HIV infections, for example, poor appetite and neuropathy. This study aimed to investigate symptom management with cannabis. Following Ethics Committee approval, HIV-positive individuals attending a large clinic were recruited into an anonymous cross-sectional questionnaire study. Up to one-third (27%, 143/523) reported using cannabis for treating symptoms. Patients reported improved appetite (97%), muscle pain (94%), nausea (93%), anxiety (93%), nerve pain (90%), depression (86%), and paresthesia (85%). Many cannabis users (47%) reported associated memory deterioration. Symptom control using cannabis is widespread in HIV outpatients. A large number of patients reported that cannabis improved symptom control. *J Pain Symptom Manage* 2005;29:358–367. © 2005 U.S. Cancer Pain Relief Committee. Published by Elsevier Inc. Key Words

Cannabis, HIV, pain, symptoms

Introduction

HIV or AIDS affects over 40 million people in the world¹ and more than 49,500 in the UK.² Although there is still no cure available for this disease, remarkable improvements in the survival of HIV-infected individuals have been achieved.³ This survival has led to an increasing prevalence of individuals with HIV infection, many on long-term treatment with combinations

of antiretroviral therapies. This has increased the clinical focus on the management of chronic symptoms associated with both HIV and the side effects of antiretroviral medication. Recently, in small sample studies of HIV patients, the medicinal use of cannabis has been documented as a treatment for varied symptoms.^{4–7}

Symptoms associated with HIV occur as both direct and indirect consequences of the disease process and as a side effect of the antiretroviral drugs used in the treatment of the disease. These symptoms include nausea and vomiting, pain (e.g., in a nerve distribution), reduced appetite, weight loss, headaches, diarrhea, constipation, anxiety, and depression. Flu-like symptoms and severe myalgia can result directly

from seroconversion early in the disease. Central pain and peripheral neuropathy can occur as a result of viral-mediated neurotoxicity, secondary to either mitochondrial damage, demyelination, or low B₁₂ levels, all of which have been observed in patients with HIV. The inflammation that occurs as a result of the mitochondrial damage can result in HIV-related encephalopathy or HIV-related colitis. Symptoms may also occur secondary to infections or tumors, which have resulted from HIV-related immunosuppression. Examples of this include nausea and dysphagia from esophageal candida, or pain from a gastrointestinal lymphoma. Symptoms commonly occurring as a side effect of HIV treatment include renal colic from nephrolithiasis associated with the protease inhibitor, indinavir; painful peripheral neuropathy from use of stavudine, a nucleoside analogue; or sleep disturbances from the non-nucleoside inhibitor, efavirenz. Thus, a wide range of symptoms can significantly affect the quality of life of individuals living with HIV as a long-term chronic infection.^{8,9}

It has been recognized that cannabinoids such as delta-9-tetrahydrocannabinol (THC), which is now available as a licensed pharmaceutical preparation, can improve appetite and relieve nausea and vomiting.¹⁰ Cannabis plant material not only contains THC but also other cannabinoids, such as cannabidiol (CBD), that may mitigate psychotic mood effects of THC.¹¹

The aim of this study was to measure the patterns and prevalence of cannabis use in patients presenting at a large HIV clinic and to evaluate its beneficial or detrimental effect on symptom control.

Methods

Subjects

Following Ethics Committee approval, HIV-positive patients were recruited into an anonymous cross-sectional questionnaire survey using a single center. The outpatient clinic provided a walk-in service as well as pre-arranged appointments, including pharmacy and phlebotomy sections. All patients entering the clinic were asked to verbally consent to participate in the study. Written consent was not obtained in order to protect patient anonymity. The number of patients who refused to take part

was recorded. Many patients were regular clinic users, had discussed their symptoms with HIV and pain specialists, and were able to distinguish between the various types of pain described on the questionnaire. A researcher was available to answer questions (e.g., on the interpretation of words). Patients completed the questionnaire while waiting and confidentiality was maintained by enumerating the papers without patient identification.

Questionnaire

The questionnaire was piloted to refine its content, word use, and format and then issued to patients attending the clinic. The questionnaire (see Appendix) was designed to contain close-ended questions with defined yes/no or categorical responses. It was divided into sections. The first included demographics (age, sex, number of years with HIV) and a validated scale to measure degree of disability described by Sharrack and Hughes.¹² The second had specific questions concerning the patient's use of cannabis medically to treat symptoms of HIV. These symptoms included those directly related to HIV plus those resulting from their medication. Those who did not use cannabis for medicinal purposes, including those who used it solely for recreation, were not required to continue completing the questionnaire, although their demographic details were recorded. The next section included questions relating to frequency, patterns, and reasons for cannabis use. Then in tabular form, a range of symptoms were listed (Table 1), and against

Table 1
Order of Symptom List in Questionnaire as Scored by Patients for Benefit or Detriment

Lack of appetite
Feeling sick (i.e., nausea)
Tremor
Depression
Anxiety
Weight loss
Weakness
Tiredness
Vision dimness
Slurred speech
Memory loss
Constipation
Headaches
Diarrhea
Pain in muscles
Nerve pain
Tingling
Numbness

each one, the patient was invited to score benefit or detriment as 'much better,' 'little better,' 'unchanged,' 'a little worse,' and 'much worse'. For the symptoms of pain and sensory changes, the questionnaire also contained 'body diagrams', that is, pain maps, so that the patients could mark where they identified their nerve or muscle pain, tingling and numbness.

Analysis

Data from the questionnaires were entered into an Access database (Windows 98 version) and analyzed using the Statistical Package for Social Sciences (SPSS 11.5, SPSS Inc., Chicago). Categorical data comparing the sex differences between the two groups and symptom severity were analyzed using the Fisher's exact test. Because the distribution of age and the number of years with HIV were not normal and had some outliers, the differences in these variables between the two groups were analyzed using the Mann-Whitney U test. Both simple frequency analysis and the sign test were used in assessing the percentage improvement or deterioration in symptoms.

Results

A total of 523 questionnaires were completed from 565 patients approached. This was a 93% response rate. Of those who completed the study, 143 (27%) used cannabis to treat symptoms associated with HIV.

Physical Data

The sex, age, years with HIV, disability, and cannabis user status are shown in Tables 2 and 3.

About 1 in 10 patients were female and few were severely disabled in this outpatient setting. Compared with females, males were statistically significantly likely to be cannabis users ($P < 0.01$) and those who had the disease for longer and were more disabled were also more likely to be users ($P < 0.01$).

When nerve pain was reported on the pain map, it was experienced mainly in the legs, and less in the feet and hands (27, 19, and 15 patients, respectively). Muscle pain was predominantly localized to the legs, but also to the lower back, shoulders and neck (46, 19, and 19 patients, respectively). Tingling and numbness was experienced in the periphery, with the hands and feet being affected (34 and 26 patients, respectively).

Patient Choice of Route and Timing for Symptom Control

Of the 143 patients who had used cannabis to treat HIV symptoms, 107 (75%) were current users. Within the whole group, smoking was the single route of administration in 101 (71%), and was combined with eating and drinking the plant in 39 (27%); ingestion was the only route in 3 (2%). On a day that cannabis was used, 50 patients (36%) would take it once, 33 (23%) twice, 23 (16%) three times, and 35 (24%) four or more times. Most patients (79/143 [55%]) were daily users and 15 (11%) used it weekly. Others reported intermittent administration during the week. Thus, all patients reported using cannabis at least once a week to relieve symptoms.

Throughout the day, the majority of patients (91/143 [64%]) took cannabis after 6 p.m. and

Table 2
Demographic Data, Disability Scores, and the Number of Patients Using Cannabis to Treat Symptoms

	Females $n = 43$ (8%)	Males $n = 480$ (92%)	All Subjects $n = 523$

^aMedian [IQR] (range).

before midnight. However, an overlapping group (66/143 [46%]) also reported use at any time if necessary. The reasons for taking the cannabis at these times were reported in a structured format, as detailed in Table 4. A number of reasons related to the time of administration, not least of which was recreational use together with medicinal use. Relief of symptoms of anxiety and depression was common, as was general symptom relief. The reported use for relaxation may reflect the time at which it was taken, namely, during the evening.

Effect on Symptoms

A lack of appetite was the most frequent symptom reported (Table 5) and 97% experienced improvement with cannabis use. Pain was the next most frequent, being present in 45% of patients and improved in 94% of them. The collective results demonstrated statistically significant improvement in half or more patients in symptoms of nausea, anxiety, nerve pain, depression, tingling, numbness, weight loss, headaches, tremor, constipation, and tiredness. Symptoms that were not improved included weakness and slurred speech, and statistically significant memory deterioration was recorded in 47% of users.

Discussion

The demographic characteristics of our cohort of patients (male:female, 11.2:1) is comparable with the UK population of HIV-positive

patients, which has a male:female ratio of 11.5:1. In addition, their ages and duration of HIV disease were comparable with the general UK data for such patients.¹³ Our sample of 523 patients has the highest response rate and is the largest study of its kind. It compares with previous studies, which have had samples ranging from 72 subjects⁷ to 442.⁶ This detailed report of cannabis use for symptom control in a clinically significantly large group of patients can form the basis for more extensive investigations using purified and standardized cannabis extracts.

Despite the fact that cannabis is still illegal, its use for medical purposes appears to be quite widespread. A report from the British Medical Association¹⁴ stated “many normally law abiding citizens—probably many thousands in the developed world” use cannabis illegally for therapy. Wesner¹⁵ reported from an anonymous mail survey of 123 HIV-positive patients in Honolulu that 36.9% of them used cannabis for therapeutic reasons. Approximately one-quarter of 228 HIV-positive men in the Sydney Men and Sexual Health study reported therapeutic use of cannabis.¹⁶ Thirty-two percent (32%) of 72 patients at a clinic in Alabama reported the medical use of marijuana.⁷ These results are comparable to a more recent study carried out in Northern California, in which 33.3% of HIV-positive patients who responded to an anonymous mailed questionnaire used cannabis to treat symptoms associated with their disease.⁶ Our study expanded these findings in a large city clinic population by focusing on the patient’s perceived improvement or worsening of symptoms for which cannabis was considered the origin.

The large number of patients using cannabis as medicinal therapy for symptoms related to HIV raises a number of issues. First, patients are being left with no alternative but to use a non-medical source of supply, which has the

Note: In ranked order of those demonstrating improvement (recorded as % much better, little better) in comparison to those recorded with no change, little worse, or much worse. The *P*-value in the last column is the exact 2-sided *P*-value for the sign test of no change.

potential for heterogeneity of active cannabinoids, toxic contaminants, inappropriate dose, and drug misuse. Second, if part of the plant material has therapeutic efficacy, the source of this material should be standardized and subjected to clinical trials so that safe and effective use is advocated. Third, the patient is unlikely to divulge cannabis use to their medical team, so that potential drug interactions with prescribed antiretroviral medications may be occurring. In addition, in this study, the number of purely recreational users was not determined so that the overall incidence of drug interactions may be far greater. The type of drug interactions to be considered include loss of cognitive function because it is well-recognized that this is an effect of both cannabis¹⁷ and antiretroviral drugs such as efavirenz.¹⁸ Certainly, the loss of memory reported by these patients is of clinical significance, particularly in the methodological design of clinical trials, and if it is the result of combining preparations, this may be investigated using known standardized cannabinoid therapies. This approach may be one way to reduce additive effects and prevent patients being subject to the effects of unpredictable concentrations of illicit drugs.

The positive responses to symptom control recorded in this study, as exemplified in Table 5, suggest that it is highly probable that cannabinoid medications have a medicinal role in this condition for a number of reasons. First, they

are reported by patients to improve appetite, reduce weight loss, and alleviate nausea.^{19–23} These effects have been recognized and synthetic THC (dronabinol) is licensed for use in the U.S. for this indication. However, no direct comparison has been attempted with a cannabis plant extract that will contain not only THC but also other cannabinoids, of which CBD is reputed to reduce the adverse effects of THC.²⁴ Secondly, pain relief appears to be significant in cannabis users, thereby suggesting a potential target for investigation in the use of cannabinoids as analgesics in HIV patients.

Patients have reported various forms of pain with HIV, such as muscular and neuropathic pain, and these were characterized in the pain maps drawn by the patients. Currently available analgesic drugs have limited efficacy, particularly for neuropathic pain.²⁵ Clearly, there is a need to develop alternative analgesic agents, such as cannabinoids, to improve the choice of therapies. There is animal evidence that cannabinoids have analgesic effects that operate in models of hyperalgesia and allodynia, both indicators of neuropathic pain states,^{26,27} and the discovery of the endogenous cannabinoid system has led scientists to explore the role of endocannabinoids in chronic pain models.^{28,29} However, in clinical practice the choice of natural or synthetic phyto- or endo-cannabinoids for clinical trials is very limited. There have been several anecdotal and clinical trial reports that

cannabis plant extract and synthetic THC and related analogues produce pain relief in humans.³⁰⁻³³ For this present select group of HIV patients, given the reported symptoms experienced using cannabis plant material, there is a strong concern from the medical community managing these patients to limit adverse side effects from self-administered drugs and to provide cannabinoids in a formulation and dosing schedule that avoids harm to the patient. For example, there is strong evidence that the smoking route of administration of cannabis is not safe long-term because of the carcinogenic properties of a cannabis cigarette.³⁴

A pattern of cannabis use emerges from this study that is regular, ongoing, and treats the symptoms of HIV patients to their satisfaction. Given the sedative properties of cannabis, it is important to assess whether evening dosing for cannabinoid therapies is more useful or appropriate. Its sedative effects may be helpful at this time but none were reported as predominant. Presumably there is tolerance to these types of effects.²⁹ More importantly, reduction of pain, anxiety, and gastrointestinal upset appears to be the constellation of symptom control sought by these HIV patients, as shown in Tables 4 and 5.

In relation to HIV, there have been anecdotal reports³⁵ of patients who were already recreational users of cannabis reporting that it improved certain symptoms, such as loss of appetite and nausea, as well as pain and general well being. A small, uncontrolled study of 10 symptomatic AIDS patients reported that dronabinol might be effective in reducing nausea and increasing appetite.¹⁰ Where patients are also medicating with antiretroviral agents, the combination of cannabis and protease inhibitors may be detrimental by altering viral loads. Thus, the effect of smoking on the viral load of HIV-infected patients was investigated by a short-term randomized placebo controlled trial.³⁶ No adverse effects of either therapy were measured with respect to RNA levels, CD4⁺ and CD8⁺ cell counts, or protease inhibitor levels. This brief trial suggests that there are no obvious harmful effects, but these need to be determined using an appropriate route of drug administration and a longer-term study.

There is accumulating evidence that suggests that cannabinoids have therapeutic applications in a variety of neurodegenerative diseases,

such as multiple sclerosis,^{37,38} Huntington's disease,³⁹ and brain injury.⁴⁰ So far, in terms of HIV, the evidence for therapeutic efficacy of cannabinoids is still mainly anecdotal. We have sought to establish if an improvement from cannabis use, albeit self-administered and not standardized, is seen in symptoms such as pain, appetite, and nausea in a large sample of HIV patients. To do this, we expanded on previous research by determining specifically the variety and groups of symptoms that patients select to modify by their use of cannabis. We also secured a therapeutic timetable in order to predict the frequency of drug administration for the patient's selected symptoms. These results will be important in the design of a randomized, placebo-controlled clinical trial comparing conventional treatments to cannabis for symptoms of HIV.

Appendix **Questionnaire**

HIV Symptoms and the Use of Cannabis

This questionnaire is designed to establish the current use of cannabis for the management of symptoms from HIV in our patients. We would be grateful for some personal details (but not details of identification) and your past and present experiences (if any) with cannabis.

Please complete the following:

General Details:

Sex: MALE/FEMALE (encircle as necessary)

Age:years

Number of years with HIV:

Degree of Disability

Please choose ONE of the following statements which best describes how severely you are affected by the HIV disease, and how it affects your activities of daily living:

- None
- Mild symptoms
- Moderate symptoms—not requiring help from others
- Moderate symptoms—requiring help from others
- Severe symptoms—almost total loss of function
- Total loss of function

Cannabis use

Have you ever used cannabis to relieve your symptoms (as listed below) of HIV? Y/N

If “NO” we thank you for answering this questionnaire and you are not required to complete any more of the questionnaire.

If “YES” please complete the following details:

How do you take the cannabis?

- Smoke Y/N
- Drink Y/N
- Eat Y/N
- Other (state).....

How many years have you used cannabis relieve some of your symptoms?.....years

How many times a day do you use cannabis?.....

How many days a week do you take cannabis?.....

When do you take cannabis: [*Please choose only ONE*]

After 6 pm and before midnight	Y/N
Between 6 am and midday	Y/N
Midday to 6 pm	Y/N
At any time when necessary	Y/N
Just before going to bed	Y/N
At regular intervals during the day	Y/N

Do you take cannabis to: [*You may choose MORE THAN ONE*]

Relieve symptoms	Y/N
Aid relaxation	Y/N
Relieve anxiety	Y/N
Relieve depression	Y/N
Reduce symptom frequency	Y/N
Obtain energy	Y/N
To get a 'high' / Recreational	Y/N

For each symptom in the left-hand column state if the symptom is now present. Then mark for each symptom, whether past or present, its response to cannabis use, i.e., better or worse.

Diagrams are provided below for the question relating to sites of pain, etc.

Symptom (past or present)	Present	Response to cannabis <i>[Please tick ONE box]</i>				
	Y/N	Much better	Little better	Not changed	Little worse	Much worse
Lack of appetite						
Feeling sick, i.e., Nausea						
Anxiety						
Depression						
Tremor						
Headaches						
Weight loss						
Weakness						
Tiredness						
Vision dimness						
Slurred speech						
Tremor						
Memory loss						
Constipation						
Diarrhea						
Muscle pain (please mark on Diagram 1 where you are affected by this)						
Nerve pain (please mark on Diagram 2 where in your body this is)						
Tingling (draw on Diagram 3 where this is)						
Numbness (draw on Diagram 4 where this is)						
Others (please state)						

N.B. Please do not forget to fill in the body diagrams on the next page if you suffer from MUSCLE PAIN, NERVE PAIN, TINGLING OR NUMBNESS.

Once completed please hand over this questionnaire to the reception desk.

THANK YOU.

Effectiveness of Cannabidiol Oil for Pediatric Anxiety and Insomnia as Part of Posttraumatic Stress Disorder: A Case Report

Scott Shannon, MD, ABIHM; Janet Opila-Lehman, ND

Perm J 2016 Fall;20(4):16-005

E-pub: 10/12/2016

<http://dx.doi.org/10.7812/TPP/16-005>

ABSTRACT

Introduction: Anxiety and sleep disorders are often the result of posttraumatic stress disorder and can contribute to an impaired ability to focus and to demonstration of oppositional behaviors.

Case Presentation: These symptoms were present in our patient, a ten-year-old girl who was sexually abused and had minimal parental supervision as a young child under the age of five. Pharmaceutical medications provided partial relief, but results were not long-lasting, and there were major side effects. A trial of cannabidiol oil resulted in a maintained decrease in anxiety and a steady improvement in the quality and quantity of the patient's sleep.

Discussion: Cannabidiol oil, an increasingly popular treatment of anxiety and sleep issues, has been documented as being an effective alternative to pharmaceutical medications. This case study provides clinical data that support the use of cannabidiol oil as a safe treatment for reducing anxiety and improving sleep in a young girl with posttraumatic stress disorder.

INTRODUCTION

Cannabidiol (CBD) oil is a naturally occurring constituent of industrial hemp and marijuana, which are collectively called cannabis. CBD oil is 1 of at least 85 cannabinoid compounds found in cannabis and is popular for its medicinal benefits. After tetrahydrocannabinol (THC), CBD oil is the second-most-abundant component of cannabis. Other names for CBD oil include CBD-rich hemp oil, hemp-derived CBD oil, or CBD-rich cannabis oil. Considered to be generally safe, CBD has been used medicinally for decades. However, CBD is not medical marijuana and should be distinguished from high-CBD strains

of medical marijuana, which do contain THC, such as “Charlotte’s Web.”

The most abundant compound in cannabis, THC is also a cannabinoid. The THC component induces the psychoactive effect, “high.” A cannabis plant has different amounts of CBD and THC depending on the strain and thus provides different recreational or medicinal effects. The cannabinoid profile of industrial hemp or medical marijuana is ideal for people looking for the medical benefits of CBD without the “high” of the THC.

The mechanism of action of CBD is multifold.¹⁻³ Two cannabinoid receptors are known to exist in the human body: CB1 and CB2 receptors. The CB1 receptors are located mainly in the brain and modulate neurotransmitter release in a manner that prevents excessive neuronal activity (thus calming and decreasing anxiety), as well as reduces pain, reduces inflammation, regulates movement and posture control, and regulates sensory perception, memory, and cognitive function.^{4,2} An endogenous ligand, anandamide, which occurs naturally in our bodies, binds to the CB1 receptors through the G-protein coupling system. CBD has an indirect effect on the CB1 receptors by stopping the enzymatic breakdown of anandamide, allowing it to stay in the system longer and provide medical benefits.⁴ CBD has a mild effect on the CB2 receptors, which are located in the periphery in lymphoid tissue. CBD helps to mediate the release of cytokines from the immune cells in a manner that helps to reduce inflammation and pain.²

Other mechanisms of action of CBD include stimulation of vanilloid pain receptors (TRPV-1 receptor), which are known to mediate pain perception, inflammation, and body temperature.⁵ In addition, CBD may exert its anti-anxiety effect by

activating adenosine receptors which play a significant role in cardiovascular function and cause a broad anti-inflammatory effect throughout the body.⁵ At high concentrations, CBD directly activates the 5-HT1A serotonin receptor, thereby conferring an antidepressant effect.⁶ Cannabidiol has been found to be an antagonist at the potentially new third cannabinoid receptor, GPR55, in the caudate nucleus and putamen, which if stimulated may contribute to osteoporosis.⁷

Since the 1940s, a considerable number of published articles have dealt with the chemistry, biochemistry, pharmacology, and clinical effects of CBD.⁸ The last decade has shown a notable increase in the scientific literature on CBD, owing to its identification for reducing nausea and vomiting, combating psychotic disorders, reducing inflammation, decreasing anxiety and depression, improving sleep, and increasing a sense of well-being.⁹⁻¹² Findings presented at the 2015 International Cannabinoid Research Society at its 25th Annual Symposium reported the use of CBD as beneficial for kidney fibrosis and inflammation, metabolic syndrome, overweight and obesity, anorexia-cachexia syndrome, and modification of osteoarthritic and other musculoskeletal conditions.¹³⁻¹⁶

Although studies have demonstrated the calming, anti-inflammatory, and relaxing effects of CBD, clinical data from actual cases is minimal. This case study offers evidence that CBD is effective as a safe alternative treatment to traditional psychiatric medications for reducing anxiety and insomnia.¹⁷

CASE PRESENTATION

A ten-year-old girl presented in January 2015 for a reevaluation of behaviors related to her diagnosis of posttraumatic stress disorder (PTSD) secondary to sexual

Scott Shannon, MD, ABIHM, is an Assistant Clinical Professor of Psychiatry at the University of Colorado School of Medicine in Fort Collins. E-mail: scottshannon@cowisp.net. Janet Opila-Lehman, ND, is a Naturopathic Physician at the Wholeness Center in Fort Collins, CO. E-mail: j.opila.lehman@gmail.com.

abuse. Her chief issues included anxiety, insomnia, outbursts at school, suicidal ideation, and self-destructive behaviors. Her grandmother, who has permanent custody of the patient and her younger brother, accompanied her.

Our patient had been seen for an initial evaluation in January 2012 and received a diagnosis of PTSD secondary to sexual abuse on the basis of her history, clinical observations, and behaviors (Table 1).

Her father had died 6 months earlier in a motor vehicle accident, and our patient's maternal grandparents became her permanent guardians. Before her father's death, our patient had no supervision from her father and very little supervision from her mother. An 11-year-old boy had molested her when she was 3 years old. Her medical history included her mother having methadone addiction, alcoholism, bipolar disorder, and depression. Her mother used

marijuana her entire pregnancy with the girl. The patient presented in January 2012 as displaying aggressive, disobedient, impulsive, and sexually inappropriate behaviors. She also demonstrated low self-esteem and anxiety and had poor sleep (restless, interrupted, and unable to sleep alone).

Workup during 2012 included laboratory studies, which ruled out a thyroid dysfunction and an iron or vitamin D deficiency. The patient was started on a

Table 1. Timeline

Date	Presentation	Medications	Supplements	Other
January 31, 2012	New evaluation: 7.5-year-old girl. History of sexual abuse and neglect. Issues: Insomnia, sexual behaviors. Diagnosis: PTSD secondary to sexual abuse.	None	Melatonin, 1 mg/night	February 14, 2012, laboratory values: TSH, 2.46 mIU/L (reference range, 0.47-4.68 mIU/L); ferritin: 21 ng/mL (reference range, 10-150 ng/mL). February 16, 2012, laboratory values: Vitamin D ₃ : 39 ng/mL (reference range, 20-50 ng/mL)
February 20, 2012	Sleeping 2-3 hours/night. Started counseling; Cooperative and good behavior at counseling session. Anxious, traumatized.	Clonidine, 0.05 mg (half tablet) at bedtime	Inositol, 3 g 3 times/d; EPA fish oil, 500 mg/d	Eye movement desensitization and reprocessing therapy recommended
February 22, 2012	Did not do well with clonidine because of hallucinations, so she discontinued that treatment. Behavior still very rough; sleep poor.	Started imipramine therapy, 25 mg at bedtime		March 7, 2012: ECG was normal
August 8, 2012 ^a	Good summer. In play therapy. Overall better sleep and energy with imipramine therapy. Patient's 6-year-old brother also now in therapy.	Imipramine, 25 mg at bedtime		
January 21, 2015	Returned for evaluation and treatment after 3 years. Suicidal ideation; cut self on leg; defiant and stubborn. Had psychotherapy 3 years straight twice a month. Sleeps with brother; can't sleep alone.	Off all medications for past 18 months	Melatonin, 5 mg; St John's wort, 450 mg twice/d; magnesium, 300 mg/d; diphenhydramine, 25 mg/night	
February 16, 2015	Hard to manage. Has outbursts at school.		Magnesium and St John's wort: stopped treatment; EPA fish oil, 750 mg/d; diphenhydramine, 25 mg/night	February 11, 2015: Normal cortisol and DHEA levels
March 16, 2015	Better overall. Started animal-assisted therapy.		EPA fish oil, 750 mg/d; diphenhydramine, 25 mg/night	Started a regimen of CBD oil, 25 mg (1 capsule)/d at 6 pm
April 14, 2015	Sleeping better with CBD treatment. Getting biofeedback. Has stomachaches. Mood is more at ease.		EPA fish oil, 750 mg/d; diphenhydramine, 25 mg/night	CBD oil, 25 mg (1 capsule)/d at 6 pm
May 26, 2015	"Ghosts" waking patient up at night.		EPA fish oil, 750 mg/d	CBD oil, 25 mg (1 capsule)/d at 6 pm
July 22, 2015	Sleeping better; able to sleep in own room 3-4 nights/wk.		EPA fish oil, 750 mg/d	CBD liquid, 12 mg (in 4 sublingual sprays)/night; 12 mg more (in 4 sublingual sprays) during the day as needed for anxiety, typically 3 or 4 times/wk
August 24, 2015	Sleeping well. Handling school well.		EPA fish oil, 750 mg/d	CBD oil, 25 mg (1 capsule)/night; CBD liquid, 6-12 mg (in 2-4 sublingual sprays) as needed for anxiety, typically 2 or 3 times/wk

^a There were additional visits in 2012 with no substantial changes.

CBD = cannabidiol; DHEA = dehydroepiandrosterone; ECG = electrocardiogram; EPA = eicosapentaenoic acid; PTSD = posttraumatic stress disorder; TSH = thyroid stimulating hormone.

regimen of 1 mg/night of melatonin, which helped her sleep duration. Three grams of inositol 3 times a day and 500 mg/d of eicosapentaenoic fish oil were also helpful in reducing her anxiety. A trial of clonidine was implemented, which resulted in hallucinations and thus was discontinued. The patient was switched to a regimen of 25 mg of imipramine at bedtime to decrease her anxiety, which appeared to be helpful. Counseling sessions were started. The patient continued psychotherapy for 3 years, but she was not seen again in our clinic until the return visit in January 2015, when she was not receiving any of her medications and supplements.

CBD oil can be an effective compound to reduce anxiety and insomnia secondary to PTSD.

At the patient's return in January 2015, she demonstrated the same prominent symptoms as at her initial presentation. At that time, the initial treatment included the following supplements and medications to assist with her sleep and anxiety: melatonin, 5 mg/night; magnesium, 300 mg/d; and diphenhydramine (Benadryl), 25 mg/night. Our patient demonstrated slight gains but was still having outbursts at school and was reportedly difficult to manage at home. In addition, her underlying anxiety continued.

Cannabidiol oil was explored as a potential additional treatment to help her insomnia and anxiety, but we deferred for two months while we waited for a response from other interventions. The grandmother preferred reducing the pharmacologic load given her granddaughter's failure to respond long term to psychiatric medications.

In March 2015, CBD oil was recommended as a potential additional treatment to help her insomnia and anxiety, and her grandmother provided full informed consent. Our patient was administered the Sleep Disturbance Scale for Children¹⁸ and the Screen for Anxiety Related Disorders (SCARED)¹⁹ before taking the CBD oil and each month afterward for the next 5 months. Test scores on the Sleep Disturbance Scale for Children and Screen for

Anxiety Related Disorders demonstrated an improvement (Table 2).

A trial of CBD supplements (25 mg) was then initiated at bedtime, and 6 mg to 12 mg of CBD sublingual spray was administered during the day as needed for anxiety. A gradual increase in sleep quality and quantity and a decrease in her anxiety were noted. After 5 months, the patient was sleeping in her own room most nights and handling the new school year with no difficulties. No side effects were observed from taking the CBD oil.

DISCUSSION

Studies repeatedly recognize the prevalence of an anxiety-provoked sleep disorder after a traumatic experience.²⁰ Our patient was definitely experiencing this phenomenon, which was aggravated by daily stressful activities.

The main finding from this case study is that CBD oil can be an effective compound to reduce anxiety and insomnia secondary to PTSD. A review of the literature suggests some benefits from the use of CBD because of its anxiolytic and sleep-inducing effects.⁹ Animal studies support use of this treatment and report that "CBD may block anxiety-induced [rapid eye movement] sleep alteration via its anxiolytic effect on the brain."²¹

The strength of this particular case is that our patient was receiving no pharmaceutical medications (other than non-prescription diphenhydramine) but only nutritional supplements and the CBD oil to control her symptoms. Her scores on the sleep scale and the anxiety scale consistently and steadily decreased during a period of 5 months (see Table 2). She

was ultimately able to sleep through the night most nights in her own room, was less anxious at school and home, and displayed appropriate behaviors. The patient's grandmother (her caregiver) reported: "My granddaughter's behaviors are definitely better being on the CBD. Her anxiety is not gone, but it is not as intense and she is much easier to be around. She now sleeps in her own room most of the time, which has never happened before."

Further study will need to be conducted to determine the permanency of our patient's positive behaviors and how long she will need to continue taking the CBD oil. We do not have a reasonable foundation to recommend dosing from the scientific literature. However, in our experience, this supplement given 12 mg to 25 mg once daily appears to provide relief of key symptoms with minimal side effects. Our patient did not voice any complaints or discomfort from the use of CBD. We routinely asked about headache, fatigue, and change in appetite or agitation in addition to conducting a routine psychiatric evaluation. Although CBD is considered generally safe,¹⁷ the long-term effects are yet to be studied.

The ultimate goal is to gradually taper her off the use of CBD oil and transition our patient into lifelong coping strategies such as yoga, meditation, and various other therapeutic activities. ❖

Marijuana and Medicine

Scientific data indicate the potential therapeutic value of cannabinoid drugs, primarily [tetrahydrocannabinol], for pain relief, control of nausea and vomiting, and appetite stimulation; smoked marijuana, however, is a crude [tetrahydrocannabinol] delivery system that also delivers harmful substances.

Who Are Medical Marijuana Patients? Population Characteristics from Nine California Assessment Clinics[†]

Craig Reinerman, Ph.D.*; Helen Nunberg, M.D., M.P.H.**;
Fran Lanthier, M.A.*** & Tom Heddleston, M.A.***

Abstract— Marijuana is a currently illegal psychoactive drug that many physicians believe has substantial therapeutic uses. The medical literature contains a growing number of studies on cannabinoids as well as case studies and anecdotal reports suggesting therapeutic potential. Fifteen states have passed medical marijuana laws, but little is known about the growing population of patients who use marijuana medicinally. This article reports on a sample of 1,746 patients from a network of nine medical marijuana evaluation clinics in California. Patients completed a standardized medical history form; evaluating physicians completed standardized evaluation forms. From this data we describe patient characteristics, self-reported presenting symptoms, physician evaluations, other treatments tried, other drug use, and medical marijuana use practices. Pain, insomnia, and anxiety were the most common conditions for which evaluating physicians recommended medical marijuana. Shifts in the medical marijuana patient population over time, the need for further research, and the issue of diversion are discussed.

Keywords— anxiety, cannabis therapeutics, insomnia, medical marijuana, pain

Medicinal preparations containing marijuana (cannabis) were widely used in many societies for centuries. Dr. William O'Shaughnessy introduced it as a modern medicine in Europe in 1839. Marijuana was

prescribed for therapeutic use in American medical practice for a variety of conditions from the mid-nineteenth century into the twentieth. Marijuana was admitted to the *United States Pharmacopoeia* in 1850 and listed in the *National Formulary* and the *US Dispensatory*. Major pharmaceutical companies including Lilly, Burroughs-Wellcome, and Parke-Davis produced cannabis-based therapeutic agents (Brecher et al. 1972).

[†]The authors thank the medical marijuana patient-applicants for providing the data, the RAND Corporation for funding data collection and data set construction, MediCann for administrative support, the Rosenbaum Foundation for financial support for this research, and Lester Grinspoon and anonymous referees for helpful comments. An earlier version of this article was presented at the 59th Annual Meeting of the Society for the Study of Social Problems, San Francisco, August 9, 2009.

In 1936, the Federal Bureau of Narcotics advocated a law prohibiting its use, which Congress passed in 1937, against the advice of the American Medical Association (Grinspoon & Bakalar 1993:9–11). This law, along with increased prescribing of aspirin and barbiturates, pushed cannabis out of the *United States Pharmacopoeia* and common medical practice by 1942.

After nonmedical cannabis use spread in the 1960s, the number of Americans reporting lifetime prevalence

increased sharply. Recent estimates from the National Survey on Drug Use and Health show that 102,404,000 Americans have used this drug, 41% of the population aged 12 and over, or about half the adult population (SAMHSA 2010). This widespread use led to a gradual rediscovery of the therapeutic uses of cannabis, albeit largely without physician involvement.

Alongside the spread of nonmedical use, in 1964 scientists determined the precise chemical structure of delta-9 tetrahydrocannabinol (THC), thought to be the most significant psychoactive ingredient in cannabis (Gaoni & Mechoulam 1964). This stimulated research in the clinical pharmacology of cannabinoids. Many physicians in clinical practice also recognized the therapeutic potential of cannabis (Irvine 2006; Charuvastra, Freidmann & Stein 2005), specifically, for example, for pain (Woolridge et al. 2005), as an antiemetic for chemotherapy patients (Doblin & Kleiman 1991), or for symptoms of AIDS (Abrams et al. 2003). More recently a broader medical literature documenting the therapeutic properties of endogenous cannabinoids has developed (e.g., Nicoll & Alger 2004; Lehmann et al. 2002; Hall, Degenhart & Currow 2001). Numerous case reports in the medical literature also have suggested that cannabis has therapeutic potential for a variety of conditions. But rigorous experimental research that might determine more precisely the therapeutic efficacy of cannabis for specific conditions has been blocked by the Drug Enforcement Administration (see Zeese 1999; *Alliance for Cannabis Therapeutics v. Drug Enforcement Administration* 1994).

This combination of increasing therapeutic use and federal government opposition ultimately led to passage of new state laws providing for the medical use of cannabis upon physician recommendation. Since 1996, 15 U.S. states and the District of Columbia have passed such laws: California, Alaska, Oregon, Washington, Nevada, Colorado, Maine, Montana, Michigan, and Washington, DC by ballot initiative; Rhode Island, New Mexico, Vermont, Hawaii, and New Jersey by state legislation.

The first of these laws was California's Proposition 215, the Compassionate Use Act, passed in 1996 (*San Francisco Chronicle* 1996). This act made it legal under state law for patients to possess and use cannabis if recommended by their physicians. Numerous medical and scientific associations endorsed medical use of cannabis and/or supported further research into its therapeutic potential. These included the American College of Physicians (2008), the American Public Health Association (1995), the British Medical Association (1997), the Canadian Medical Association (2005), and the Institute of Medicine of the National Academy of Sciences (1999).

Such elections and endorsements notwithstanding, the Bush Administration's Office of National Drug Control Policy threatened to revoke the licenses of physicians who recommended cannabis to patients. One physician

challenged this policy and the U.S. Court of Appeals ruled (in *Conant v. Walters*) in 2002 that it unconstitutionally infringed physicians' First Amendment rights to freedom of speech with their patients (McCarthy 2004). Subsequent legislation and case law have left medical marijuana (MM) patients and their physicians in legal limbo:

- In 2003, the California legislature passed SB 420 to provide specific implementation guidelines for Proposition 215, including how counties should handle MM patient ID cards.
- Most drug law enforcement is done by local police who enforce state, not federal, drug laws. In 2005, The California Attorney General ruled that Proposition 215 is the legitimate will of the voters and is therefore valid under the California Constitution for purposes of state law enforcement. He advised the Highway Patrol and other state law enforcement agencies that under California law MM patients were legally entitled to possess and use cannabis for therapeutic purposes (Hoge 2005).
- In 2006, Bush administration Attorney General Gonzales sought to invalidate state MM laws, and the U.S. Supreme Court ruled (*Gonzales v. Raich* 2006) that the Compassionate Use Act—its legitimate electoral provenance notwithstanding—neither supersedes nor invalidates federal laws that prohibit marijuana use (see Mikos 2009 for a legal analysis of the states' neglected power to legalize behavior that is criminalized under federal law).
- In 2008 the Supreme Court denied without comment an appeal by two California counties that had refused to implement Proposition 215 (*County of San Diego v. San Diego NORML* 2008), thereby letting stand a lower court ruling that upheld SB 420's provisions regarding counties issuing MM identification cards.
- In 2009, Attorney General Eric Holder issued a policy stating that federal drug control agencies would no longer raid MM dispensaries if they operated within state and local laws (Moore 2009).
- That policy notwithstanding, the DEA has continued to raid MM dispensaries in California into 2011 (e.g., Blankstein 2009).

Within this grey area between conflicting state and federal laws, the number of patients who have received recommendations for medical marijuana from physicians has continued to grow, albeit by how much remains unknown. Over 1,000 MM dispensaries, delivery services, and cooperatives are said to be operating in California to meet the demand (NORML 2007). A rough estimate of the number of MM patients in California can be extrapolated from Oregon figures. Unlike California's Compassionate Use Act, Oregon's MM law set up an Oregon Medical Marijuana Program that requires centralized record keeping. As of July, 2009, some 2,983 Oregon-licensed physicians had approved 20,307 applications for MM (Oregon

Department of Human Services 2008). The population of California is 9.7 times that of Oregon (U.S. Census 2007), which yields a crude estimate of 196,978 MM patients in California. This is likely an underestimate because the California statute affords greater latitude to physicians regarding the conditions for which they can recommend MM (“... any other illness for which marijuana provides relief”). Americans for Safe Access (2008), a MM patient advocacy group, has estimated that there are well over 200,000 physician-sanctioned MM patients in California.

Despite their growing numbers, however, the ambiguous legal status of MM patients renders them a half-hidden population whose characteristics are not well documented, with the partial exception of the San Francisco Bay Area (O’Connell & Bou-Matar 2007; Reiman 2007a). Medical marijuana will likely continue to be a contentious issue, but across fifteen states and the District of Columbia several hundred thousand people are using marijuana as a medicine recommended by physicians, and yet little is known about them as a patient population.

We intend this study as a modest contribution toward filling this gap. It presents data on the demographic characteristics, presenting symptoms, physician evaluations, conventional treatments tried, and MM use practices of patients from a network of MM assessment clinics in California.

METHODS

These data were drawn from 1,746 consecutive admissions to nine MM assessment clinics operating in California in July, August, and September 2006. These assessment clinics are not dispensaries and are not connected to dispensaries. They were located throughout the state—in the north and south, coast and central valley, and large and small cities: Modesto, Oakland, Sacramento, Hollywood, San Diego, Santa Cruz, Ukiah, San Francisco, and Santa Rosa. They charged \$100 to \$125 for an assessment. At the time our sample was drawn, these assessment clinics had evaluated over 54,000 MM patients. Without a comprehensive patient database or representative household surveys, there is no way to determine precisely how representative this sample is of the overall population of MM patients. Moreover, there is a large albeit unknown number of people who use marijuana medicinally but who have not sought physician recommendations or official patient ID cards, perhaps because of the expense of the assessment.¹

Evaluating physicians interviewed potential patients and evaluated their patient medical histories for purposes of recommending MM and issuing patient identification cards under the Compassionate Use Act and SB 420. The evaluation instruments were (1) a basic patient-administered medical history questionnaire covering demographics, presenting symptoms or conditions, brief medical history,

conventional and alternative medical treatments tried, drug use history, and MM use practices; and (2) a physician evaluation form using International Classification of Diseases codes (ICD-9). Each patient received and signed an extensive informed consent form noting confidentiality, which was approved by the clinics’ IRB.

Most prior studies of MM patients are based on small, symptom-specific samples. Initially, the population of MM patients in the San Francisco Bay Area were people with HIV/AIDS and cancer (e.g., Harris, Mendelson & Jones 1998). Later, physicians began to recommend cannabis to patients with chronic pain, mood disorders and other psychiatric conditions (Gieringer 2002). The data reported here describe what is among the largest and most symptomatically and demographically diverse samples of medical cannabis patients to date (cf., O’Connell & Bou-Matar 2007).

RESULTS

As Table 1 indicates, the MM patients are three-fourths male and three-fifths White. Compared to the US Census of California, the patients in this sample are on average somewhat younger, report slightly more years of formal education, and are more often employed. The comparison also indicates that women, Latinos, and Asian Americans are underrepresented. Given the limitations of our data, we can offer only informed speculation as to why.

The underrepresentation of women may be in part an epidemiological artifact of the gender distribution of certain kinds of injuries (e.g., workplace, sports, and motorcycle accidents). It may also have to do with the double stigma women face in seeking MM—for using an illicit drug and for violating gender-specific norms against illegal behavior in general. Moreover, as with alcohol use, pregnant women and women considering pregnancy are likely to have health concerns and many may fear that MM could put them in jeopardy if discovered by child protection agencies.

Given the high poverty rate among Latinos and their concentration in the manual labor end of the occupational structure, Latinos are exposed to equal or greater risks of work-related injuries and to no less epidemiologic risk of other conditions for which MM is sometimes used. It seems likely that their under-representation has to do with the undocumented status of many Latinos in California. The undocumented often avoid contact with government agencies for fear of apprehension by law enforcement, for beyond arrest and incarceration this carries the risk of deportation. Such fears reduce the likelihood of Latinos accessing health care in general and MM in particular. Asian Americans are also underrepresented, but this may be because they have lower prevalence of marijuana use than other racial/ethnic groups and/or because they have their own venerable traditions of herbal medicine.

TABLE 1
Demographic Characteristics of California Medical Marijuana Patients Compared to California Census 2000, Age 18 and Over (n = 1746)

	MM Patients	U.S. Census 2000 – California
Female	27.1%	50.7%
Male	72.9%	49.3%
White	61.5%	59.5%

*Data not available in California Census.

African-Americans, conversely, are over-represented in this sample. This does not appear to stem from their prevalence of marijuana use, for representative national surveys show that Blacks generally do not have significantly higher prevalence of marijuana use than Whites (SAMHSA 2005). African-Americans may be more likely to seek MM for any of several reasons: because they are disproportionately poor, more often lack health insurance, are significantly less likely to be prescribed other medication for pain (Pletcher et al. 2008) or to receive treatment for cancer (Gross et al. 2008), and because African-Americans are a growing proportion of HIV/AIDS cases. Some of these same reasons may help to explain why Native Americans are also overrepresented, although their proportion of both this sample and the general population is too small to judge representativeness accurately.

In their medical history questionnaires, patients were asked "Which of the following best describe the therapeutic benefit you receive from medicinal cannabis? (Check the most important)." Patients typically reported more than one therapeutic benefit (mean = 3). Early studies showed most patients used MM to relieve symptoms of HIV/AIDS (Woolridge et al. 2005) or cancer, and it is likely that the majority of patients in our sample who reported "nausea" were cancer patients receiving chemotherapy. However, Table 2 suggests that cancer and AIDS patients are now a

TABLE 2
Patient Self-Reports of Therapeutic Benefits from Medicinal Marijuana*

*N = 1,745; patients could report more than one benefit in more than one category.

significantly smaller proportion of the total (e.g., "to relieve nausea/vomiting" 27.7%, "to improve appetite" 37.7%) and that the MM patient population has become more diverse since the Compassionate Use Act was passed in 1996 (cf. Ware, Adams & Guy 2005, on MM use in the UK, and Grotenherman 2002 on MM use in Germany).

Instead, relief of pain, muscle spasms, headache, and anxiety, as well as to improve sleep and relaxation were the most common reasons patients cited for using MM. Chronic pain also topped the list of maladies for which MM was used in another California clinical sample (Reiman 2007b).

Table 3 shows the ICD-9 diagnostic codes most frequently recorded by evaluating physicians. Pain from back and neck injuries was the most frequently coded. This appears consistent with a nationally representative Medical Expenditure Panel Survey, which found a 19.3% increase in the prevalence of spine problems between 1997 and 2005 (Martin et al. 2008). Back and neck pain was followed in frequency by sleep disorders (also increasing), anxiety/depression, muscle spasms, and arthritis. Fully half of this sample reported using MM as a substitute

TABLE 3

*N = 1746; patients could report multiple other treatments.

for prescription drugs, consistent with other studies (e.g., Reiman 2007a).

Table 4 indicates that the MM patients in the sample had tried a variety of other treatments, conventional and alternative, for the conditions for which they were seeking a MM identification card. Four in five (79.3%) reported having tried other medications prescribed by their physicians (almost half were opiates); about half (48.7%) had tried physical therapy; over a third (36.3%) had tried chiropractic; nearly one-fourth (22.3%) reported having had surgery for their condition.

Table 5 compares patient responses to the drug use questions to those in the 2006 National Survey on Drug Use and Health (SAMHSA 2007). Prevalence of tobacco

TABLE 5
Medical Marijuana Patients' Self-Reported Current Nonmedical Drug Use, Compared to 2006 National Survey on Drug Use And Health (SAMHSA 2007)

	MM Patients	NSDUH*
Tobacco	29.4%	25.0%
Alcohol	47.5	61.9
Cocaine	0.3	1.9
Methamphetamine	0.4	0.5
Heroin	0.1	0.3
Other Opiates	1.2	**

Note: Participants were asked "Do you currently use . . ."; answers are percent responding "yes." N = 1745; patients could report more than one drug. Of smokers, 65.5% used ten or less cigarettes/day; of drinkers, 58.7% used \leq one or less drinks/day.

*NSDUH figures for "past month" prevalence used as a proxy for "current use".

**Data not available in comparable form.

use was somewhat higher than in the general population, but prevalence of alcohol use was significantly lower. Many patients reported that they valued MM because it allowed them to reduce their alcohol use. It is possible that self-reports on a self-administered instrument will underestimate illicit drug use, particularly if patients felt that admitting illicit drug use could reduce their chances of obtaining a MM identification card. Rigorous assessments of the reliability of such data must await further research, but limitations aside, these data suggest low prevalence of other illicit drug use among MM patients. While it is true that the great majority of our respondents had used marijuana recreationally, in response to a separate question over two-fifths (41.2%) reported that they had *not* been using it recreationally prior to trying it for medicinal purposes.

Table 6 presents data on patients' medical marijuana use practices. Amounts used per week varied from three grams or less (40.1%) to seven or more grams (23.3%). Two-thirds (67%) reported using MM daily while one-fourth (26%) reported using less than once a week. Half (52.9%) reported using one or two times per day while one in ten (10%) reported using three or more times per day. Patients consumed MM primarily in the evenings (52.3%) or prior to sleep (56.1%). More than two in five (42.3%) reported that when they used depended on their medical symptoms. Patients ingested MM predominantly by smoking (86.1%), although one-fourth (24.4%) reported ingesting orally and nearly a fourth (21.8%) reported using a vaporizer. These latter figures suggest that at least some of the time, many MM patients are choosing modes of ingestion that reduce the perceived risk of harms from smoking (Tan et al. 2009; Hashibe et al. 2006).

TABLE 6
Medical Marijuana Use Practices

All Day	5.3% (93)
Mode of Ingestion (N = 1745)	
Smoke	86.1% (1503)
Oral Ingestion	24.4% (426)
Vapor	21.8% (380)
Topical	2.8% (49)
Amount Used per Week (N = 1431)	
0–3 Grams	40.1% (574)
4–7 Grams	36.5% (523)
>7 Grams	23.3% (334)

*Total n = 1745, but N's vary across questions because patients could choose more than one response and because not all responded to each question.

DISCUSSION

Rediscovery of Medicinal Utility and Diversifying Patient Population

Compared to earlier studies of MM patients, these data suggest that the patient population has evolved from mostly HIV/AIDS and cancer patients to a significantly more diverse array. The diffusion of marijuana as a medicine may have been slower than that of other medicines in conventional clinical practice because the flow of information from physician to patient is impeded by MM's ambiguous legal status. Thus, information about the potential therapeutic utility of cannabis is spread mostly via word of mouth and other informal means. This suggests that the patient population is likely to continue evolving as new patients and physicians discover the therapeutic uses of cannabis. Ironically, this trend toward increasing therapeutic uses is bringing marijuana back to the position it held in the U.S. Pharmacopeia prior to its prohibition in 1937.

Further Research

Like other medicines, marijuana's therapeutic efficacy varies across conditions and patient groups. This variation seems more likely when supplies remain illicit because standardized dosages or other quality controls are more difficult to achieve. To gain maximum therapeutic potential across the growing range of conditions for which MM is being recommended, more systematic research is needed. Longitudinal, case control, and double-blind studies are required to rigorously assess marijuana's therapeutic efficacy for specific patient groups, conditions, and diseases. With regard to shifts in the patient population, it also would be very useful to have follow-up studies of patients accessing the assessment clinics in our sample and others drawn from similar assessment clinics.

Diversion

Critics have argued that some MM patients are "gaming the system" to get marijuana for nonmedical use. Neither our data nor any other data we are aware of allow any clear-cut, empirical estimate of the scale of such diversion. Given the widespread nonmedical use marijuana in the general population (102,404,000 Americans report lifetime prevalence; see SAMHSA 2010) and the risk of arrest (847,864 Americans were arrested for marijuana offenses in 2008, 754,224 or 88.96% of them for possession alone; FBI 2009), it seems likely that at least some MM patients use MM dispensaries as sources of supply for nonmedical use.

Defining and measuring such diversion, however, is complicated at best. Given the high prevalence of nonmedical use, it is not surprising that most MM patients in our sample reported having used it recreationally before using it therapeutically. But as noted above, two-fifths had *not* been using marijuana recreationally prior to trying it for medicinal purposes. Their self-reported rates of other illicit drug use are slightly lower than those found among the general population, and their levels of educational attainment and rate of employment are comparable to the California population. Our data have clear limitations, but they contain no obvious signs that MM patients differ from the general population.

Nor is drug diversion unique to medical marijuana. A significant albeit unknown proportion of other patients obtain prescriptions for numerous drugs through legal medical channels that they then use for nonmedical purposes, for example, Valium and other benzodiazepines (Haafkens 1997), Ritalin and other stimulants prescribed for ADHD, and Oxycontin and other opiates prescribed for pain.

The diversion issue will likely become more important as the line between medical and nonmedical drug use is increasingly blurred (Murray, Gaylin & Macklin 1984). Beyond the spread of MM, Prozac and other SSRI-type antidepressants, for example, are often prescribed

for patients who do not meet DSM criteria for clinical depression but who simply feel better when taking it. Such “cosmetic psychopharmacology” (Kramer 1993) is likely to grow as new psychiatric medications come to market. The line between medical and nonmedical drug use has also been blurred by performance enhancing drugs such as steroids, so-called “smart drugs” that combine vitamins with psychoactive ingredients, and herbal remedies like *ma huang* (ephedra) available in health food stores (Burros & Jay 1996).

These examples suggest that despite the best intentions of physicians and law makers, much drug use does not fit into two neat boxes, medical and nonmedical, but rather exists on a continuum where one shades into the other as

patients’ purposes shift to suit situational exigencies in their health and their daily lives. It is not clear where a border line between medical and nonmedical marijuana or other drug use might be drawn nor how it might be effectively policed (see Reinarman & Levine 1997: 334–44).

NOTE

1. We are grateful to one anonymous reviewer for pointing out that the cost of these assessments may well have prevented some potential MM patients—including many impoverished HIV/AIDS patients—from obtaining ID cards, which may have affected the demographics of this sample.

Therapeutic Benefits of Cannabis: A Patient Survey

Charles W. Webb MD and Sandra M. Webb RN, BSN

Abstract

Clinical research regarding the therapeutic benefits of cannabis ("marijuana") has been almost non-existent in the United States since cannabis was given Schedule I status in the Controlled Substances Act of 1970. In order to discover the benefits and adverse effects perceived by medical cannabis patients, especially with regards to chronic pain, we hand-delivered surveys to one hundred consecutive patients who were returning for yearly re-certification for medical cannabis use in Hawai'i.

The response rate was 94%. Mean and median ages were 49.3 and 51 years respectively. Ninety-seven per cent of respondents used cannabis primarily for chronic pain. Average pain improvement on a 0-10 pain scale was 5.0 (from 7.8 to 2.8), which translates to a 64% relative decrease in average pain. Half of all respondents also noted relief from stress/anxiety, and nearly half (45%) reported relief from insomnia. Most patients (71%) reported no adverse effects, while 6% reported a cough or throat irritation and 5% feared arrest even though medical cannabis is legal in Hawai'i. No serious adverse effects were reported.

These results suggest that Cannabis is an extremely safe and effective medication for many chronic pain patients. Cannabis appears to alleviate pain, insomnia, and may be helpful in relieving anxiety. Cannabis has shown extreme promise in the treatment of numerous medical problems and deserves to be released from the current Schedule I federal prohibition against research and prescription.

Introduction

Research into the therapeutic benefits of cannabis has been severely limited by the federal Schedule I classification, which essentially prohibits any ability to acquire or to provide cannabis for studies investigating possible therapeutic effects. Limited studies have been done in Canada and in Europe, as well as several in California.

Hawai'i is one of twenty states (plus the District of Columbia) which allow certifications for use of medical cannabis. The authors have been certifying patients for use of medical cannabis in Hawai'i for more than four years. In an attempt to discover the perceived benefits and adverse effects of medical cannabis, we conducted a survey of medical cannabis patients.

Methods

Sample Selection

Between July of 2010 and February of 2011, we hand-delivered questionnaires to one hundred consecutive patients who had been certified for the medical use of cannabis for a minimum of one year and were currently re-applying for certification.

Survey Design and Administration

The subjects were verbally instructed to complete the questionnaire in the office at the time of re-certification or were provided a stamped and addressed envelope so they could complete the questionnaire at home. All patients were instructed to remain anonymous and to answer the questions as honestly as possible.

A universal pain scale was used to assess pain before and after treatment (0 = no pain, 10 = worst pain ever). Open-ended questions were asked to ascertain the following:

- (1) "Any adverse effects you have had from using medical cannabis?"
- (2) "Does medical cannabis help you with any other problems? If so, what?"

The purpose of the last question was to explore benefits outside the parameters of the state of Hawai'i's medical cannabis qualifying conditions.

Results

The overall response rate was 94%. The mean age was 49.3 years and the median age was 51. No data was collected on sex or race/ethnicity. Almost all respondents (97%) used medical cannabis primarily for relief of chronic pain.

Average reported pain relief from medical cannabis was substantial. Average pre-treatment pain on a zero to ten scale was 7.8, whereas average post-treatment pain was 2.8, giving a reported average improvement of 5 points. This translates to a 64% average relative decrease in pain.

Other reported therapeutic benefits included relief from stress/anxiety (50% of respondents), relief of insomnia (45%), improved appetite (12%), decreased nausea (10%), increased focus/concentration (9%), and relief from depression (7%). Several patients wrote notes (see below) relating that cannabis helped them to decrease or discontinue medications for pain, anxiety, and insomnia. Other reported benefits did not extend to 5% or more of respondents.

Six patients (6%) wrote brief notes relating how cannabis helped them to decrease or to discontinue other medications. Comments included the following: "Medical cannabis replaced my need for oxycodone. Now I don't need them at all." "I do not need Xanax anymore." "In the last two years I have been able to drop meds for anxiety, sleep, and depression." "I've cut back 18 pills on my morphine dosage."

A majority (71%) reported no adverse effects, while 6% reported a cough and/or throat irritation and 5% reported a fear of arrest. All other adverse effects were less than 5%. No serious adverse effects were reported.

Discussion

According to the Institute of Medicine, chronic pain afflicts 116 million Americans and costs the nation over \$600 billion every year in medical treatment and lost productivity.¹ Chronic pain is a devastating disease that frequently leads to major depression and even suicide.² Unfortunately, the therapeutic options for chronic pain are limited and extremely risky.

Spurred by efforts to encourage physicians to become more pro-active in treating chronic pain, US prescription opioids (synthetic derivatives of opium) have increased ten-fold since 1990.³ By 2009 prescription opioids were responsible for almost half a million emergency department visits per year.⁴ In 2010 prescription opioid overdoses were responsible for well over 16,000 deaths.⁵ A 2010 article in the *New England Journal of Medicine* addressing this problem is aptly titled “A Flood of Opioids, a Rising Tide of Deaths.”³ Drugs such as OxyContin[®] are so dangerous that the manufacturer’s boxed warning states that “respiratory depression, including fatal cases, may occur with use of OxyContin, even when the drug has been used as recommended and not misused or abused.”⁶ Clearly safer analgesics are needed.

The Hippocratic Oath reminds to “first, do no harm.” It cannot be over-emphasized that there has never been a death from overdose attributed to cannabis.⁷ In fact, no deaths whatsoever have been attributed to the direct effects of cannabis.⁷ Cannabis has a safety record that is vastly superior to all other pain medications.

Many physicians worry that cannabis smoke might be as dangerous as cigarette smoke; however, epidemiologic studies have found no increase in oropharyngeal or pulmonary malignancies attributable to marijuana.⁸⁻¹⁰ Still, since smoke is something best avoided, medical cannabis patients are encouraged to use smokeless vaporizers which can be purchased on-line or at local “smoke-shops.” In states that (unlike Hawai‘i) allow cannabis dispensaries, patients can purchase “vapor pens,” analogous to e-cigarettes and fully labeled regarding doses of THC and other relevant cannabinoids.

Tests have proven that smoke-free vaporizers deliver THC as well or even more efficiently than smoking, and that most patients prefer vaporizers over smoking.¹¹ Like smoking, vaporizers allow patients to slowly titrate their medicine just to effect, analogous to IV patient-controlled analgesia (PCA) that has been so successful in hospital-based pain control. This avoids the unwanted psychoactive side-effects often associated with oral medication such as prescription Marinol[®] (100% THC in oil) capsules which tend to be slowly and erratically absorbed and are often either ineffectually weak or overpoweringly strong.^{12,13} Because inhaled cannabis is rapid, reliable, and titratable, most patients strongly prefer inhaled cannabis over Marinol[®] capsules.¹⁴

While the relative safety of cannabis as medication is easily established, the degree of efficacy is still being established. The reported pain relief by patients in this survey is enormous. One reason for this is that patients were already self-selected for success: they had already tried cannabis and found that it worked for them. For this sample, the benefits of cannabis outweighed any negative effects. The study design may therefore lend itself to over-estimating the benefits and under-estimating the negative side-effects if extrapolated to the general population.

Another reason that the reported pain relief is so significant is that cannabis has been proven effective for many forms of

recalcitrant chronic pain. A University of Toronto systematic review of randomized controlled trials (RCT’s) examining cannabinoids in the treatment of chronic pain found that fifteen of eighteen trials demonstrated significant analgesic effect of cannabinoids and that there were no serious adverse effects.¹⁵

While opioids are generally considered to have little benefit in chronic neuropathic pain, several RCT’s have shown that cannabinoids can relieve general neuropathic pain,¹⁶ as well as neuropathic pain associated with HIV and with multiple sclerosis (MS).^{17,18} One study found that cannabis had continuing efficacy at the same dose for at least two years.¹⁹

Even low dose inhaled cannabis has been proven to reduce neuropathic pain. In a randomized, double-blind, placebo-controlled crossover trial involving patients with refractory neuropathic pain, Ware, et al, found that therapeutic blood levels of THC (mean 45 ng/ml achieved by a single inhalation three times a day) were much lower than those necessary to produce a cannabis euphoria or “high”(> 100 ng/ml).¹⁹

Cannabis is relatively non-addicting, and patients who stop using it (eg, while traveling) report no withdrawal symptoms. One author (Webb C.) worked for 26 years in a high volume emergency department where he never witnessed a single visit for cannabis withdrawal symptoms, whereas dramatic symptoms from alcohol, benzodiazepine, and/or opioid withdrawal were a daily occurrence.

So why is cannabis still held hostage by the DEA as a Schedule I substance? On June 18, 2010, the Hawai‘i Medical Association passed a resolution stating in part that:

“Whereas, 1) Cannabis has little or no known withdrawal syndrome and is therefore considered to be minimally or non-addicting; and

Whereas, 2) Cannabis has many well-known medical benefits (including efficacy for anorexia, nausea, vomiting, pain, muscle spasms, and glaucoma) and is currently recommended by thousands of physicians; and

Whereas 3) Cannabis has been used by millions of people for many centuries with no history of recorded fatalities and with no lethal dosage ever discovered; and

Whereas, Cannabis therefore fulfills none of the required three criteria (all of which are required) to maintain its current restriction as a Schedule I substance...

The Hawai‘i Medical Association recommends that Medical Cannabis be re-scheduled to a status that is either equal to or less restrictive than the Schedule III status of synthetic THC (Marinol[®]), so as to reduce barriers to needed research and to humanely increase availability of cannabinoid medications to patients who may benefit.”²⁰

Medical cannabis remains controversial mainly because the federal government refuses to recognize cannabis as an accepted medication. To this we would echo the words of Melanie Thernstrom in her excellent book *The Pain Chronicles*,² “How could treating pain be controversial?” one might ask, “ Why wouldn’t it be treated? Who are the opponents of relief?”

Conclusions

Cannabis is an extremely safe and effective medication for many patients with chronic pain. In stark contrast to opioids and other available pain medications, cannabis is relatively non-addicting and has the best safety record of any known pain medication (no deaths attributed to overdose or direct effects of medication). Adverse reactions are mild and can be avoided by titration of dosage using smokeless vaporizers.

More research needs to be pursued to discover degrees of efficacy in other areas of promise such as in treating anxiety, depression, bipolar disorder, autism, nausea, vomiting, muscle spasms, seizures, and many neurologic disorders. Patients deserve to have cannabis released from its current federal prohibition so that scientific research can proceed and so that physicians can prescribe cannabis with the same freedom accorded any other safe and effective medications.

Conflict of Interest

None of the authors identify a conflict of interest.

Authors' Biography:

Dr. Webb graduated from Dartmouth Medical School (BS Medicine) and from UC San Francisco School of Medicine (MD 1974). General Residency US Public Health Hospital (San Francisco) and Highland Hospital (Oakland). Emergency Medicine Physician 1975-2006 (Colorado), Urgent Care Physician 2007-present (Kailua Kona). Sandra Webb RN, since 1979 (emergency and radiology nurse). Dr. Webb and nurse Webb have been certifying patients for medical use of cannabis since 2009.

Medical Cannabis in Arizona: Patient Characteristics, Perceptions, and Impressions of Medical Cannabis Legalization

William D. Troutt, N.M.D. & Matthew D. DiDonato, Ph.D.

Abstract—Many advances have been made toward understanding the benefits of medical cannabis. However, less is known about medical cannabis patients themselves. Prior research has uncovered many important patient characteristics, but most of that work has been conducted with participants in California, who may not represent medical cannabis patients throughout the United States. Furthermore, it is unknown if medical cannabis legalization, which typically imposes strict regulations on cannabis cultivation and sale, impacts patients' experiences acquiring and using cannabis. The goal of this study was to address these limitations by (1) examining the characteristics, perceptions, and behaviors of medical cannabis patients in Arizona; and (2) questioning participants with a history of cannabis use regarding their experiences with cannabis before and after legalization. Patients in Arizona share many characteristics with those in California, but also key differences, such as average age and degree of cannabis consumption. Participants also had positive perceptions of the effect of medical cannabis legalization, reporting that feelings of safety and awareness were higher after legalization compared to before. The results are discussed in relation to evidence from patients in other states and in terms of their potential policy implications.

Keywords—Arizona, medical cannabis, medical cannabis legalization, patient characteristics, perceptions

Support for the use of cannabis for medical purposes is growing throughout the United States. To date, 23 states and the District of Columbia have enacted laws legalizing medical cannabis, and 16 states have similar legislation under consideration. Recent polls also show that the majority of Americans believe that cannabis should be legalized for medical purposes (Anderson Robbins Research & Shaw & Company Research 2013; Associated Press-CNBC 2010), and the popularity of this sentiment has

increased over time (Anderson Robbins Research & Shaw & Company Research 2013).

Support may be on the rise, in part, due to research that shows the potential therapeutic effects of medical cannabis. Animal studies, for example, show that cannabis-derived extracts mitigate cancer cell proliferation and tumor growth (Aviello et al. 2012) and have antidepressant-like effects (Jiang et al. 2005). Studies also show that cannabis may be beneficial for humans. Bar-Sela and colleagues (2013) found that nausea, vomiting, weight loss, sleep disorders, and pain were reduced in cancer patients after 6–8 weeks of cannabis use. Studies also show that cannabis significantly reduces chronic pain (see Lynch and Campbell 2011),

inflammatory bowel disease (Allegretti et al. 2013), post-traumatic stress disorder (Greer, Grob, and Halberstadt 2014), and seizure disorders (Lorenz 2004).

Although many advances have been made in understanding the benefits of medical cannabis, less is known about US medical cannabis patients themselves. Demographically, most patients are White, male, and approximately 35 to 45 years of age (Bonn-Miller et al. 2014; Grella, Rodriguez, and Kim 2014; Ryan-Ibarra, Induni, and Ewing 2015; Aggarwal et al. 2013; Ilgen et al. 2013; Nunberg et al. 2011; Reinerman et al. 2011; Aggarwal et al. 2009; Reiman 2009; O'Connell and Bou-Matar 2007; Harris et al. 2000). Most patients report medicating with cannabis daily (Bonn-Miller et al. 2014; Ilgen et al. 2013; Reinerman et al. 2011; O'Connell and Bou-Matar 2007), consuming six to nine grams of cannabis per week (Bonn-Miller et al. 2014; Reinerman et al. 2011; O'Connell and Bou-Matar 2007), and prefer inhalation as the method of consumption (O'Connell and Bou-Matar 2007).

Studies also show that the majority of patients use medical cannabis to relieve pain. However, patients also report using cannabis to treat a variety of other conditions, including anxiety, sleep apnea, hypertension, incontinence, and depression (Aggarwal et al. 2013; Nunberg et al. 2011; Reinerman et al. 2011). Generally, patients report that medical cannabis is effective for helping them manage their condition(s) (Bonn-Miller et al. 2014; Ryan-Ibarra, Induni, and Ewing 2015; Aggarwal et al. 2013; Harris et al. 2000). For example, Aggarwal and colleagues (2013) found that, on a scale from 1 to 10, where 10 indicated absolute symptom control, patients reported that cannabis provided symptom control in the range of 7 to 10 across a variety of conditions. Patients also often reduce their use of other medications (i.e., prescription and over-the-counter drugs) when using medical cannabis (Nunberg et al. 2011; Aggarwal et al. 2009; Reiman 2009, 2007).

Though these studies are informative, one limitation is that most were conducted with samples of patients living in California. California patients may not represent those living in other areas of the country because the regulations that govern patients in California are different from those in other states. For example, residents of California may legally obtain medical cannabis to treat a number of ailments, including any chronic or persistent condition that considerably limits major life activities or that, if not alleviated, may compromise the patient's safety or health (California Senate Bill 420 2003). Because the list of conditions for which the legal medical use of cannabis is granted in other states is often less inclusive, patients from these states may differ from those in California.

Considering that medical cannabis has been legalized in many states, there is an opportunity to paint a more comprehensive picture of American medical cannabis patients by conducting similar studies in other geographic locations.

Scientists have begun to conduct such research through the examination of patients living in Washington State (Aggarwal et al. 2013, 2009) and Michigan (Ilgen et al. 2013). Our first goal was to continue this line of research by studying medical cannabis patients in Arizona. To aid comparisons with previous research, we assessed patient characteristics, behaviors, and perceptions that have been examined in prior studies. These included patterns of use (e.g., frequency of consumption, amount of consumption, preferred method of consumption), degree of relief experienced when using medical cannabis, and use of other medications.

In addition to the limited research on medical cannabis patients outside of California, to our knowledge there has been no systematic examination of patients' perceptions of the outcomes of medical cannabis legalization. One objective of legalizing cannabis for medical use is to safeguard its acquisition and production, which often involves strict regulation of its cultivation and sale. For instance, the rules and regulations of the Arizona Medical Marijuana Program require that those authorized to operate medical cannabis dispensaries and cultivation facilities enact strict security policies and procedures (Arizona Department of Health Services Medical Marijuana Rules 2012). In addition, many dispensaries and facilities employ third-party laboratories to test cannabis products for possible contaminants. However, it is unknown if such regulations translate to changes in patient safety or product quality.

Because individuals who use cannabis medicinally are those most affected by these regulations, surveying patients regarding their experiences purchasing and using medical cannabis may uncover the changes legalization has had on patient safety and product quality. In particular, patients with a history of using cannabis medicinally prior to legalization can provide their perspective on the changes that legalization has generated. The second goal of the present study was to determine the effectiveness of measures invoked to regulate and secure the cultivation and sale of medical cannabis by examining the perceptions of patients that used cannabis medicinally prior to legalization. Patients were asked to compare their perceptions of safety, product knowledge, and the effectiveness of cannabis for treating their condition(s) before and after legalization. Because of the regulations imposed with the legalization of medical cannabis, we hypothesized that patients would feel greater safety, have better knowledge, and that cannabis effectiveness would be greater after legalization.

METHOD

Participants and Procedures

Participants were 367 patients recruited from four medical cannabis dispensaries located throughout Arizona. The majority of the patients were male (63.8%), and

ranged from 18 to 83 years of age ($M = 45.78$ years; $SD = 13.76$ years). Most of the patients were White (86.4%), whereas the rest were Hispanic (6.3%), Black (2.5%), Native American (1.9%), Asian (0.8%), or Other (2.1%). These figures are similar to those reported by the Arizona Department of Health Services (2014) for this patient population.

To protect patient confidentiality, the authors did not directly contact patients, but approached dispensary owners to request assistance in recruiting participants. Dispensary owners informed their patients of the study, and interested patients were directed to a website that provided information about the research, including a description of the study, an explanation of patients' rights as participants, and information regarding the collection and storage of participant responses (i.e., responses were anonymous and would be stored on a password-protected server and/or computer only accessible to the researchers). If the patient agreed to participate, he or she checked a box indicating his or her agreement and the survey questions appeared.

Measures

Patient conditions. Participants were asked to select from an extensive list of conditions for which they use medical cannabis to control or treat. For each condition selected, participants completed subsequent questions and rated them on five-point Likert-type scales regarding the degree of relief experienced overall (1 = No relief at all; 5 = Almost complete relief), the degree of relief compared to other medications (1 = Much less relief; 5 = Much more relief), and the use of other medications since using medical cannabis (1 = I use other medications much less frequently; 5 = I use other medications much more frequently). Higher scores indicated greater relief or more frequent use of other medications.

Patterns and methods of cannabis use. Patients reported on the frequency ("On average, how frequently do you medicate with medical cannabis?": "Less than once per month" to "Several times per day") and amount ("On average, how much medical cannabis do you consume in a month?": "Less than one gram" to "More than one ounce") of consumption. Patients also completed a single-item measure regarding their preferred method of consumption (smoking, edibles, tinctures, vaporizing, raw consumption, or oils).

Perceptions of prior medical cannabis users. Participants were asked if they had used cannabis to treat their condition(s) before its legalization in Arizona. Those who replied "yes" were asked to complete four additional items. These items included the perceived safety of acquiring cannabis ("Compared to when you did not have a medical marijuana card, acquiring cannabis as a medical marijuana card holder feels": 1 = Much more dangerous; 5 = Much safer), knowledge of strain

characteristics ("Compared to when you did not have a medical marijuana card, your knowledge of what strain you are acquiring and its characteristics is": 1 = Much worse; 5 = Much better), confidence in a safe product ("Compared to when you did not have a medical marijuana card, your confidence that you are receiving a safe, uncontaminated product is": 1 = Much lower; 5 = Much higher), and product effectiveness for treating their condition(s) ("Compared to when you did not have a medical marijuana card, the effectiveness of the cannabis you receive to treat your condition is": 1 = Much worse; 5 = Much better).

RESULTS

The conditions for which patients reported using medical cannabis are displayed in Table 1. Consistent with previous research, the majority of patients reported suffering from chronic pain. Other commonly reported conditions included anxiety, depression, headaches, insomnia, muscle spasms, nausea, and stress.

Figure 1 shows the distributions of patients for frequency of cannabis use (Figure 1A), amount of cannabis consumed per month (Figure 1B), and preferred method of cannabis consumption (Figure 1C). The large majority of patients (83.7%) reported using medical cannabis several times per week or more, with most using medical cannabis daily (61%). Most patients consumed one-half of an ounce of cannabis or less per month (78.1%), and the most popular method of consumption was inhalation (i.e., smoking or vaporizing; 67.2%).

Perceived Effectiveness of Medical Cannabis

Patients' perceptions of the effectiveness of medical cannabis for treating their condition(s) are presented in Table 1. The values reflect the percent of patients who reported experiencing, overall, *a lot of relief* or *almost complete relief* from their symptoms and conditions when using medical cannabis (second column), *a little more relief* or *much more relief* from medical cannabis compared to other medications (third column), and using other medications *a little less frequently* or *much less frequently* when medicating with cannabis (fourth column).

For many of the conditions, patients reported that cannabis was effective for helping them manage their ailments. For example, at least 70% of patients reported experiencing *a lot of relief* or *almost complete relief* for 24 of the 42 conditions. Similarly, for 27 of the 42 conditions, at least 70% of patients reported experiencing *a little more relief* or *much more relief* from medical cannabis compared to other medications. Finally, at least 70% of patients reported using other medications *a little less frequently* or *much less frequently* for 24 of the 42 conditions.

TABLE 1
Percent of Patients Who Experience Relief and Less Frequently Use other Medications Due to Medical Cannabis Use, by Condition

Condition	Number of patients (%)	General relief ^a	Relief compared to other medications ^b	Less frequent use of other medications ^c
Alcohol Dependency	23 (6.3%)	91.30%	100%	100%
Anxiety	181 (49.3%)	82.90%	79.30%	85.90%

Weight Loss	24 (6.5%)	62.50%	80.00%	70.00%

^aThe percent of patients with this condition who reported that they experienced a lot or almost complete overall relief.
^bThe percent of patients with this condition who reported that they experienced a lot or almost complete overall relief.
^cThe percent of patients with this condition who reported that they use other medications a little or much less frequently.

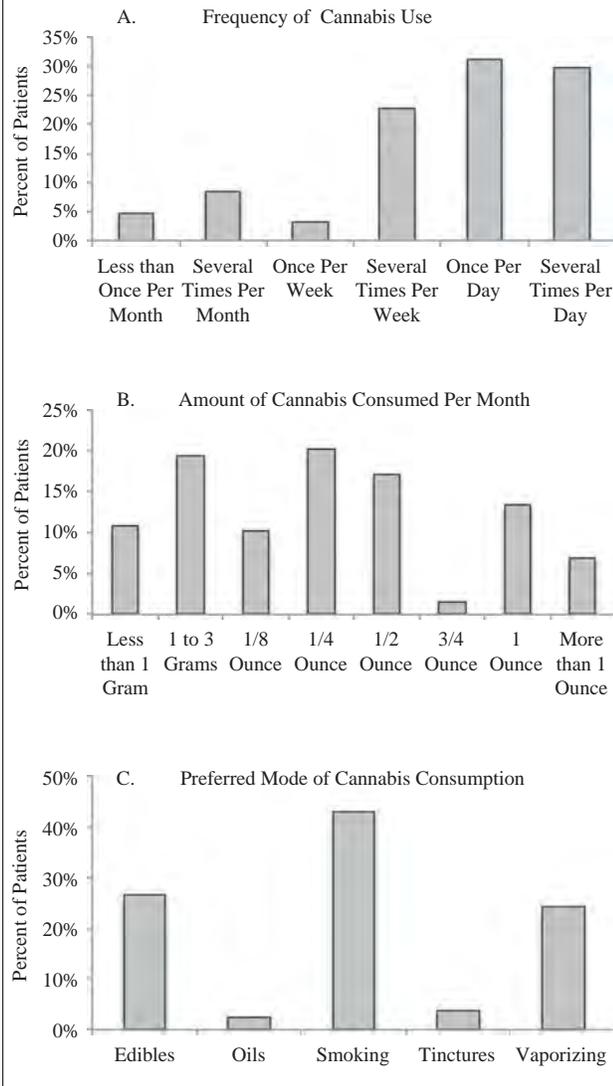

Perceived Effects of Medical Cannabis Legalization

Nearly two-thirds of participants (*n* = 239) reported using cannabis medicinally prior to legalization. These patients were asked to compare their current experiences

acquiring, their knowledge of, and their experiences using medical cannabis to their experiences and knowledge before legalization. Distributions of the patient's responses are shown in [Figure 2](#). Compared to their experiences

FIGURE 1

Distributions of patient responses, by percentage, for cannabis-related behaviors and perceptions: (A) the frequency of patient’s cannabis use; (B) the amount of cannabis consumed by patients per month; (C) patient’s preferred mode of cannabis consumption.

before legalization, 89.1% of patients reported that acquiring cannabis after legalization felt *somewhat safer* or *much safer*, 80.3% reported that their knowledge of the cannabis strains they acquired was *somewhat better* or *much better*, 85.4% reported that they had *somewhat more confidence* or *much more confidence* that they were purchasing a safe and uncontaminated product, and 79.5% reported that the medical cannabis was *somewhat more effective* or *much more effective* for treating their condition(s).

DISCUSSION

The goals of this study were to (1) examine the characteristics, perceptions, and behaviors of medical cannabis patients in Arizona; and (2) question participants with a history of cannabis use regarding their perceptions of safety acquiring cannabis, the quality of the cannabis they have obtained, their knowledge of the cannabis, and its perceived effectiveness, before and after legalization.

Patient Characteristics, Perceptions, and Behaviors

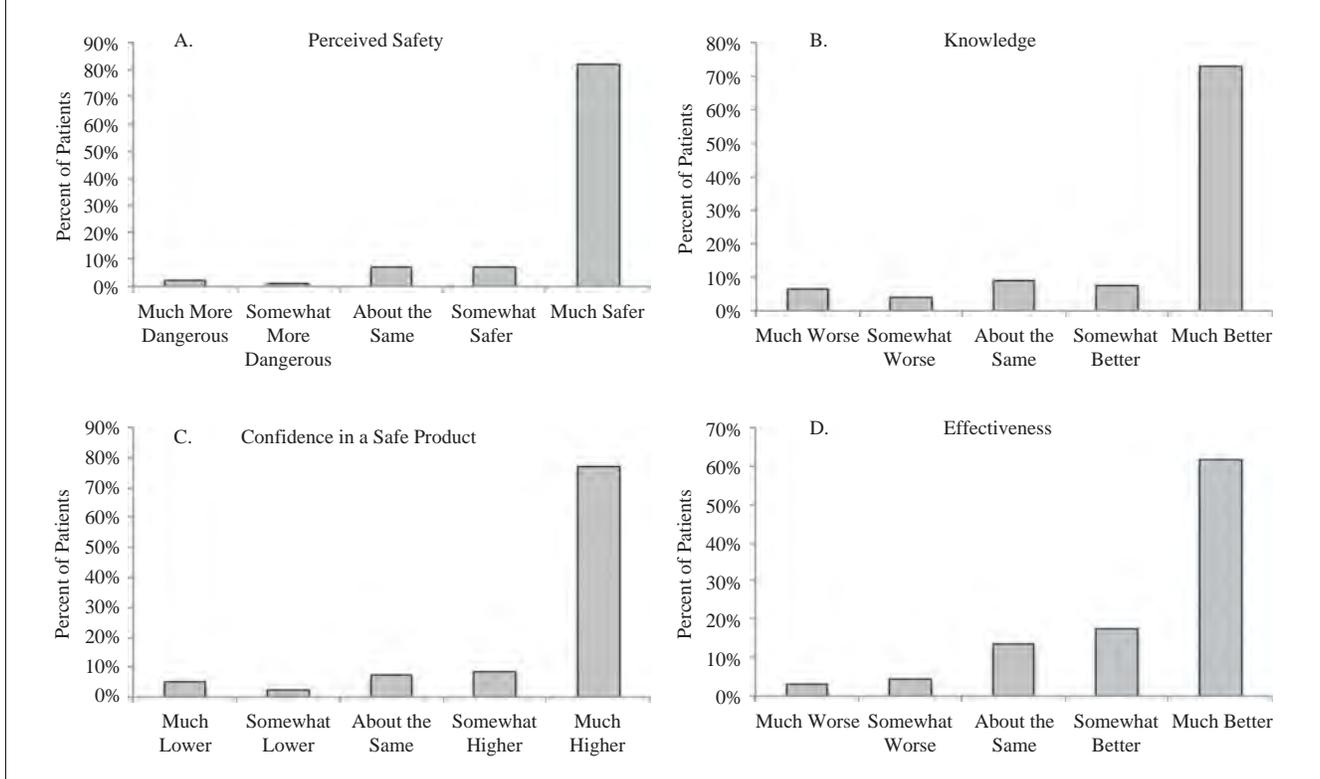

Consistent with research in other states (Bonn-Miller et al. 2014; Aggarwal et al. 2013; Ilgen et al. 2013; Nunberg et al. 2011; Reinerman et al. 2011; Aggarwal et al. 2009; Reiman 2009; O’Connell and Bou-Matar 2007; Harris et al. 2000), participants in the present study were mostly White men. Average patient age, approximately 46 years, differed from that in other states. For example, average ages reported in studies of patients from California range from 28 to 41 years (Bonn-Miller et al. 2014; Grella, Rodriguez, and Kim 2014; Reiman 2009, 2007; Harris et al. 2000). Average patient age is somewhat higher in Colorado (42 years of age; Colorado Department of Public Health and Environment 2014) and Washington State (41 to 47 years of age; Aggarwal et al. 2013, 2009). In Michigan (46 years of age; Murphy 2013) and Montana (47 years of age; Montana Department of Public Health and Human Services 2014), average patient age more closely approximates that of Arizona.

State-level variation in the average age of medical cannabis patients may in part be explained by the conditions that qualify a person to use medical cannabis in each state. For example, the qualifying conditions in Arizona, Colorado, Montana, Michigan, and Washington State are less inclusive than those in California, and are generally limited to more debilitating diseases. Individuals who suffer from more serious conditions may also be older, which may account for higher average patient ages in states other than California. The variability in these statistics underscores the risk of generalizing findings from patients living in California to those residing in other states and highlights the importance of studying patients throughout the United States. State-level differences in regulations also present an opportunity to explore how such regulations shape patient characteristics. A potential avenue for future work may be to study and compare patients in all states that have legalized the medical use of cannabis, ideally using a national sample to aid state-level comparisons.

Participants in the present study reported that, on average, they consumed cannabis on a daily basis and that inhalation was the preferred method of consumption, patterns of use that reflect those found in prior work (Bonn-Miller et al. 2014; Ilgen et al. 2013; Reinerman et al. 2011; O’Connell and Bou-Matar 2007). However, previous research shows that patients consume between

FIGURE 2

Distributions of patient responses, by percentage, of their current experiences acquiring and knowledge of medical cannabis compared to their experiences before legalization: (A) the perceived safety of acquiring cannabis; (B) knowledge of medical cannabis characteristics; (C) perceived confidence in a safe product; and (D) perceived effectiveness of cannabis for treating their condition(s).

six and nine grams of cannabis per week or, equivalently, 0.85 to 1.25 ounces per month (Bonn-Miller et al. 2014; Reinerman et al. 2011; O’Connell and Bou-Matar 2007). This is in contrast to the findings of the present study, which show that 78% of patients consumed 0.5 ounces of cannabis per month or less.

State-level differences in average patient age, in particular, may affect variation in consumption. Patients in Arizona are, on average, older than those in California, and older patients may consume less cannabis than younger patients. Evidence from the present study supports this hypothesis, as there is a small, but significant, negative correlation between age and the amount of cannabis consumed per month ($r = -.11, p < .05$). Relatedly, Grella and colleagues (2014) found that younger patients visited dispensaries more frequently than older patients. Although there are likely other factors that contribute to consumption disparities, these findings also highlight the importance of studying medical cannabis patients across the US.

Patients reported using medical cannabis to treat a variety of conditions. The most commonly reported conditions included chronic pain, muscle spasms, nausea, anxiety, arthritis, depression, headaches, insomnia, and stress. Patients also reported that cannabis was effective for treating the symptoms of many of these conditions, findings that are consistent with previous research (Bonn-Miller et al. 2014; Ryan-Ibarra, Induni, and Ewing 2015; Aggarwal et al. 2013; Harris et al. 2000). This effectiveness included feelings of general relief and relief compared to other medications. The conditions for which the highest proportions of patients reported relief included alcohol dependency, anxiety, bowel distress, depression, insomnia, muscle spasms, and stress. Furthermore, patients reported using other medications less frequently when using cannabis. This is consistent with findings from other studies of patient perceptions (Reiman 2007, 2009; Nunberg et al. 2011; Reinerman et al. 2011), as well as a study of opiate overdose mortality, which showed that states with legalized medical cannabis had significantly lower opiate overdose mortality compared

to those without legalized medical cannabis (Bachhuber et al. 2014).

Medical cannabis may benefit Arizona patients suffering from a variety of conditions. This conclusion has potential policy implications, as patients report deriving benefit not only for conditions that fall under the list of conditions that qualify a person to use medical cannabis (e.g., cancer, chronic pain, muscle spasms), but also for conditions that are not listed (e.g., anxiety, depression, insomnia). Officials in Arizona previously considered research on post-traumatic stress disorder (PTSD; Greer, Grob, and Halberstadt 2014) in their decision to include PTSD among Arizona's qualifying conditions. Thus, officials may consider the findings from the present study, in conjunction with other research, to determine the suitability of expanding the list of qualifying conditions in Arizona.

Legalization and Patient Experiences

The present study was, to our knowledge, the first to examine the effect of legalization on patient's experiences with medical cannabis. Regarding safety, the majority of patients reported feeling safer acquiring medical cannabis after legalization, and their confidence that they were acquiring a safe, uncontaminated product was higher. Patients also reported that their knowledge of the strains they acquired was better and that the cannabis they acquired after legalization was more effective for treating their condition(s) than the cannabis they acquired before legalization.

These findings show that the Arizona medical cannabis program has had some success, as regulations have provided a safe environment for patients to acquire a safe and high-quality product. However, the potential negative effects of medical cannabis legalization were not assessed in the present study. For example, participants in other studies have reported difficulties affording legal medical cannabis (Aggarwal et al. 2009), a factor which may preclude some individuals from taking advantage of the program, leaving them seeking other, potentially illegal means of cannabis acquisition. Other factors, such as limits on the amount of cannabis that can be purchased or legal

issues related to medical cannabis use, may also have negative consequences for some segments of the patient population.

The results of this study should be considered in light of some limitations. First, participant recruitment was conducted through medical cannabis dispensaries. Although this is a common method of recruitment (e.g., Bonn-Miller et al. 2014; Grella, Rodriguez, and Kim 2014; Aggarwal et al. 2013; Reiman 2009, 2007; Harris et al. 2000), such samples may have a positive bias for medical cannabis, as individuals who medicate with cannabis but for whom it was not effective are unlikely to be available to participate. However, at least one study using a large, representative sample of current and former medical cannabis users reported similar findings (Ryan-Ibarra, Induni, and Ewing 2015), lending validity to the results of the present study and those of previous research. Second, relatively few patients reported using medical cannabis for some of the conditions. Although this is not surprising, given the low incidence of some conditions, conclusions should be tempered for these conditions with respect to the effectiveness of medical cannabis for providing relief and/or for use as a substitute for other medications. Finally, patients' experiences acquiring and their knowledge of medical cannabis before and after legalization were assessed retrospectively, using a single measurement time-point.

Despite these limitations, this study has significance for understanding the characteristics, behaviors, and perceptions of Arizona medical cannabis patients. Additionally, it highlights the importance of studying patients throughout the US and understanding the potential effects of state-level regulatory differences on patient populations. The findings regarding the effectiveness of cannabis for treating various conditions have potential policy implications for the state of Arizona, as patients reported that cannabis was effective for treating conditions that currently do not qualify individuals for medical cannabis use. Furthermore, the results showed that the majority of patients report positive experiences as a result of legalization, although more work is needed to fully understand the consequences of Arizona's medical cannabis program.

REVIEW

Taming THC: potential cannabis synergy and phytocannabinoid-terpenoid entourage effects

Tetrahydrocannabinol (THC) has been the primary focus of cannabis research since 1964, when Raphael Mechoulam isolated and synthesized it. More recently, the synergistic contributions of cannabidiol to cannabis pharmacology and analgesia have been scientifically demonstrated. Other phytocannabinoids, including tetrahydrocannabivarin, cannabigerol and cannabichromene, exert additional effects of therapeutic interest. Innovative conventional plant breeding has yielded cannabis chemotypes expressing high titres of each component for future study. This review will explore another echelon of phytotherapeutic agents, the cannabis terpenoids: limonene, myrcene, α -pinene, linalool, β -caryophyllene, caryophyllene oxide, nerolidol and phytol. Terpenoids share a precursor with phytocannabinoids, and are all flavour and fragrance components common to human diets that have been designated Generally Recognized as Safe by the US Food and Drug Administration and other regulatory agencies. Terpenoids are quite potent, and affect animal and even human behaviour when inhaled from ambient air at serum levels in the single digits $\text{ng}\cdot\text{mL}^{-1}$. They display unique therapeutic effects that may contribute meaningfully to the entourage effects of cannabis-based medicinal extracts. Particular focus will be placed on phytocannabinoid-terpenoid interactions that could produce synergy with respect to treatment of pain, inflammation, depression, anxiety, addiction, epilepsy, cancer, fungal and bacterial infections (including methicillin-resistant *Staphylococcus aureus*). Scientific evidence is presented for non-cannabinoid plant components as putative antidotes to intoxicating effects of THC that could increase its therapeutic index. Methods for investigating entourage effects in future experiments will be proposed. Phytocannabinoid-terpenoid synergy, if proven, increases the likelihood that an extensive pipeline of new therapeutic products is possible from this venerable plant.

The roots of cannabis synergy

Cannabis has been a medicinal plant of unparalleled versatility for millennia (Mechoulam, 1986; Russo, 2007; 2008), but whose mechanisms of action were an unsolved mystery until the discovery of tetrahydrocannabinol (THC) (Gaoni and Mechoulam, 1964a), the first cannabinoid receptor, CB₁ (Devane *et al.*, 1988), and the endocannabinoids, anandamide (arachidonylethanolamide, AEA) (Devane *et al.*, 1992) and 2-arachidonoylglycerol (2-AG) (Mechoulam *et al.*, 1995; Sugiura *et al.*, 1995). While a host of phytocannabinoids were discovered in the 1960s: cannabidiol (CBD) (Mechoulam and Shvo, 1963), cannabigerol (CBG) (Gaoni and Mechoulam, 1964b), cannabichromene (CBC) (Gaoni and Mechoulam, 1966), cannabidivarin (CBDV) (Vollner *et al.*, 1969) and tetrahydrocannabivarin (THCV) (Gill *et al.*, 1970), the overwhelming preponderance of research focused on psychoactive THC. Only recently has renewed interest been manifest in THC analogues, while other key components of the activity of cannabis and its extracts, the cannabis terpenoids, remain understudied (McPartland and Russo, 2001b; Russo and McPartland, 2003). The current review will reconsider essential oil (EO) agents, their peculiar pharmacology and possible therapeutic interactions with phytocannabinoids. Nomenclature follows conventions in Alexander *et al.* (2009).

Phytocannabinoids and terpenoids are synthesized in cannabis, in secretory cells inside glandular trichomes (Figure 1) that are most highly concentrated in unfertilized female flowers prior to senescence (Potter, 2004; Potter, 2009). Geranyl pyrophosphate is formed as a precursor via the deoxyxylulose pathway in cannabis (Fellermeier *et al.*, 2001), and is a parent compound to both phytocannabinoids and terpenoids (Figure 2). After coupling with either olivetolic acid or divarinic acid, pentyl or propyl cannabinoid acids are produced, respectively, via enzymes that accept either substrate (de Meijer *et al.*, 2003), a manifestation of Mechoulam's postulated 'Nature's Law of Stinginess'. Although having important biochemical properties in their own right, acid forms of phytocannabinoids are most commonly decarboxylated via heat to produce the more familiar neutral phytocannabinoids (Table 1). Alternatively, geranyl

Cannabis capitate glandular (EBR by permission of Bedrocan BV, Netherlands).

pyrophosphate may form limonene and other monoterpenoids in secretory cell plastids, or couple with isopentenyl pyrophosphate in the cytoplasm to form farnesyl pyrophosphate, parent compound to the sesquiterpenoids, that co-localizes with transient receptor potential vanilloid receptor (TRPV) 1 in human dorsal root ganglion, suggesting a role in sensory processing of noxious stimuli (Bradshaw *et al.*, 2009), and which is the most potent endogenous ligand to date on the G-protein coupled receptor (GPR) 92 (Oh *et al.*, 2008).

An obvious question pertains to the chemical ecology of such syntheses that require obvious metabolic demands on the plant (Gershenzon, 1994), and these will be considered.

Is cannabis merely a crude vehicle for delivery of THC? Might it rather display herbal synergy (Williamson, 2001) encompassing potentiation of activity by active or inactive components, antagonism (evidenced by the ability of CBD to reduce side effects of THC; Russo and Guy, 2006), summation, pharmacokinetic and metabolic interactions? Recently, four basic mechanisms of synergy have been proposed (Wagner and Ulrich-Merzenich, 2009): (i) multi-target effects; (ii) pharmacokinetic effects such as improved solubility or bioavailability; (iii) agent interactions affecting bacterial resistance; and (iv) modulation of adverse events. Cannabis was cited as an illustration.

Could phytocannabinoids function analogously to the endocannabinoid system (ECS) with its combination of active and 'inactive' synergists, first described as an entourage (Ben-Shabat *et al.*, 1998), with subsequent refinement (Mechoulam and Ben-Shabat, 1999) and qualification (p. 136): 'This type of synergism may play a role in the widely held (but not experimentally based) view that in some cases plants are better drugs than the natural products isolated from them'. Support derives from studies in which cannabis extracts demonstrated effects two to four times greater than THC (Carlini *et al.*, 1974); unidentified THC antagonists and synergists were claimed (Fairbairn and Pickens, 1981), anti-convulsant activity was observed beyond the cannabinoid fraction (Wilkinson *et al.*, 2003), and extracts of THC and CBD modulated effects in hippocampal neurones distinctly from pure compounds (Ryan *et al.*, 2006). Older literature also presented refutations: no observed differences were noted by humans ingesting or smoking pure THC versus herbal cannabis (Wachtel *et al.*, 2002); pure THC seemed to account for all tetrad-type effects in mice (Varvel *et al.*, 2005); and smoked cannabis with varying CBD or CBC content failed to yield subjective differences combined with THC (Ilan *et al.*, 2005). Explanations include that the cannabis employed by Wachtel yielded 2.11% THC, but with only 0.3% cannabinol (CBN) and 0.05% CBD (Russo and McPartland, 2003), and Ilan's admission that CBN and CBD content might be too low to modulate THC. Another factor is apparent in that terpenoid yields from vaporization of street cannabis were 4.3–8.5 times of those from US National Institute on Drug Abuse cannabis (Bloor *et al.*, 2008). It is undisputed that the black market cannabis in the UK (Potter *et al.*, 2008), Continental Europe (King *et al.*, 2005) and the USA (Mehmedic *et al.*, 2010) has become almost exclusively a high-THC preparation to the almost total exclusion of other phytocannabinoids. If – as many consumers and experts maintain (Clarke, 2010) – there are biochemical, pharmacological and

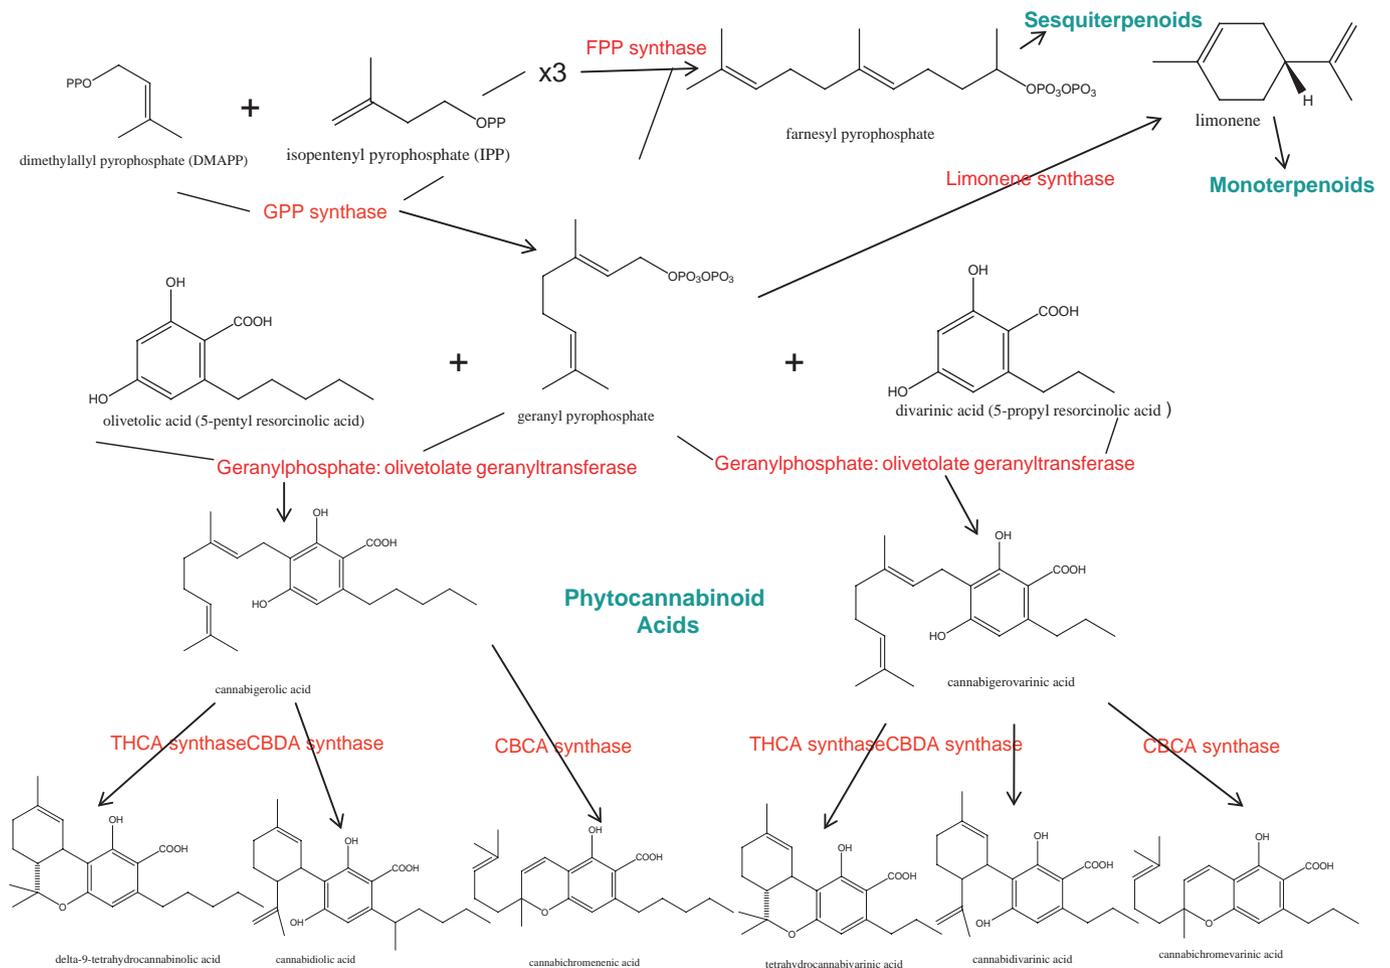

Figure 2
Phytocannabinoid and cannabis terpenoid biosynthesis.

phenomenological distinctions between available cannabis ‘strains’, such phenomena are most likely related to relative terpenoid contents and ratios. This treatise will assess additional evidence for putative synergistic phytocannabinoid-terpenoid effects exclusive of THC, to ascertain whether this botanical may fulfil its promise as, ‘a neglected pharmacological treasure trove’ (Mechoulam, 2005).

Phytocannabinoids, beyond THC: a brief survey

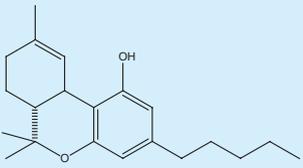

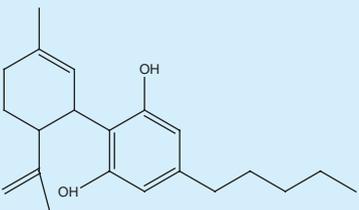

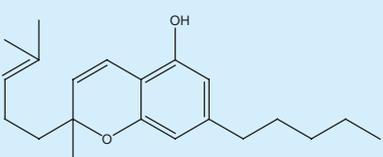

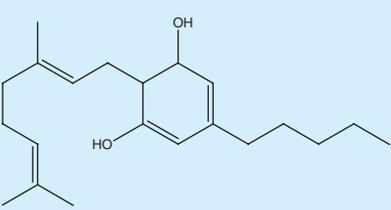

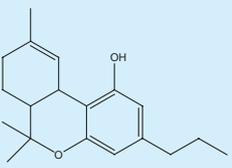

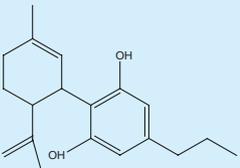

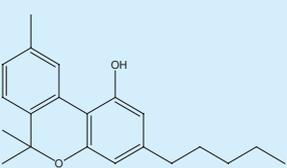

Phytocannabinoids are exclusively produced in cannabis (*vide infra* for exception), but their evolutionary and ecological *raison d’être* were obscure until recently. THC production is maximized with increased light energy (Potter, 2009). It has been known for some time that CBG and CBC are mildly antifungal (ElSohly *et al.*, 1982), as are THC and CBD against a cannabis pathogen (McPartland, 1984). More pertinent, however, is the mechanical stickiness of the trichomes, capable of trapping insects with all six legs

(Potter, 2009). Tetrahydrocannabinolic acid (THCA) and cannabichromenic acid (Morimoto *et al.*, 2007), as well as cannabidiolic acid and cannabigerolic acid (CBGA; Shoyama *et al.*, 2008) produce necrosis in plant cells. Normally, the cannabinoid acids are sequestered in trichomes away from the flower tissues. Any trichome breakage at senescence may contribute to natural pruning of lower fan leaves that otherwise utilize energy that the plant preferentially diverts to the flower, in continued efforts to affect fertilization, generally in vain when subject to human horticulture for pharmaceutical production. THCA and CBGA have also proven to be insecticidal in their own right (Sirikantaramas *et al.*, 2005).

Over 100 phytocannabinoids have been identified (Brenneisen, 2007; Mehmedic *et al.*, 2010), but many are artefacts of analysis or are produced in trace quantities that have not permitted thorough investigation. The pharmacology of the more accessible phytocannabinoids has received excellent recent reviews (Pertwee *et al.*, 2007; Izzo *et al.*, 2009; De Petrocellis and Di Marzo, 2010; De Petrocellis *et al.*, 2011), and will be summarized here, with emphasis on activities with particular synergistic potential.

Table 1

Phytocannabinoid activity table

Phytocannabinoid structure	Selected pharmacology (reference)	Synergistic terpenoids
 <p>delta-9-tetrahydrocannabinol (THC)</p>	<p>Analgesic via CB₁ and CB₂ (Rahn and Hohmann, 2009) AI/antioxidant (Hampson <i>et al.</i>, 1998) Bronchodilatory (Williams <i>et al.</i>, 1976) ↓ Sx. Alzheimer disease (Volicer <i>et al.</i>, 1997; Eubanks <i>et al.</i>, 2006) Benefit on duodenal ulcers (Douthwaite, 1947) Muscle relaxant (Kavia <i>et al.</i>, 2010) Antipruritic, cholestatic jaundice (Neff <i>et al.</i>, 2002)</p>	<p>Various Limonene <i>et al.</i> Pinene Limonene, pinene, linalool Caryophyllene, limonene Linalool? Limonene</p>

5-HT, 5-hydroxytryptamine (serotonin); AEA, arachidonylethanolamide (anandamide); AI, anti-inflammatory; CB₁/CB₂, cannabinoid receptor 1 or 2; GABA, gamma aminobutyric acid; TRPV, transient receptor potential vanilloid receptor; MRSA, methicillin-resistant *Staphylococcus aureus*; Sx, symptoms.

THC (Table 1) is the most common phytocannabinoid in cannabis drug chemotypes, and is produced in the plant via an allele co-dominant with CBD (de Meijer *et al.*, 2003). THC is a partial agonist at CB₁ and cannabinoid receptor 2 (CB₂) analogous to AEA, and underlying many of its activities as a psychoactive agent, analgesic, muscle relaxant and antispasmodic (Pacher *et al.*, 2006). Additionally, it is a bronchodilator (Williams *et al.*, 1976), neuroprotective antioxidant (Hampson *et al.*, 1998), antipruritic agent in cholestatic jaundice (Neff *et al.*, 2002) and has 20 times the anti-inflammatory power of aspirin and twice that of hydrocortisone (Evans, 1991). THC is likely to avoid potential pitfalls of either COX-1 or COX-2 inhibition, as such activity is only noted at concentrations far above those attained therapeutically (Stott *et al.*, 2005).

CBD is the most common phytocannabinoid in fibre (hemp) plants, and second most prevalent in some drug chemotypes. It has proven extremely versatile pharmacologically (Table 1) (Pertwee, 2004; Mechoulam *et al.*, 2007), displaying the unusual ability to antagonize CB₁ at a low nM level in the presence of THC, despite having little binding affinity (Thomas *et al.*, 2007), and supporting its modulatory effect on THC-associated adverse events such as anxiety, tachycardia, hunger and sedation in rats and humans (Nicholson *et al.*, 2004; Murillo-Rodriguez *et al.*, 2006; Russo and Guy, 2006). CBD is an analgesic (Costa *et al.*, 2007), is a neuroprotective antioxidant more potent than ascorbate or tocopherol (Hampson *et al.*, 1998), without COX inhibition (Stott *et al.*, 2005), acts as a TRPV1 agonist analogous to capsaicin but without noxious effect (Bisogno *et al.*, 2001), while also inhibiting uptake of AEA and weakly inhibiting its hydrolysis. CBD is an antagonist on GPR55, and also on GPR18, possibly supporting a therapeutic role in disorders of cell migration, notably endometriosis (McHugh *et al.*, 2010). CBD is anticonvulsant (Carlini and Cunha, 1981; Jones *et al.*, 2010), anti-nausea (Parker *et al.*, 2002), cytotoxic in breast cancer (Ligresti *et al.*, 2006) and many other cell lines while being cyto-preservative for normal cells (Parolaro and Massi, 2008), antagonizes tumour necrosis factor- α (TNF- α) in a rodent model of rheumatoid arthritis (Malfait *et al.*, 2000), enhances adenosine receptor A_{2A} signalling via inhibition of an adenosine transporter (Carrier *et al.*, 2006), and prevents prion accumulation and neuronal toxicity (Dirikoc *et al.*, 2007). A CBD extract showed greater anti-hyperalgesia over pure compound in a rat model with decreased allodynia, improved thermal perception and nerve growth factor levels and decreased oxidative damage (Comelli *et al.*, 2009). CBD also displayed powerful activity against methicillin-resistant *Staphylococcus aureus* (MRSA), with a minimum inhibitory concentration (MIC) of 0.5–2 $\mu\text{g}\cdot\text{mL}^{-1}$ (Appendino *et al.*, 2008). In 2005, it was demonstrated that CBD has agonistic activity at 5-hydroxytryptamine (5-HT)_{1A} at 16 μM (Russo *et al.*, 2005), and that despite the high concentration, may underlie its anti-anxiety activity (Resstel *et al.*, 2009; Soares Vde *et al.*, 2010), reduction of stroke risk (Mishima *et al.*, 2005), anti-nausea effects (Rock *et al.*, 2009) and ability to affect improvement in cognition in a mouse model of hepatic encephalopathy (Magen *et al.*, 2009). A recent study has demonstrated that CBD 30 $\text{mg}\cdot\text{kg}^{-1}$ i.p. reduced immobility time in the forced swim test compared to imipramine ($P < 0.01$), an effect blocked by pre-treatment with the 5-HT_{1A} antagonist

WAY100635 (Zanelati *et al.*, 2010), supporting a prospective role for CBD as an antidepressant. CBD also inhibits synthesis of lipids in sebocytes, and produces apoptosis at higher doses in a model of acne (*vide infra*). One example of CBD antagonism to THC would be the recent observation of lymphopenia in rats (CBD 5 $\text{mg}\cdot\text{kg}^{-1}$) mediated by possible CB₂ inverse agonism (Ignatowska-Jankowska *et al.*, 2009), an effect not reported in humans even at doses of pure CBD up to 800 mg (Crippa *et al.*, 2010), possibly due to marked interspecies differences in CB₂ sequences and signal transduction. CBD proved to be a critical factor in the ability of nabiximols oromucosal extract in successfully treating intractable cancer pain patients unresponsive to opioids (30% reduction in pain from baseline), as a high-THC extract devoid of CBD failed to distinguish from placebo (Johnson *et al.*, 2010). This may represent true synergy if the THC–CBD combination were shown to provide a larger effect than a summation of those from the compounds separately (Berenbaum, 1989).

CBC (Table 1) was inactive on adenylate cyclase inhibition (Howlett, 1987), but showed activity in the mouse cannabinoid tetrad, but only at 100 $\text{mg}\cdot\text{kg}^{-1}$, and at a fraction of THC activity, via a non-CB₁, non-CB₂ mechanism (Delong *et al.*, 2010). More pertinent are anti-inflammatory (Wirth *et al.*, 1980) and analgesic activity (Davis and Hatoum, 1983), its ability to reduce THC intoxication in mice (Hatoum *et al.*, 1981), antibiotic and antifungal effects (ElSohly *et al.*, 1982), and observed cytotoxicity in cancer cell lines (Ligresti *et al.*, 2006). A CBC-extract displayed pronounced antidepressant effect in rodent models (Deyo and Musty, 2003). Additionally, CBC was comparable to mustard oil in stimulating TRPA1-mediated Ca²⁺ in human embryonic kidney 293 cells (50–60 nM) (De Petrocellis *et al.*, 2008). CBC recently proved to be a strong AEA uptake inhibitor (De Petrocellis *et al.*, 2011). CBC production is normally maximal, earlier in the plant's life cycle (de Meijer *et al.*, 2009a). An innovative technique employing cold water extraction of immature leaf matter from selectively bred cannabis chemotypes yields a high-CBC 'enriched trichome preparation' (Potter, 2009).

CBG (Table 1), the parent phytocannabinoid compound, has a relatively weak partial agonistic effect at CB₁ (K_i 440 nM) and CB₂ (K_i 337 nM) (Gauson *et al.*, 2007). Older work supports gamma aminobutyric acid (GABA) uptake inhibition greater than THC or CBD (Banerjee *et al.*, 1975) that could suggest muscle relaxant properties. Analgesic and anti-erythemic effects and the ability to block lipooxygenase were said to surpass those of THC (Evans, 1991). CBG demonstrated modest antifungal effects (ElSohly *et al.*, 1982). More recently, it proved to be an effective cytotoxic in high dosage on human epithelioid carcinoma (Baek *et al.*, 1998), is the next most effective phytocannabinoid against breast cancer after CBD (Ligresti *et al.*, 2006), is an antidepressant in the rodent tail suspension model (Musty and Deyo, 2006) and is a mildly anti-hypertensive agent (Maor *et al.*, 2006). Additionally, CBG inhibits keratinocyte proliferation suggesting utility in psoriasis (Wilkinson and Williamson, 2007), it is a relatively potent TRPM8 antagonist for possible application in prostate cancer (De Petrocellis and Di Marzo, 2010) and detrusor over-activity and bladder pain (Mukerji *et al.*, 2006). It is a strong AEA uptake inhibitor (De Petrocellis *et al.*, 2011) and a powerful agent against MRSA (Appendino *et al.*, 2008; *vide infra*). Finally, CBG behaves as a potent α -2 adrenorecep-

tor agonist, supporting analgesic effects previously noted (Formukong *et al.*, 1988), and moderate 5-HT_{1A} antagonist suggesting antidepressant properties (Cascio *et al.*, 2010). Normally, CBG appears as a relatively low concentration intermediate in the plant, but recent breeding work has yielded cannabis chemotypes lacking in downstream enzymes that express 100% of their phytocannabinoid content as CBG (de Meijer and Hammond, 2005; de Meijer *et al.*, 2009a).

THCV (Table 1) is a propyl analogue of THC, and can modulate intoxication of the latter, displaying 25% of its potency in early testing (Gill *et al.*, 1970; Hollister, 1974). A recrudescence of interest accrues to this compound, which is a CB₁ antagonist at lower doses (Thomas *et al.*, 2005), but is a CB₁ agonist at higher doses (Pertwee, 2008). THCV produces weight loss, decreased body fat and serum leptin concentrations with increased energy expenditure in obese mice (Cawthorne *et al.*, 2007; Riedel *et al.*, 2009). THCV also demonstrates prominent anticonvulsant properties in rodent cerebellum and pyriform cortex (Hill *et al.*, 2010). THCV appears as a fractional component of many southern African cannabis chemotypes, although plants highly predominant in this agent have been produced (de Meijer, 2004). THCV recently demonstrated a CB₂-based ability to suppress carageenan-induced hyperalgesia and inflammation, and both phases of formalin-induced pain behaviour via CB₁ and CB₂ in mice (Bolognini *et al.*, 2010).

CBDV (Table 1), the propyl analogue of CBD, was first isolated in 1969 (Vollner *et al.*, 1969), but formerly received little investigation. Pure CBDV inhibits diacylglycerol lipase [50% inhibitory concentration (IC₅₀) 16.6 µM] and might decrease activity of its product, the endocannabinoid, 2-AG (De Petrocellis *et al.*, 2011). It is also anticonvulsant in rodent hippocampal brain slices, comparable to phenobarbitone and felbamate (Jones *et al.*, 2010).

Finally, CBN is a non-enzymatic oxidative by-product of THC, more prominent in aged cannabis samples (Merzouki and Mesa, 2002). It has a lower affinity for CB₁ (K_i 211.2 nM) and CB₂ (K_i 126.4 nM) (Rhee *et al.*, 1997); and was judged inactive when tested alone in human volunteers, but produced greater sedation combined with THC (Musty *et al.*, 1976). CBN demonstrated anticonvulsant (Turner *et al.*, 1980), anti-inflammatory (Evans, 1991) and potent effects against MRSA (MIC 1 µg·mL⁻¹). CBN is a TRPV2 (high-threshold thermosensor) agonist (EC 77.7 µM) of possible interest in treatment of burns (Qin *et al.*, 2008). Like CBG, it inhibits keratinocyte proliferation (Wilkinson and Williamson, 2007), independently of cannabinoid receptor effects. CBN stimulates the recruitment of quiescent mesenchymal stem cells in marrow (10 µM), suggesting promotion of bone formation (Scutt and Williamson, 2007) and inhibits breast cancer resistance protein, albeit at a very high concentration (IC₅₀ 145 µM) (Holland *et al.*, 2008).

Cannabis terpenoids: neglected entourage compounds?

Terpenoids are EO components, previously conceived as the quintessential fifth element, 'life force' or spirit (Schmidt,

2010), and form the largest group of plant chemicals, with 15–20 000 fully characterized (Langenheim, 1994). Terpenoids, not cannabinoids, are responsible for the aroma of cannabis. Over 200 have been reported in the plant (Hendriks *et al.*, 1975; 1977; Malingre *et al.*, 1975; Davalos *et al.*, 1977; Ross and ElSohly, 1996; Mediavilla and Steinemann, 1997; Rothschild *et al.*, 2005; Brenneisen, 2007), but only a few studies have concentrated on their pharmacology (McPartland and Pruitt, 1999; McPartland and Mediavilla, 2001a; McPartland and Russo, 2001b). Their yield is less than 1% in most cannabis assays, but they may represent 10% of trichome content (Potter, 2009). Monoterpenes usually predominate (limonene, myrcene, pinene), but these headspace volatiles (Hood *et al.*, 1973), while only lost at a rate of about 5% before processing (Gershenson, 1994), do suffer diminished yields with drying and storage (Turner *et al.*, 1980; Ross and ElSohly, 1996), resulting in a higher relative proportion of sesquiterpenoids (especially caryophyllene), as also often occurs in extracts. A 'phytochemical polymorphism' seems operative in the plant (Franz and Novak, 2010), as production favours agents such as limonene and pinene in flowers that are repellent to insects (Nerio *et al.*, 2010), while lower fan leaves express higher concentrations of bitter sesquiterpenoids that act as anti-feedants for grazing animals (Potter, 2009). Evolutionarily, terpenoids seem to occur in complex and variable mixtures with marked structural diversity to serve various ecological roles. Terpenoid composition is under genetic control (Langenheim, 1994), and some enzymes produce multiple products, again supporting Mechoulam's 'Law of Stinginess'. The particular mixture of mono- and sesquiterpenoids will determine viscosity, and in cannabis, this certainly is leveraged to practical advantage as the notable stickiness of cannabis exudations traps insects (McPartland *et al.*, 2000), and thus, combined with the insecticidal phytocannabinoid acids (Sirikantaramas *et al.*, 2005), provides a synergistic mechano-chemical defensive strategy versus predators.

As observed for cannabinoids, terpenoid production increases with light exposure, but decreases with soil fertility (Langenheim, 1994), and this is supported by the glasshouse experience that demonstrates higher yields if plants experience relative nitrogen lack just prior to harvest (Potter, 2004), favouring floral over foliar growth. EO composition is much more genetically than environmentally determined, however (Franz and Novak, 2010), and while cannabis is allogamous and normally requires repeat selective breeding for maintenance of quality, this problem may be practically circumvented by vegetative propagation of high-performance plants under controlled environmental conditions (light, heat and humidity) (Potter, 2009), and such techniques have proven to provide notable consistency to tight tolerances as Good Manufacturing Practice for any pharmaceutical would require (Fischedick *et al.*, 2010).

The *European Pharmacopoeia*, Sixth Edition (2007), lists 28 EOs (Pauli and Schilcher, 2010). Terpenoids are pharmacologically versatile: they are lipophilic, interact with cell membranes, neuronal and muscle ion channels, neurotransmitter receptors, G-protein coupled (odorant) receptors, second messenger systems and enzymes (Bowles, 2003; Buchbauer, 2010). All the terpenoids discussed herein are Generally Recognized as Safe, as attested by the US Food and Drug Admin-

istration as food additives, or by the Food and Extract Manufacturers Association and other world regulatory bodies. Germane is the observation (Adams and Taylor, 2010) (p. 193), 'With a high degree of confidence one may presume that EOs derived from food are likely to be safe'. Additionally, all the current entries are non-sensitizing to skin when fresh (Tisserand and Balacs, 1995; Adams and Taylor, 2010), but may cause allergic reactions at very low rates when oxidized (Matura *et al.*, 2005). For additional pharmacological data on other common cannabis terpenoids not discussed herein (1,8-cineole, also known as eucalyptol, pulegone, α -terpineol, terpineol-4-ol, p -cymene, borneol and Δ -3-carene), please see McPartland and Russo (2001b).

Are cannabis terpenoids actually relevant to the effects of cannabis? Terpenoid components in concentrations above 0.05% are considered of pharmacological interest (Adams and Taylor, 2010). Animal studies are certainly supportive (Buchbauer *et al.*, 1993). Mice exposed to terpenoid odours inhaled from ambient air for 1 h demonstrated profound effects on activity levels, suggesting a direct pharmacological effect on the brain, even at extremely low serum concentrations (examples: linalool with 73% reduction in motility at 4.22 ng·mL⁻¹, pinene 13.77% increase at trace concentration, terpineol 45% reduction at 4.7 ng·mL⁻¹). These levels are comparable to those of THC measured in humans receiving cannabis extracts yielding therapeutic effects in pain, or symptoms of multiple sclerosis in various randomized controlled trials (RCTs) (Russo, 2006; Huestis, 2007). Positive effects at undetectable serum concentrations with orange terpenes (primarily limonene, 35.25% increase in mouse activity), could be explainable on the basis of rapid redistribution and concentration in lipophilic cerebral structures. A similar rationale pertains to human studies (Komori *et al.*, 1995), subsequently discussed. Limonene is highly bioavailable with 70% human pulmonary uptake (Falk-Filipsson *et al.*, 1993), and a figure of 60% for pinene with rapid metabolism or redistribution (Falk *et al.*, 1990). Ingestion and percutaneous absorption is also well documented in humans (Jäger *et al.*, 1992): 1500 mg of lavender EO with 24.7% linalool (total 372 mg) was massaged into the skin of a 60 kg man for 10 min, resulting in a peak plasma concentration of 100 ng·mL⁻¹ at 19 min, and a half-life of 13.76 min in serum (Jäger *et al.*, 1992). EO mixtures (including limonene and pinene) also increase permeation of estradiol through mouse skin (Monti *et al.*, 2002).

Government-approved cannabis supplied to patients in national programmes in the Netherlands and Canada is gamma-irradiated to sterilize coliform bacteria, but the safety of this technique for a smoked and inhaled product has never been specifically tested. Gamma-radiation significantly reduced linalool titres in fresh cilantro (Fan and Sokorai, 2002), and myrcene and linalool in orange juice (Fan and Gates, 2001).

D-limonene, common to the lemon and other citrus EOs (Table 2), is the second most widely distributed terpenoid in nature (Noma and Asakawa, 2010), and is the precursor to other monoterpenoids (Figure 2) through species-specific synthetic schemes. Unfortunately, these pathways have not yet been investigated in cannabis. The ubiquity of limonene serves, perhaps, as a demonstration of convergent evolution that supports an important ecological role for this monoter-

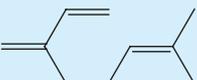

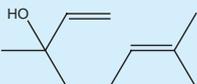

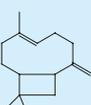

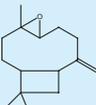

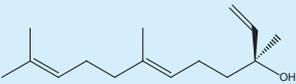

pene. Studies with varying methodology and dosing in citrus oils in mice suggest it to be a powerful anxiolytic agent (Carvalho-Freitas and Costa, 2002; Pultrini Ade *et al.*, 2006), with one EO increasing serotonin in the prefrontal cortex, and dopamine (DA) in hippocampus mediated via 5-HT_{1A} (Komiya *et al.*, 2006). Compelling confirmatory evidence in humans was provided in a clinical study (Komori *et al.*, 1995), in which hospitalized depressed patients were exposed to citrus fragrance in ambient air, with subsequent normalization of Hamilton Depression Scores, successful discontinuation of antidepressant medication in 9/12 patients and serum evidence of immune stimulation (CD4/8 ratio normalization). Limonene also produces apoptosis of breast cancer cells, and was employed at high doses in Phase II RCTs (Vigushin *et al.*, 1998). Subsequent investigation in cancer treatment has centred on its immediate hepatic metabolite, perillic acid, which demonstrates anti-stress effects in rat brain (Fukumoto *et al.*, 2008). A patent has been submitted, claiming that limonene effectively treats gastro-oesophageal reflux (Harris, 2010). Citrus EOs containing limonene proved effective against dermatophytes (Sanguinetti *et al.*, 2007; Singh *et al.*, 2010), and citrus EOs with terpenoid profiles resembling those in cannabis demonstrated strong radical scavenging properties (Choi *et al.*, 2000). As noted above, limonene is highly bioavailable (Falk-Filipsson *et al.*, 1993), and rapidly metabolized, but with indications of accumulation and retention in adipose tissues (e.g. brain). It is highly non-toxic (estimated human lethal dose 0.5–5 g·kg⁻¹) and non-sensitizing (Von Burg, 1995).

β -Myrcene is another common monoterpene in cannabis (Table 2) with myriad activities: diminishing inflammation via prostaglandin E-2 (PGE-2) (Lorenzetti *et al.*, 1991), and blocking hepatic carcinogenesis by aflatoxin (De-Oliveira *et al.*, 1997). Interestingly, myrcene is analgesic in mice, but this action can be blocked by naloxone, perhaps via the α -2 adrenoreceptor (Rao *et al.*, 1990). It is non-mutagenic in the Ames test (Gomes-Carneiro *et al.*, 2005). Myrcene is a recognized sedative as part of hops preparations (*Humulus lupulus*), employed to aid sleep in Germany (Bisset and Wichtl, 2004). Furthermore, myrcene acted as a muscle relaxant in mice, and potentiated barbiturate sleep time at high doses (do Vale *et al.*, 2002). Together, these data would support the hypothesis that myrcene is a prominent sedative terpenoid in cannabis, and combined with THC, may produce the 'couch-lock' phenomenon of certain chemotypes that is alternatively decried or appreciated by recreational cannabis consumers.

α -Pinene is a bicyclic monoterpene (Table 2), and the most widely encountered terpenoid in nature (Noma and Asakawa, 2010). It appears in conifers and innumerable plant EOs, with an insect-repellent role. It is anti-inflammatory via PGE-1 (Gil *et al.*, 1989), and is a bronchodilator in humans at low exposure levels (Falk *et al.*, 1990). Pinene is a major component of *Sideritis* spp. (Kose *et al.*, 2010) and *Salvia* spp. EOs (Ozek *et al.*, 2010), both with prominent activity against MRSA (*vide infra*). Beyond this, it seems to be a broad-spectrum antibiotic (Nissen *et al.*, 2010). α -Pinene forms the biosynthetic base for CB₂ ligands, such as HU-308 (Hanus *et al.*, 1999). Perhaps most compelling, however, is its activity as an acetylcholinesterase inhibitor aiding memory (Perry *et al.*, 2000), with an observed IC₅₀ of 0.44 mM (Miyazawa

Table 2

Cannabis Terpenoid Activity Table

Terpenoid	Structure	Commonly encountered in	Pharmacological activity (Reference)	Synergistic cannabinoid
Limonene		 Lemon	Potent AD/immunostimulant via inhalation (Komori <i>et al.</i> , 1995) Anxiolytic (Carvalho-Freitas and Costa, 2002; Pultrini Ade <i>et al.</i> , 2006) via 5-HT _{1A} (Komiya <i>et al.</i> , 2006) Apoptosis of breast cancer cells (Vigushin <i>et al.</i> , 1998) Active against acne bacteria (Kim <i>et al.</i> , 2008) Dermatophytes (Sanguinetti <i>et al.</i> , 2007; Singh <i>et al.</i> , 2010) Gastro-oesophageal reflux (Harris, 2010)	CBD CBD CBD, CBG CBD CBG THC
α -Pinene		 Pine	Anti-inflammatory via PGE-1 (Gil <i>et al.</i> , 1989) Bronchodilatory in humans (Falk <i>et al.</i> , 1990) Acetylcholinesterase inhibitor, aiding memory (Perry <i>et al.</i> , 2000)	CBD THC THC?, CBD
β -Myrcene		 Hops	Blocks inflammation via PGE-2 (Lorenzetti <i>et al.</i> , 1991) Analgesic, antagonized by naloxone (Rao <i>et al.</i> , 1990) Sedating, muscle relaxant, hypnotic (do Vale <i>et al.</i> , 2002) Blocks hepatic carcinogenesis by aflatoxin (de Oliveira <i>et al.</i> , 1997)	CBD CBD, THC THC CBD, CBG
Linalool		 Lavender	Anti-anxiety (Russo, 2001) Sedative on inhalation in mice (Buchbauer <i>et al.</i> , 1993) Local anesthetic (Re <i>et al.</i> , 2000) Analgesic via adenosine A _{2A} (Peana <i>et al.</i> , 2006) Anticonvulsant/anti-glutamate (Elisabetsky <i>et al.</i> , 1995) Potent anti-leishmanial (do Socorro <i>et al.</i> , 2003)	CBD, CBG? THC THC CBD CBD, THCV, CBDV ?
β -Caryophyllene		 Pepper	AI via PGE-1 comparable phenylbutazone (Basile <i>et al.</i> , 1988) Gastric cytoprotective (Tambe <i>et al.</i> , 1996) Anti-malarial (Campbell <i>et al.</i> , 1997) Selective CB ₂ agonist (100 nM) (Gertsch <i>et al.</i> , 2008) Treatment of pruritus? (Karsak <i>et al.</i> , 2007) Treatment of addiction? (Xi <i>et al.</i> , 2010)	CBD THC ? THC THC CBD
Caryophyllene Oxide		 Lemon balm	Decreases platelet aggregation (Lin <i>et al.</i> , 2003) Antifungal in onychomycosis comparable to ciclopiroxolamine and sulconazole (Yang <i>et al.</i> , 1999) Insecticidal/anti-feedant (Bettarini <i>et al.</i> , 1993)	THC CBC, CBG THCA, CBGA
Nerolidol		 Orange	Sedative (Binet <i>et al.</i> , 1972) Skin penetrant (Cornwell and Barry, 1994) Potent antimalarial (Lopes <i>et al.</i> , 1999, Rodrigues Goulart <i>et al.</i> , 2004) Anti-leishmanial activity (Arruda <i>et al.</i> , 2005)	THC, CBN – ? ?
Phytol		 Green tea	Breakdown product of chlorophyll Prevents Vitamin A teratogenesis (Arnhold <i>et al.</i> , 2002) \uparrow GABA via SSADH inhibition (Bang <i>et al.</i> , 2002)	– – CBG

Representative plants containing each terpenoid are displayed as examples to promote recognition, but many species contain them in varying concentrations. 5-HT, 5-hydroxytryptamine (serotonin); AD, antidepressant; AI, anti-inflammatory; CB₁/CB₂, cannabinoid receptor 1 or 2; GABA, gamma aminobutyric acid; PGE-1/PGE-2, prostaglandin E-1/prostaglandin E-2; SSADH, succinic semialdehyde dehydrogenase.

and Yamafuji, 2005). This feature could counteract short-term memory deficits induced by THC intoxication (*vide infra*).

D-Linalool is a monoterpenoid alcohol (Table 2), common to lavender (*Lavandula angustifolia*), whose psychotropic anxiolytic activity has been reviewed in detail (Russo, 2001). Interestingly, linalyl acetate, the other primary terpenoid in lavender, hydrolyses to linalool in gastric secretions (Bickers *et al.*, 2003). Linalool proved sedating to mouse activity on inhalation (Buchbauer *et al.*, 1991; Jirovetz *et al.*, 1992). In traditional aromatherapy, linalool is the likely suspect in the remarkable therapeutic capabilities of lavender EO to alleviate skin burns without scarring (Gattefosse, 1993). Pertinent to this, the local anaesthetic effects of linalool (Re *et al.*, 2000) are equal to those of procaine and menthol (Ghelardini *et al.*, 1999). Another explanation would be its ability to produce hot-plate analgesia in mice ($P < 0.001$) that was reduced by administration of an adenosine A_{2A} antagonist (Peana *et al.*, 2006). It is also anti-nociceptive at high doses in mice via ionotropic glutamate receptors (Batista *et al.*, 2008). Linalool demonstrated anticonvulsant and anti-glutamatergic activity (Elisabetsky *et al.*, 1995), and reduced seizures as part of *Ocimum basilicum* EO after exposure to pentylenetetrazole, picrotoxin and strychnine (Ismail, 2006). Furthermore, linalool decreased K^+ -stimulated glutamate release and uptake in mouse synaptosomes (Silva Brum *et al.*, 2001). These effects were summarized (Nunes *et al.*, 2010, p. 303): 'Overall, it seems reasonable to argue that the modulation of glutamate and GABA neurotransmitter systems are likely to be the critical mechanism responsible for the sedative, anxiolytic and anticonvulsant properties of linalool and EOs containing linalool in significant proportions'. Linalool also proved to be a powerful anti-leishmanial agent (do Socorro *et al.*, 2003), and as a presumed lavender EO component, decreased morphine opioid usage after inhalation versus placebo ($P = 0.04$) in gastric banding in morbidly obese surgical patients (Kim *et al.*, 2007).

β -Caryophyllene (Table 2) is generally the most common sesquiterpenoid encountered in cannabis (Mediavilla and Steinemann, 1997), wherein its evolutionary function may be due to its ability to attract insect predatory green lacewings, while simultaneously inhibiting insect herbivory (Langenheim, 1994). It is frequently the predominant terpenoid overall in cannabis extracts, particularly if they have been processed under heat for decarboxylation (Guy and Stott, 2005). Caryophyllene is common to black pepper (*Piper nigrum*) and Copaiba balsam (*Copaifera officinalis*) (Lawless, 1995). It is anti-inflammatory via PGE-1, comparable in potency to the toxic phenylbutazone (Basile *et al.*, 1988), and an EO containing it was on par with etodolac and indomethacin (Ozturk and Ozbek, 2005). In contrast to the latter agents, however, caryophyllene was a gastric cytoprotective (Tambe *et al.*, 1996), much as had been claimed in the past in treating duodenal ulcers in the UK with cannabis extract (Douthwaite, 1947). Caryophyllene may have contributed to anti-malarial effects as an EO component (Campbell *et al.*, 1997). Perhaps the greatest revelation regarding caryophyllene has been its demonstration as a selective full agonist at CB_2 (100 nM), the first proven phytocannabinoid beyond the cannabis genus (Gertsch *et al.*, 2008). Subsequent work has demonstrated that this dietary component produced anti-inflammatory analgesic activity at the lowest dose of

5 mg·kg⁻¹ in wild-type, but not CB_2 knockout mice (Gertsch, 2008). Given the lack of attributed psychoactivity of CB_2 agonists, caryophyllene offers great promise as a therapeutic compound, whether systemically, or in dermatological applications such as contact dermatitis (Karsak *et al.*, 2007). Sensitization reactions are quite rare, and probably due to oxidized product (Skold *et al.*, 2006).

Nerolidol is a sesquiterpene alcohol with sedative properties (Binet *et al.*, 1972), present as a low-level component in orange and other citrus peels (Table 2). It diminished experimentally induced formation of colon adenomas in rats (Wattenberg, 1991). It was an effective agent for enhancing skin penetration of 5-fluorouracil (Cornwell and Barry, 1994). This could be a helpful property in treating fungal growth, where it is also an inhibitor (Langenheim, 1994). It seems to have anti-protozoal parasite control benefits, as a potent antimalarial (Lopes *et al.*, 1999; Rodrigues Goulart *et al.*, 2004) and anti-leishmanial agent (Arruda *et al.*, 2005). Nerolidol is non-toxic and non-sensitizing (Lapczynski *et al.*, 2008).

Caryophyllene oxide (Table 2) is a sesquiterpenoid oxide common to lemon balm (*Melissa officinalis*), and to the eucalyptus, *Melaleuca stypheloides*, whose EO contains 43.8% (Farag *et al.*, 2004). In the plant, it serves as an insecticidal/anti-feedant (Bettarini *et al.*, 1993) and as broad-spectrum antifungal in plant defence (Langenheim, 1994). Analogously, the latter properties may prove therapeutic, as caryophyllene oxide demonstrated antifungal efficacy in a model of clinical onychomycosis comparable to ciclopiroxamine and sulconazole, with an 8% concentration affecting eradication in 15 days (Yang *et al.*, 1999). Caryophyllene oxide is non-toxic and non-sensitizing (Opdyke, 1983). This agent also demonstrates anti-platelet aggregation properties *in vitro* (Lin *et al.*, 2003). Caryophyllene oxide has the distinction of being the component responsible for cannabis identification by drug-sniffing dogs (Stahl and Kunde, 1973).

Phytol (Table 2) is a diterpene (McGinty *et al.*, 2010), present in cannabis extracts, as a breakdown product of chlorophyll and tocopherol. Phytol prevented vitamin A-induced teratogenesis by inhibiting conversion of retinol to a harmful metabolite, all-*trans*-retinoic acid (Arnhold *et al.*, 2002). Phytol increased GABA expression via inhibition of succinic semialdehyde dehydrogenase, one of its degradative enzymes (Bang *et al.*, 2002). Thus, the presence of phytol could account for the alleged relaxing effect of wild lettuce (*Lactuca sativa*), or green tea (*Camellia sinensis*), despite the latter's caffeine content.

Selected possibilities for phytocannabinoid-terpenoid synergy

Cannabis and acne

AEA simulates lipid production in human sebocytes of sebaceous glands at low concentrations, but induces apoptosis at higher levels, suggesting that this system is under ECS control (Dobrosi *et al.*, 2008). CBD 10–20 μ M did not affect basal lipid synthesis in SZ95 sebocytes, but did block such stimulation by AEA and arachidonate (Biro *et al.*, 2009). Higher doses of CBD (30–50 μ M) induced sebocyte apoptosis, which was augmented in the presence of AEA. The effect of CBD to increase

Ca⁺⁺ was blocked by ruthenium red, a TRP-inhibitor. RNA-mediated silencing of TRPV1 and TRPV3 failed to attenuate CBD effects, but experiments did support the aetiological role of TRPV4, a putative regulator of systemic osmotic pressure (T. Bíró, 2010, pers. comm.). Given the observed ability of CBD to be absorbed transcutaneously, it offers great promise to attenuate the increased sebum production at the pathological root of acne.

Cannabis terpenoids could offer complementary activity. Two citrus EOs primarily composed of limonene inhibited *Propionibacterium acnes*, the key pathogen in acne (MIC 0.31 $\mu\text{L}\cdot\text{mL}^{-1}$), more potently than triclosan (Kim *et al.*, 2008). Linalool alone demonstrated an MIC of 0.625 $\mu\text{L}\cdot\text{mL}^{-1}$. Both EOs inhibited *P. acnes*-induced TNF- α production, suggesting an adjunctive anti-inflammatory effect. In a similar manner, pinene was the most potent component of a tea-tree eucalyptus EO in suppression of *P. acnes* and *Staph* spp. in another report (Raman *et al.*, 1995).

Considering the known minimal toxicities of CBD and these terpenoids and the above findings, new acne therapies utilizing whole CBD-predominant extracts, via multi-targeting (Wagner and Ulrich-Merzenich, 2009), may present a novel and promising therapeutic approach that poses minimal risks in comparison to isotretinoin.

MRSA

MRSA accounted for 10% of cases of septicaemia and 18 650 deaths in the USA in 2005, a number greater than that attributable to human immunodeficiency virus/acquired immunodeficiency syndrome (Bancroft, 2007). Pure CBD and CBG powerfully inhibit MRSA (MIC 0.5–2 $\mu\text{g}\cdot\text{mL}^{-1}$) (Appendino *et al.*, 2008).

Amongst terpenoids, pinene was a major component of *Sideritis erythrantha* EO that was as effective against MRSA and other antibiotic-resistant bacterial strains as vancomycin and other agents (Kose *et al.*, 2010). A *Salvia rosifolia* EO with 34.8% pinene was also effective against MRSA (MIC 125 $\mu\text{g}\cdot\text{mL}^{-1}$). The ability of monoterpenoids to enhance skin permeability and entry of other drugs may further enhance antibiotic benefits (Wagner and Ulrich-Merzenich, 2009).

Given that CBG can be produced in selected cannabis chemotypes (de Meijer and Hammond, 2005; de Meijer *et al.*, 2009a), with no residual THC as a possible drug abuse liability risk, a whole plant extract of a CBG-chemotype also expressing pinene would seem to offer an excellent, safe new anti-septic agent.

Psychopharmacological applications: depression, anxiety, insomnia, dementia and addiction

Scientific investigation of the therapeutic application of terpenoids in psychiatry has been hampered by methodological concerns, subjective variability of results and a genuine dearth of appropriate randomized controlled studies of high quality (Russo, 2001; Bowles, 2003; Lis-Balchin, 2010). The

same is true of phytocannabinoids (Fride and Russo, 2006). Abundant evidence supports the key role of the ECS in mediating depression (Hill and Gorzalka, 2005a,b), as well as anxiety, whether induced by aversive stimuli, such as post-traumatic stress disorder (Marsicano *et al.*, 2002) or pain (Hohmann *et al.*, 2005), and psychosis (Giuffrida *et al.*, 2004). With respect to the latter risk, the presence of CBD in smoked cannabis based on hair analysis seems to be a mitigating factor reducing its observed incidence (Morgan and Curran, 2008). A thorough review of cannabis and psychiatry is beyond the scope of this article, but several suggestions are offered with respect to possible therapeutic synergies operative with phytocannabinoids-terpenoid combinations. While the possible benefits of THC on depression remain controversial (Denson and Earleywine, 2006), much less worrisome would be CBD- or CBG-predominant preparations. Certainly the results obtained in human depression solely with a citrus scent (Komori *et al.*, 1995), strongly suggest the possibility of synergistic benefit of a phytocannabinoid-terpenoid preparation. Enriched odour exposure in adult mice induced olfactory system neurogenesis (Rocheffort *et al.*, 2002), an intriguing result that could hypothetically support plasticity mechanisms in depression (Delgado and Moreno, 1999), and similar hypotheses with respect to the ECS in addiction treatment (Gerdeeman and Lovinger, 2003). Phytocannabinoid-terpenoid synergy might theoretically apply.

The myriad effects of CBD on 5-HT_{1A} activity provide a strong rationale for this and other phytocannabinoids as base compounds for treatment of anxiety. Newer findings, particularly imaging studies of CBD in normal individuals in anxiety models (Fusar-Poli *et al.*, 2009; 2010; Crippa *et al.*, 2010) support this hypothesis. Even more compelling is a recent randomized control trial of pure CBD in patients with social anxiety disorder with highly statistical improvements over placebo in anxiety and cognitive impairment (Crippa *et al.*, 2011). Addition of anxiolytic limonene and linalool could contribute to the clinical efficacy of a CBD extract.

THC was demonstrated effective in a small crossover clinical trial versus placebo in 11 agitated dementia patients with Alzheimer's disease (Volicer *et al.*, 1997). THC was also observed to be an acetylcholinesterase inhibitor in its own right, as well as preventing amyloid β -peptide aggregation in that disorder (Eubanks *et al.*, 2006). Certainly, the anti-anxiety and anti-psychotic effects of CBD may be of additional benefit (Zuardi *et al.*, 1991; 2006; Zuardi and Guimaraes, 1997). A recent study supports the concept that CBD, when present in significant proportion to THC, is capable of eliminating induced cognitive and memory deficits in normal subjects smoking cannabis (Morgan *et al.*, 2010b). Furthermore, CBD may also have primary benefits on reduction of β -amyloid in Alzheimer's disease (Iuvone *et al.*, 2004; Esposito *et al.*, 2006a,b). Psychopharmacological effects of limonene, pinene and linalool could putatively extend benefits in mood in such patients.

The effects of cannabis on sleep have been reviewed (Russo *et al.*, 2007), and highlight the benefits that can accrue in this regard, particularly with respect to symptom reduction permitting better sleep, as opposed to a mere hypnotic effect. Certainly, terpenoids with pain-relieving, anti-anxiety or sedative effects may supplement such activity, notably, caryophyllene, linalool and myrcene.

The issue of cannabis addiction remains controversial. Some benefit of oral THC has been noted in cannabis withdrawal (Hart *et al.*, 2002; Haney *et al.*, 2004). More intriguing, perhaps, are claims of improvement on other substance dependencies, particularly cocaine (Labigalini *et al.*, 1999; Dreher, 2002). The situation with CBD is yet more promising. CBD and THC at doses of 4 mg·kg⁻¹ i.p. potentiated extinction of cocaine- and amphetamine-induced conditioned place preference in rats, and CBD produced no hedonic effects of its own (Parker *et al.*, 2004). CBD 5 mg·kg⁻¹·d⁻¹ in rats attenuated heroin-seeking behaviour by conditioned stimuli, even after a lapse of 2 weeks (Ren *et al.*, 2009). A suggested mechanism of CBD relates to its ability to reverse changes in α -amino-3-hydroxyl-5-methyl-4-isoxazole-propionate glutamate and CB₁ receptor expression in the nucleus accumbens induced by heroin. The authors proposed CBD as a treatment for heroin craving and addiction relapse. A recent study demonstrated the fascinating result that patients with damage to the insula due to cerebrovascular accident were able to quit tobacco smoking without relapse or urges (Naqvi *et al.*, 2007), highlighting this structure as a critical neural centre mediating addiction to nicotine. Further study has confirmed the role of the insula in cocaine, alcohol and heroin addiction (Naqvi and Bechara, 2009; Naqvi and Bechara, 2010). In a provocative parallel, CBD 600 mg p.o. was demonstrated to deactivate functional magnetic resonance imaging (fMRI) activity in human volunteers in the left insula versus placebo ($P < 0.01$) without accompanying sedation or psychoactive changes (Borgwardt *et al.*, 2008), suggesting the possibility that CBD could act as a pharmaceutical surrogate for insular damage in exerting an anti-addiction therapeutic benefit. Human studies have recently demonstrated that human volunteers smoking cannabis with higher CBD content reduced their liking for drug-related stimuli, including food (Morgan *et al.*, 2010a). The authors posited that CBD can modulate reinforcing properties of drugs of abuse, and help in training to reduce relapse to alcoholism. A single case report of a successful withdrawal from cannabis dependency utilizing pure CBD treatment was recently published (Crippa *et al.*, 2010).

Perhaps terpenoids can provide adjunctive support. In a clinical trial, 48 cigarette smokers inhaling vapour from an EO of black pepper (*Piper nigrum*), a mint-menthol mixture or placebo (Rose and Behm, 1994). Black pepper EO reduced nicotine craving significantly ($P < 0.01$), an effect attributed to irritation of the bronchial tree, simulating the act of cigarette smoking, but without nicotine or actual burning of material. Rather, might not the effect have been pharmacological? The terpenoid profile of black pepper suggests possible candidates: myrcene via sedation, pinene via increased alertness, or especially caryophyllene via CB₂ agonism and a newly discovered putative mechanism of action in addiction treatment.

CB₂ is expressed in dopaminergic neurones in the ventral tegmental area and nucleus accumbens, areas mediating addictive phenomena (Xi *et al.*, 2010). Activation of CB₂ by the synthetic agonist JWH144 administered systemically, intranasally, or by microinjection into the nucleus accumbens in rats inhibited DA release and cocaine self-administration. Caryophyllene, as a high-potency selective CB₂ agonist (Gertsch *et al.*, 2008), would likely produce

similar effects, and have the advantage of being a non-toxic dietary component. All factors considered, CBD, with caryophyllene, and possibly other adjunctive terpenoids in the extract, offers significant promise in future addiction treatment.

Taming THC: cannabis entourage compounds as antidotes to intoxication

Various sources highlight the limited therapeutic index of pure THC, when given intravenously (D'Souza *et al.*, 2004) or orally (Favrat *et al.*, 2005), especially in people previously naïve to its effects. Acute overdose incidents involving THC or THC-predominant cannabis usually consist of self-limited panic reactions or toxic psychoses, for which no pharmacological intervention is generally necessary, and supportive counselling (reassurance or 'talking down') is sufficient to allow resolution without sequelae. CBD modulates the psychoactivity of THC and reduces its adverse event profile (Russo and Guy, 2006), highlighted by recent results above described. Could it be, however, that other cannabis components offer additional attenuation of the less undesirable effects of THC? History provides some clues.

In 10th century Persia, Al-Razi offered a prescription in his *Manafi al-agdhiya wa-daf madarri-ha* (p. 248), rendered (Lozano, 1993, p. 124; translation EBR) ' – and to avoid these harms {from ingestion of cannabis seeds or hashish}, one should drink fresh water and ice or eat any acid fruits'. This concept was repeated in various forms by various authorities through the ages, including ibn Sina (ibn Sina (Avicenna), 1294), and Ibn al-Baytar (ibn al-Baytar, 1291), until O'Shaughnessy brought Indian hemp to Britain in 1843 (O'Shaughnessy, 1843). Robert Christison subsequently cited lemon (Figure 3A) as an antidote to acute intoxication in numerous cases (Christison, 1851) and this excerpt regarding morning-after residua (Christison, 1848) (p. 973):

Next morning there was an ordinary appetite, much torpidity, great defect and shortness of memory, extreme apparent protraction of time, but no peculiarity of articulation or other effect; and these symptoms lasted until 2 P.M., when they ceased entirely in a few minutes after taking lemonade.

Literary icons on both sides of the Atlantic espoused similar support for the citrus cure in the 19th century, notably Bayard Taylor after travels in Syria (Taylor, 1855), and Fitzhugh Ludlow after his voluntary experiments with ever higher cannabis extract doses in the USA (Ludlow, 1857). The sentiment was repeated by Calkins (1871), who noted the suggestion of a friend in Tunis that lemon retained the confidence of cure of overdoses by cannabis users in that region. This is supported by the observation that lemon juice, which normally contains small terpenoid titres, is traditionally enhanced in North Africa by the inclusion in drinks of the limonene-rich rind, as evidenced by the recipe for *Agua Limón* from modern Morocco (Morse and Mamane, 2001). In his comprehensive review of cannabis in the first half of the 20th century, Walton once more supported its prescription (Walton, 1938).

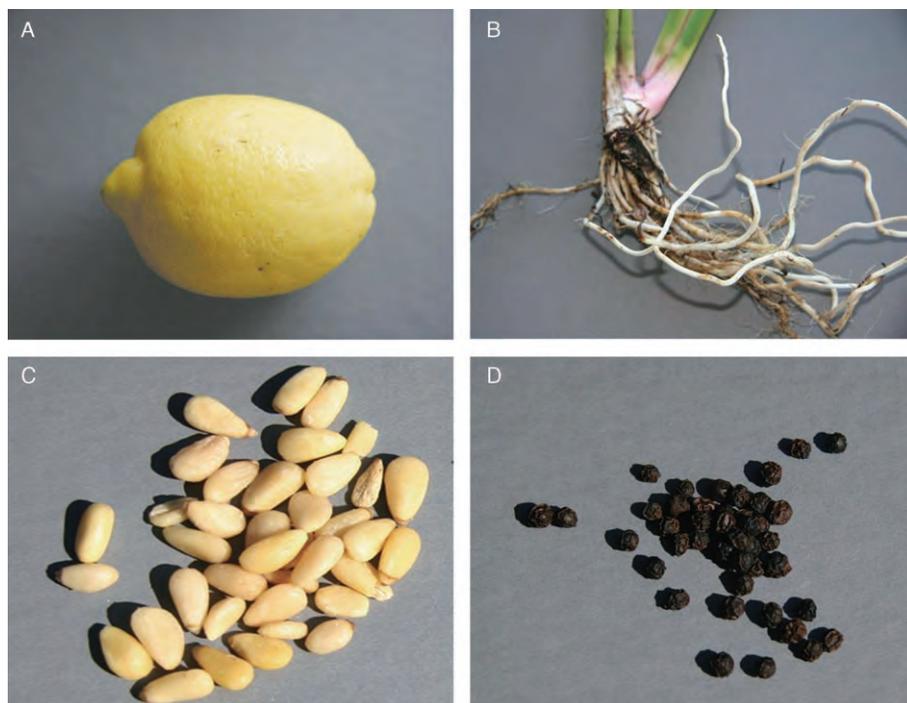

Figure 3

Ancient cannabis antidotes. (A) Lemon (*Citrus limon*). (B) Calamus plant roots (*Acorus calamus*). (C) Pine nuts (*Pinus* spp.). (D) Black pepper (*Piper nigrum*).

Another traditional antidote to cannabis employing *Acorus calamus* (Figure 3B) is evident from the Ayurvedic tradition of India (Lad, 1990, p. 131):

Calamus root is the best antidote for the ill effects of marijuana. . . . if one smokes a pinch of calamus root powder with the marijuana, this herb will completely neutralize the toxic side effects of the drug.

This claim has gained credence, not only through force of anecdotal accounts that abound on the Internet, but with formal scientific case reports and scientific analysis (McPartland *et al.*, 2008) documenting clearer thinking and improved memory with the cannabis–calamus combination, and with provision of a scientific rationale: calamus contains beta-asarone, an acetylcholinesterase inhibitor with 10% of the potency of physostigmine (Mukherjee *et al.*, 2007). Interestingly, the cannabis terpenoid, α -pinene, also has been characterized as a potent inhibitor of that enzyme (Miyazawa and Yamafuji, 2005), bolstering the hypothesis of a second antidote to THC contained in cannabis itself. Historical precedents also support pinene in this pharmacological role.

In the first century, Pliny wrote of cannabis in his *Natural History*, Book XXIV (Pliny, 1980, p. 164):

The gelotophyllis [‘leaves of laughter’ = cannabis] grows in Bactria and along the Borysthenes. If this be taken in myrrh and wine all kinds of phantoms beset the mind, causing laughter which persists until the kernels of pine-nuts are taken with pepper and honey in palm wine.

Of the components, palm wine is perhaps the most mysterious. Ethanol does not reduce cannabis intoxication (Mello

and Mendelson, 1978). However, ancient wines were stored in clay pots or goatskins, and required preservation, usually with addition of pine tar or terebinth resin (from *Pistacia* spp.; McGovern *et al.*, 2009). Pine tar is rich in pinene, as is terebinth resin (from *Pistacia terebinthus*; Tsokou *et al.*, 2007), while the latter also contains limonene (Duru *et al.*, 2003). Likewise, the pine nuts (Figure 3C) prescribed by Pliny the Elder harbour pinene, along with additional limonene (Salvadeo *et al.*, 2007). Al-Ukbari also suggested pistachio nuts as a cannabis antidote in the 13th century (Lozano, 1993), and the ripe fruits of *Pistacia terebinthus* similarly contain pinene (Couladis *et al.*, 2003). The black pepper (Figure 3D), might offer the mental clarity afforded by pinene, sedation via myrcene and helpful contributions by β -caryophyllene. The historical suggestions for cannabis antidotes are thus supported by modern scientific rationales for the claims, and if proven experimentally would provide additional evidence of synergy (Berenbaum, 1989; Wagner and Ulrich-Merzenich, 2009).

Conclusions and suggestions for future study

Considered ensemble, the preceding body of information supports the concept that selective breeding of cannabis chemotypes rich in ameliorative phytocannabinoid and terpenoid content offer complementary pharmacological activities that may strengthen and broaden clinical applications and improve the therapeutic index of cannabis extracts containing THC, or other base phytocannabinoids. Psychopharmacological and dermatological indications show the greatest promise.

One important remaining order of business is the elucidation of mono- and sesquiterpenoid biosynthetic pathways in cannabis, as has been achieved previously in other species of plants (Croteau, 1987; Gershenzon and Croteau, 1993; Bohlmann *et al.*, 1998; Turner *et al.*, 1999; Trapp and Croteau, 2001).

Various cannabis component combinations or cannabis extracts should be examined via high throughput pharmacological screening where not previously accomplished. Another goal is the investigation of the biochemical targets of the cannabis terpenoids, along with their mechanisms of action, particularly in the central nervous system. Possible techniques for such research include radio-labelling of select agents in animals with subsequent necropsy. On a molecular level, investigation of terpenoid changes to phytocannabinoid signal transduction and trafficking may prove illuminating. While it is known that terpenoids bind to odorant receptors in the nasal mucosa (Friedrich, 2004) and proximal olfactory structures (Barnea *et al.*, 2004), it would be essential to ascertain if direct effects in limbic or other cerebral structures are operative. Given that farnesyl pyrophosphate is a sesquiterpenoid precursor and the most potent endogenous agonist yet discovered for GPR92 (McHugh *et al.*, 2010), *in silico* studies attempting to match minor cannabinoids and terpenoids to orphan GPCRs may prove fruitful. Behavioural assays of agents in animal models may also provide clues. Simple combinations of phytocannabinoids and terpenoids may demonstrate synergy as antibiotics if MICs are appreciably lowered (Wagner and Ulrich-Merzenich, 2009). Ultimately, fMRI and single photon emission computed tomography studies in humans, with simultaneous drug reaction questionnaires and psychometric testing employing individual agents and phytocannabinoid-terpenoid pairings via vaporization or oromucosal application, would likely offer safe and effective methods to investigate possible interactions and synergy.

Should positive outcomes result from such studies, phytopharmaceutical development may follow. The development of zero-cannabinoid cannabis chemotypes (de Meijer *et al.*, 2009b) has provided extracts that will facilitate discernment of the pharmacological effects and contributions of different fractions. Breeding work has already resulted in chemotypes that produce 97% of monoterpenoid content as myrcene, or 77% as limonene (E. de Meijer, pers. comm.). Selective cross-breeding of high-terpenoid- and high-phytocannabinoid-specific chemotypes has thus become a rational target that may lead to novel approaches to such disorders as treatment-resistant depression, anxiety, drug dependency, dementia and a panoply of dermatological disorders, as well as industrial applications as safer pesticides and antiseptics. A better future via cannabis phytochemistry may be an achievable goal through further research of the entourage effect in this versatile plant that may help it fulfil its promise as a pharmacological treasure trove.

Acknowledgements

The author offers appreciation to the following individuals, who provided materials and/or consultation: David Potter, Etienne de Meijer, John McPartland, David Watson, Rob Clarke, Indalecio Lozano, Tamas Bíró, José Crippa, Roger

Pertwee, Colin Stott, Vincenzo Di Marzo, Luciano De Petrocellis, Patrick McGovern, John Riddle and Elisaldo Carlini. Most of all, I would like to thank Raphael Mechoulam for his example, guidance, friendship, a life of good works and for listening to many 'crazy ideas'.

Conflict of Interest

The author is a Senior Medical Advisor to GW Pharmaceuticals and serves as a consultant.

Patient-Reported Symptom Relief
Following Medical Cannabis
Consumption.
Front. Pharmacol. 9:916.
doi: 10.3389/fphar.2018.00916

Background: The Releaf App™ mobile software application (app) data was used to measure self-reported effectiveness and side effects of medical cannabis used under naturalistic conditions.

Methods: Between 5/03/2016 and 12/16/2017, 2,830 Releaf App™ users completed 13,638 individual sessions self-administering medical cannabis and indicated their primary health symptom severity rating on an 11-point (0–10) visual analog scale in real-time prior to and following cannabis consumption, along with experienced side effects.

Results: Releaf App™ responders used cannabis to treat myriad health symptoms, the most frequent relating to pain, anxiety, and depressive conditions. Significant symptom severity reductions were reported for all the symptom categories, with mean reductions between 2.8 and 4.6 points (ds ranged from 1.29–2.39, $ps < 0.001$). On average, higher pre-dosing symptom levels were associated with greater reported symptom relief, and users treating anxiety or depression-related symptoms reported significantly more relief ($ps < 0.001$) than users with pain symptoms. Of the 42 possible side effects, users were more likely to indicate and showed a stronger correlation between symptom relief and experiences of positive (94% of sessions) or a context-specific side effects (76%), whereas negative side effects (60%) were associated with lessened, yet still significant symptom relief and were more common among patients treating a depressive symptom relative to patients treating anxiety and pain-related conditions.

Conclusion: Patient-managed cannabis use is associated with clinically significant improvements in self-reported symptom relief for treating a wide range of health conditions, along with frequent positive and negative side effects.

Keywords: pain, anxiety, depression, cannabis, marijuana, quality of life, symptom management, side effects

INTRODUCTION

Medicinal cannabis use is expanding rapidly in the United States, with thousands of new users daily, particularly older patients and people with significant health concerns, treating many different symptoms (Centers for Disease Control and Prevention, 2016; Han et al., 2016). Most patients have a wide variety of medicinal cannabis products available to them, ranging from traditional flower to edibles and tinctures. Naturalistic observational studies are generally well-suited for capturing how patients manage their treatment decisions in real-life, and how patient-managed cannabis therapies may contribute to symptom relief and potential side effects from use. Observational research designs allow patients to use the myriad *Cannabis* strains and cannabis-derived formulations (e.g., concentrates, tinctures, edibles, topicals, suppositories, toothpaste) made at home and/or commercially available and widely used in society, and can incorporate the breadth of health conditions for which medical cannabis has been sanctioned for use at the state-level. Lastly, observational studies also circumvent research barriers associated with cannabis' Schedule I status under United States federal law, which makes randomized controlled trials (RCTs) challenging to conduct (Stith and Vigil, 2016; National Academies of Sciences, Engineering, and Medicine, 2017).

Since its release in 2016, the commercially developed Releaf App™ application (app; Releaf App, 2018) has been the only publically available, incentive-free patient educational software program designed for recording how individual cannabis usage sessions may correspond to immediate changes in primary symptom intensity levels and experienced side effects. This electronic assessment tool enables patients to monitor and manage their cannabis consumption decisions under naturalistic conditions while avoiding the limitations of retrospective survey collection methods (e.g., memory bias, social desirability effects). We used the Releaf App™ repository of over 2,830 patients and 13,368 individual cannabis administration sessions to examine two research questions: How does cannabis used under naturalistic conditions affect user-experienced symptom relief and side effects? Does the magnitude of experienced symptom relief and the prevalence of side effects vary across symptom categories? The results have clinical relevance for understanding how patient-managed medical cannabis therapies may correspond to changes in symptom intensity and potential side effects among people using cannabis for treating distinct health conditions (Hill and Weiss, 2016; Rubin, 2017).

MATERIALS AND METHODS

Study Design

A naturalistic observational research design, approved by the Institutional Review Board at the University of New Mexico, was used to analyze the Releaf App™ user-submitted data recorded between 5/03/2016 and 12/16/2017. Releaf App™ is a cross-platform (iOS and Android) mobile and tablet app backed by a secure cloud programming interface for capturing, processing, and storing anonymized user data. Out of 4,369 total

users and 23,373 user interactions, we included only cannabis consumption sessions with reported starting symptom levels greater than 0 (on a 0–10, 11-point scale) and ending symptom levels reported within 90 min of the start of the session, resulting in a final sample of 2,830 users and 13,638 individual sessions for analysis. The Releaf App™ measures 27 possible negative symptom categories and 42 possible side effects. Symptoms were ultimately derived from qualifying conditions across medical cannabis programs in the United States, along with a few suggested by dispensaries and patients. The side effects (called “feelings” within the app) were crowd-sourced among Releaf App™ developers, beta testers, dispensaries, and patients, and included 19 positive, 12 negative, and 11 context-specific side effects available for selection. **Supplementary Tables S1, S2** in the **Supplemental Appendix** provide descriptive statistics for all symptoms and side effects.

User sessions consist of a series of electronic instructions for recording characteristics of the cannabis medication (e.g., strain, potency, formulation), pre-dosing symptom severity rating along an 11-point visual analog facial pain scale from 0 (no detectable symptom level) to 10 (severe), the timing of cannabis consumption, a post-dosing symptom severity rating, and the option to indicate any of the 42 listed side effects at any time during the session. Among our primary sample of users, 2,332 users reported side effects during 10,535 sessions.

Study Outcomes

Our goal was to calculate changes in patient-perceived symptom severity, the prevalence of positive and negative side effects associated with cannabis consumption, and whether the reported-effects differs depending on the symptom for which users were seeking treatment. We measured changes in symptom relief by subtracting the ending symptom level from the beginning symptom (possible range from –10 to 10). (**Supplementary Figure S1** in the **Supplemental Appendix** provides a frequency table for each level of symptom relief.) Side effects were recorded as {0,1} variables for whether the user selected that side effect from the menu. We categorize the side effects as positive, negative, or context-specific and then convert these categories of side effects into {0,1} outcomes, count outcomes and outcomes measuring the portion of total available side effects in that category a user selected.

Statistical Analysis

We use means comparisons and least squares regression models to estimate the absolute and relative symptom changes and side effect profiles resulting from the cannabis user sessions. We also created an *adjusted symptom relief profile score*, the mean change in symptom levels plus the absolute number of listed negative side effects, to provide a relative metric of cost-benefit tradeoffs associated with cannabis use. Due to the small user counts for some of the reported symptoms, the large number of possible symptoms, and to facilitate interpretation in our regression analysis, we aggregate the most commonly reported symptoms across three broad symptom categories that included: Anxiety Symptoms (agitation/irritability, anxiety, insomnia, stress, and muscle spasms), Pain Symptoms (ten pain categories), and

Depression Symptoms (depression). The remaining types of symptoms are less frequently reported or not clearly categorized. We also report the full regression results for the three categories of side effects (positive, negative, and context-specific) and the sign for regressions of symptom relief on the full range of 42 side effects. Standard errors are clustered at the user level to control for heteroskedasticity and arbitrary correlation.

RESULTS

Figure 1 shows the starting and ending symptom severity levels, the change in levels, the Cohen's d of the difference, and the adjusted symptom relief profile score for each of the 27 discrete symptom categories. For all symptoms, the null hypothesis that the starting symptom severity level is less than or equal to the ending symptom severity can be rejected at the $p < 0.001$ level. Using the adjusted symptom relief measure (symptom relief plus negative side effects), all but users with convulsions, dizziness, excessive appetite, or tremors experienced a net improvement in their symptom severity levels. Even for these symptoms, the adjusted mean symptom relief score still indicates a net benefit from use and the lack of a statistically significant change likely relates more to the small number of observations rather than the lack of an effect, given that these symptoms together constituted less than 3% of users and less than 1% of our sample. For all other symptoms, the null hypothesis of an increase or no change in the adjusted symptom relief score can be rejected at the $p < 0.001$ level.

Table 1 provides additional information on starting and ending symptom severity levels, mean symptom relief, and

the prevalence of positive, negative, and context-specific side effects by the aggregated symptom categories (anxiety, pain, and depression symptoms). For completeness, we include a fifth column including the remaining discrete symptom categories which did not fall under the three aggregated symptom categories. Little variation exists in starting and ending symptom levels and the symptom relief experienced, with the average user reporting a symptom decrease of 3.7. With regards to side effects, those with depression have a higher probability of reporting negative or context-specific side effects. The most common positive side effects are “relaxed” (64%), “peaceful” (54%), and “comfy” (38%), the most common negative side effects are “dry mouth” (23%), “foggy” (22%), and “forgetful” (13%) and the most common context-specific side effects are “high” (32%), “sleepy” (27%), and “thirsty” (27%).

Table 2 examines how symptom relief varies across the broader symptom categories, with the constant representing the mean adjusted symptom change for the omitted category, (patients with pain-related symptoms). The first two regressions shown in **Table 2** indicate that people with anxiety and depression report greater relief from using cannabis than people with chronic pain, and users with higher starting symptom levels report greater symptom relief. (The effects of cannabis on anxiety and depression symptoms are not statistically different from each other, although they are both greater than the effect of cannabis on pain-related symptoms). Negative responses or increases in symptom severity do occur, but the intercept in combination with the starting symptom level predicts that increases in symptom severity levels predominantly occur among users with starting symptoms equal to one. The third column in **Table 2** shows that cannabis is more effective for anxiety and depression symptoms than for pain-related symptoms among patients reporting higher

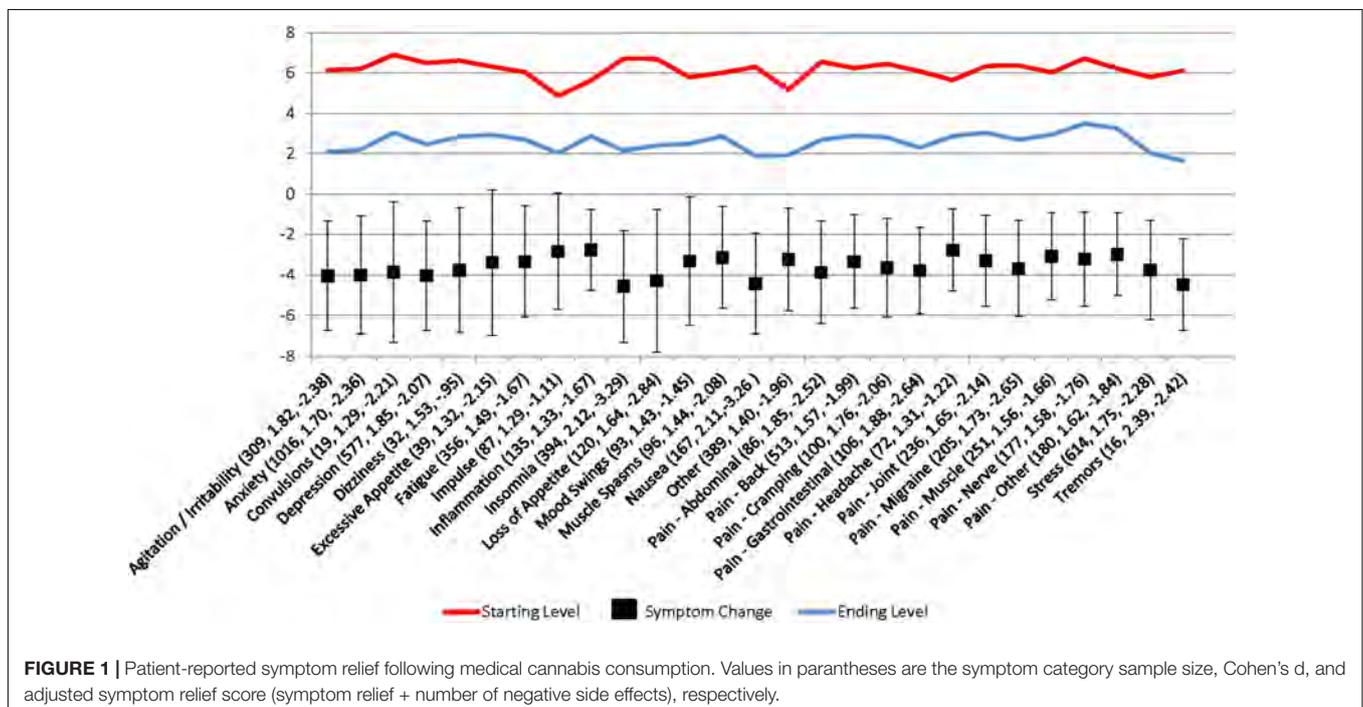

TABLE 1 | Descriptive statistics – symptom levels and experienced side effects.

	Overall	Anxiety symptoms	Pain symptoms	Depression symptoms	Other

Symptoms designated as treatable with benzodiazepines (Anxiety Symptoms) include agitation/irritability, anxiety, insomnia, muscle spasms, and stress. Symptoms associated with Opioid treatment (Pain Symptoms) include all ten pain conditions. Depression is the only symptom designated as treatable with antidepressants.

TABLE 2 | Reported symptom relief for users treating anxiety, pain, and depression.

	Outcome = symptom relief		
	(1)	(2)	(3)
Constant (opioid mean)	-3.309*** (-3.459 to -3.160)	1.120*** (0.804 to 1.436)	0.355** (0.034 to 0.675)
Anxiety symptoms	-0.704*** (-0.944 to -0.465)	-0.763*** (-0.953 to -0.574)	0.365* (-0.062 to 0.792)
Depression symptoms	-0.723*** (-1.060 to -0.385)	-0.563*** (-0.817 to -0.310)	0.643* (-0.021 to 1.308)

Each column represents a separate regression. The omitted category is symptoms treatable with an opioid medication. Robust standard errors are clustered at the user level. The coefficients are reported in line with the variable names with confidence intervals below. Coefficients are reported with 95% Confidence Intervals below. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.10$.

symptom severity levels (A graphical representation of this relationship is presented in **Supplementary Figure S2** in the **Supplemental Appendix**).

In order to take advantage of the full range of symptom categories available to Releaf AppTM users, we also ran regressions including dummy variables for each of the symptoms, using back pain as the omitted category. After controlling for starting symptom level, clustering the standard errors at the user level, and using a statistical significance threshold of $p < 0.05$, our results indicate that patients report greater symptom relief for treating agitation/irritability, anxiety, depression, excessive

appetite, insomnia, loss of appetite, nausea, gastrointestinal pain, stress, and tremors than they do for treating back pain. Patients reported less symptom relief for treating impulsivity, headache, and nerve pain as compared to relief for treating back pain. The symptom relief for the other discrete symptom categories was indistinguishable from the reported symptom relief associated with back pain.

Table 3 explores whether patients using cannabis to treat pain, anxiety, or depressive symptoms differ in their experiences of positive, negative, or context-specific side effects. Chows tests (Chow, 1960) showed that users with anxiety-related symptoms

The first panel uses {0,1} outcomes for the presence of side effects in each category, the second uses the count of side effects reported by category, and the third uses the number of reported side effects for each category divided by the total number of possible side effects a user could select in that category. Robust standard errors are clustered at the user level. Coefficients are reported with 95% Confidence Intervals below. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.10$.

are no more or less likely than those with pain symptoms to report any of the three categories of side effects. Individuals with depression, however, are more likely to report negative and context-specific side effects than positive side effects. Higher starting symptom levels are also associated with more negative or context-specific side effect reporting and this relationship persists whether the side effect profile is defined as any of the side effects from that category of side effects, the number of side effects by category, or the percent of possible side effects in a category.

Table 4 tests whether different types of side effects are associated with differences in symptom relief. The results are robust across specifications; reporting positive or context-specific side effects is associated with greater symptom relief, while reporting negative side effects is associated with less symptom relief. For example, based on Column (4), a person with a starting symptom level of 5 who reports 100% of negative side effects would experience a 0.5 point increase in symptom severity on a 1–10 scale, whereas a similar user who does not report any negative side effects would experience 2.2 points of symptom

relief, highlighting the importance of adjusting for starting symptom severity level and side effect profiles when evaluating the overall effectiveness of cannabis as a treatment modality.

DISCUSSION

This is the largest observational study to measure immediate changes in patient-reported symptom severity ratings and experienced side effects in real-time from using cannabis under naturalistic conditions. Building on previous research showing that cannabis may be an effective substitute for opioids (Hurd, 2016; Vigil et al., 2017) and other classes of prescription medications (e.g., sedatives; Piper et al., 2017; Stith et al., 2017), we provide evidence that cannabis is used to treat many different types of symptoms for which conventional pharmaceutical medications are typically prescribed, and that the magnitude of reported symptom relief and side effect profiles from using cannabis varies for people with different symptoms.

TABLE 4 | Association of positive, negative, and context-specific side effects with symptom relief.

	Outcome = symptom relief			
	(1)	(2)	(3)	(4)
	Any {0,1}		Percent of possible in category	
Positive	−1.100*** (−1.360 to −0.841)	−1.344*** (−1.578 to −1.111)	−2.345*** (−3.046 to −1.643)	−2.899*** (−3.653 to −2.145)

R ²	0.015	0.349	0.036	0.376

The first two columns measure use the existence of each category of side effect as independent variables, while the second two columns use the percent of possible in each category of side effects. The second and fourth columns include the starting symptom level. In all four regressions, the outcome is the change in symptom severity. Robust standard errors are clustered at the user level. Coefficients are reported with 95% Confidence Intervals below. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.10$.

The Releaf App™ users consumed cannabis to treat a wide range of health symptoms, the most frequent relating to pain, anxiety, or depression. Clinically and statistically significant reductions in patient-reported symptom severity levels existed in every single symptom category, suggesting that cannabis may be an effective substitute for several classes of medications with potentially dangerous and uncomfortable side effects and risky polypharmaceutical interactions, including opioids, benzodiazepines, and antidepressants (Weich et al., 2014; Centers for Disease Control and Prevention, 2016; Fontanella et al., 2016; Rudd et al., 2016; Sharma et al., 2016). Higher pre-dosing symptom levels were generally associated with greater post-dosing symptom relief and users treating an anxiety-related symptom or depression showed stronger symptom relief than users treating a pain symptom, even though depression is not a condition approved for medical cannabis use in most states.

Similar to clinical reviews showing that cannabis is associated with numerous, yet generally non-serious side effects (Wang et al., 2008; Whiting et al., 2016), positive and context-specific side effects were more commonly reported than negative side effects by the Releaf App™ users, with the most frequent reported side effects being positive (relaxed, peaceful, comfy) and the least frequent side effects being negative (paranoid, confused, headache). Positive side effect reporting was associated with the greatest reported symptom relief, followed by context-specific side effects, while negative side effects were associated with lower reported symptom relief. In general, patients treating depression were more likely to indicate a negative side effect than patients treating anxiety- or pain-related symptoms, though even users who reported only negative side effects reported significant decreases in moderate to severe symptom intensity levels after using cannabis.

One of the most striking patterns in the current results was the breadth of symptoms that appeared to improve following

cannabis consumption. This pattern of responses could have been a function of characteristics of the software user interface (e.g., symptom intensity scale range), manner in which responders interacted with their mobile device (e.g., visual attention to common symptom severity levels), or with the systemic nature by which phytocannabinoids may affect the human mind and body. According to the endocannabinoid deficiency theory, many mental and physical health disturbances result from the dysregulation of the body's innate endocannabinoid system (ECS; Smith and Wagner, 2014; Di Marzo et al., 2015; Karhson et al., 2016; Russo, 2018), often described as a master network of chemical signals that promote somatic and psychological homeostasis, or psychobiological state-efficiency (Bermudez-Silva et al., 2010; Silvestri and Di Marzo, 2013; Acharya et al., 2017). The ECS consists of natural ligands (e.g., anandamide and 2-AG) and receptors (CB1 and CB2) that appear to play a major role in efficient regulation of a wide range of systems that include sleep, feeding (e.g., gut permeability and adipogenesis), libido and fertility, pain perception, motivation, happiness, anxiety, learning and memory, social functioning, autoimmune responses, cellular redox, and cancer pathophysiology (Valvassori et al., 2009; Muccioli et al., 2010; Abdel-Salam et al., 2012; Cani, 2012; Burstein, 2015; Du Plessis et al., 2015; McPartland et al., 2015; Karhson et al., 2016; Pava et al., 2016; Tegeder, 2016; Turcotte et al., 2016; Androvicova et al., 2017; Sierra et al., 2018). In other words, unlike conventional pharmaceutical approaches, which largely target specific neurotransmitter sites (e.g., monoamine neurotransmitter hypothesis; Delgado, 2000; Ng et al., 2015), cannabis may act to improve a broad spectrum of symptoms by regulating homeostatic functioning, perhaps best described as a system-modulating rather than symptom-modulating form of therapy.

Notwithstanding the strengths of the naturalistic research design and the potential implications of the study's findings,

the study was limited primarily by the lack of a control group, e.g., non-cannabis users with the same symptom using a mobile device to indicate their immediate symptom intensity levels. There is also the potential confound of user-selection bias and exclusion of users that failed to complete sessions or even use the Releaf App™ due to a lack of symptom relief or negative side effects. (It is possible that selection bias could have worked in the opposite way, excluding patients that are already satisfied with their cannabis choices and therefore choose not to use the software app). This study chose to focus on the existence of symptom relief and side effects rather than offer clinical guidance as to which cannabis products offer preferential symptom relief and side effects profiles. As such we did not include product characteristics, e.g., routes of administration, quantity and method of ingestion, and cannabinoid content, all of which are likely crucial for understanding how cannabis affects symptom relief and side effect manifestation. We only show that, on average, most cannabis users experience symptom relief. Future research will benefit by incorporating these contextual factors into measurements of patient decisions and by dissecting how fundamental characteristics of the cannabis products themselves affect immediate and longer term changes in symptom relief and potential adverse consequences.

Patients with certain health conditions such as neurological disorders (e.g., multiple sclerosis, seizures, epilepsy, headache) may face differential risks for experiencing adverse effects or exacerbating their symptoms, for instance, depending on the amount of delta-9-tetrahydrocannabinol they consume, and caution should be used for patients considering using highly potent cannabis products (Solimini et al., 2017). Complicating matters are the allogamous (variable) and unstable nature of the *Cannabis* plant and the inherent inconsistencies in the chemical contents across plant batches and derived formulations, which are affected by genetic characteristics, but also environmental, cultivation, and storage conditions (Thomas and Pollard, 2016; Pacifici et al., 2017, 2018). These factors present challenges for both medical cannabis consumers and researchers as patients never have continuous access to cannabis products with precisely consistent chemotypes. Cannabis-based products (e.g., dried

flower vs. oils) can differ in their dose reliability, and researchers have offered guidelines for dosing titration and experimental usage (Kahan et al., 2014; Pichini et al., 2018). However, until federal laws currently restricting pharmacodynamics research in the United States are reformed (Stith and Vigil, 2016) investigators still have tremendous opportunities to develop and incorporate innovative assessment tools, like the Releaf App™, into observational research designs for measuring how patients experience self-directed cannabis treatment in their normal everyday lives outside of clinical settings.

AUTHOR CONTRIBUTIONS

JV and SS conceived the study. FB, KK, and BH independently designed and developed the Releaf App™ and server infrastructure as part of their effort to help create an education tool for medical cannabis patients. SS conducted the analyses. JV and SS drafted the manuscript. All authors contributed substantially to its intellectual content and revision.

FUNDING

This research was supported in part by the University of New Mexico Medical Cannabis Research Fund (mcrf.unm.edu).

ACKNOWLEDGMENTS

All authors had access to the data in the study and take responsibility for the integrity of the data and the accuracy of the data analyses.

Abstract

Background: There are indications that marijuana is increasingly used to alleviate symptoms and for the treatment of a variety of medical conditions both physical and psychological. The purpose of this study was to describe the health concerns and problems that prompt some adolescents to use marijuana for therapeutic reasons, and their beliefs about the risks and benefits of the therapeutic use of marijuana.

Methods: As part of a larger ethnographic study of 63 adolescents who were regular marijuana users, we analyzed interviews conducted with 20 youth who self-identified as using marijuana to relieve or manage health problems.

Results: Thematic analysis revealed that these teens differentiated themselves from recreational users and positioned their use of marijuana for relief by emphasizing their inability to find other ways to deal with their health problems, the sophisticated ways in which they titrated their intake, and the benefits that they experienced. These teens used marijuana to gain relief from difficult feelings (including depression, anxiety and stress), sleep difficulties, problems with concentration and physical pain. Most were not overly concerned about the risks associated with using marijuana, maintaining that their use of marijuana was not 'in excess' and that their use fit into the realm of 'normal.'

Conclusion: Marijuana is perceived by some teens to be the only available alternative for teens experiencing difficult health problems when medical treatments have failed or when they lack access to appropriate health care.

Background

There is lively public debate surrounding the use of medical marijuana. While some remain sceptical about the therapeutic value of marijuana, there is a growing body of research that emphasizes its salutary effects. The literature points to the use of marijuana among adults to alleviate a

variety of symptoms including pain, nausea, muscle spasm, insomnia, anorexia and anxiety as well as the treatment of a variety of medical conditions that are both physical and psychological [1-5]. However, less is known about adolescents' use of marijuana for therapeutic purposes.

Background Literature

For individuals who set out to "feel better" through the use of marijuana, use has also been referred to as "self-medication," a hypothesis which posits that people do not misuse substances solely for the experience of being "high;" rather, they do so as a means of gaining relief from psychological and emotional pain [6]. In contrast to the adult literature on marijuana use where therapeutic use is linked to treatment of specific symptoms and illnesses, in the adolescent literature there is less clarity about how to define non-recreational uses of marijuana.

A motivationally-driven approach is one way that researchers have attempted to understand marijuana use among adolescents [7]. It is proposed that different reasons for using marijuana may shape patterns and contexts of use, which in turn may be associated with different problems related to use. Social motives for marijuana use, for example, have been associated with patterns of recreational use (e.g., sensation seeking). Coping motives have been used to classify adolescents using marijuana for non-recreation purposes. Differences have been observed among youth using marijuana for social and coping reasons that support the motives framework. In contrast to youth aged 16–24 years using marijuana for social reasons, users of the same age reporting coping motives have been observed to have lower mental health, higher psychopathology, more psychosocial distress and more stressful life events than non-cannabis-using youth [8].

Although there is a large body of literature related to recreational use of marijuana among adolescents [9,10] less is known about other motivations for the use of marijuana in this population. Several hypotheses have emerged related to non-recreational uses of marijuana among adolescents. The "self-medication hypothesis" [11-14] is most closely associated with the therapeutic use of marijuana. Instrumental use is another term applied to taking drugs for specific pharmacological effects of the substance rather than for pleasure or recreational purposes. For example, Glassner [15] examined the notion of instrumental drug use in a qualitative study of young drug users, and found that marijuana was used for its calming effects, to relieve tension, and to gain self-confidence. Further, support for a typology of drug related beliefs that included relief-oriented beliefs [16] was demonstrated in a study of cannabis use in a sample of 285 French high school students [17]. In this study, four 'positive' relief-oriented beliefs were identified related to how the substance creates relaxation and calms anxiety, reduces suffering, relieves boredom, and makes one feel better. The presence of relief-oriented beliefs was the only predictor of cannabis dependence.

Associations between marijuana and psychological problems have also lead researchers to consider other possible

explanations, including whether marijuana use may reinforce psychiatric symptoms or increase the risk of developing a psychiatric illness later in life [18-21]. A full understanding of marijuana use and its potential adverse effects, however, will require further research.

The trend toward the use of marijuana for therapeutic purposes among adults raises questions regarding how this may influence young people's use of marijuana for similar reasons. Recent studies suggest that adolescents are aware that marijuana is sometimes used to gain relief from physical and psychological pain [22-24]. Furthermore, there is evidence suggesting that adolescents may be using marijuana for reasons that are analogous to adults who use marijuana for therapeutic reasons. For example, young marijuana users with coping motives report more stressful life events (e.g., death of a family member or friend), personal injury and illness than socially motivated marijuana users and non-users [8]. There is also indirect evidence that adolescents with mental health conditions might be seeking relief through marijuana use. In a sample of 992 adolescents in drug treatment programs in four U.S. cities, more than half had at least one comorbid mental disorder. In total, 72.5% of these youth were dependent on marijuana [25]. Among youth entering outpatient treatment programs for cannabis use disorders, 76% were reported to have concurrent mental health conditions [26]. Finally, in a sample of homeless young people in the UK who used a variety of drugs including marijuana, participants were found to be self-medicating to deal with the stress and problems they encountered including depression, loneliness, and physical problems such as aches and pains [13].

As part of a larger study to understand the culture of frequent marijuana use among young people, we were struck by the extent to which some participants spontaneously described using marijuana to gain relief from symptoms. In order to develop these emergent findings, we conducted a focused ethnography in which we examined the ways in which youth use marijuana to seek relief.

Methods

This study was designed to understand and describe adolescents' experiences in using marijuana for therapeutic reasons, and explore how their constructions of these experiences are influenced by social norms. Compared to other types of ethnographic studies, focused ethnographies occur on a smaller scale and seek to examine a specific problem or phenomenon [27]. Typically, focused ethnographies are time-limited, involve a limited number of participants drawn from a specific population who have experience and understanding directly related to the area of inquiry, and are conducted through selected episodes of participant observation and/or interview [28]. In this focused ethnography, both in-depth interviews and participant observation were employed.

We drew data from a larger ethnographic study of frequent marijuana use among adolescents conducted in two rural and one urban location in British Columbia (BC), Canada. In the study communities, as is the case in much of BC, marijuana is readily accessible to youth despite the fact that it is illegal to grow, sell or possess. The use of marijuana for medical reasons is legally supported in Canada in limited circumstances; individuals meeting the criteria are provided with cannabis or given a license to grow a limited quantity for personal use.

Ethical approval for this study was obtained from the University Behavioral Research Ethics Board. Given the sensitivity of the topic and because we successfully argued that teens were able to provide consent for research participation, we did not require parental consent. As a courtesy, we provided the youth with a parent/guardian information letter which outlined the study's focus as pertaining to attitudes about marijuana use in general. Participants were told that they could take the letter home if they so chose. Prior to the interviews, written consent was obtained from the participants. Confidentiality was ensured at the outset and participants were informed that all identifying information would be removed from the data.

Sample

In the larger study, participants were recruited by means of information fliers posted at high schools which invited youth to share their "views on marijuana use and teens." Youth who expressed interest in participating were screened for eligibility by the research team. Eligibility criteria included being 13–18 years of age and reporting having smoked marijuana at least once in the previous week. In total, 63 young people participated in the study. Although many youth described "feeling better" after they smoked marijuana, a subset [$n = 20$] explicitly described experiences of using marijuana on a regular basis specifically to manage, reduce or eliminate unpleasant and uncomfortable feelings or other health problems. They constructed marijuana as a treatment for health problems, often suggesting it had significantly greater benefit than other medical treatments they had been offered. None of these students were legally provided with cannabis for medical treatment or given a licence to grow marijuana for medicinal use. Characteristics of this sub-set of participants are presented in Table 1. The majority of youth using marijuana for relief were male, and the average age of initiation of marijuana was 13 years of age. Youth in this subset were of diverse ethnic backgrounds. Most [$n = 12$] indicated that they were "Canadian" or "Caucasian;" More specifically, 2 participants identified as First Nations, 6 individuals were part First Nations, 3 of UK descent and 3 were of European background including Italian, Croatian, and Ukrainian. Compared to those who

* some participants used marijuana for more than one reason

used marijuana for the purpose of relief, those recruited to this study who smoked marijuana for recreational purposes ($n = 43$) smoked marijuana less frequently (average of 11 days in the last 30 days) and used marijuana more often with others.

Data Collection

The primary source of data was in-depth, semi-structured interviews with youth to glean accounts of their experiences with marijuana. We used a short questionnaire prior to beginning the qualitative interview to collect demographic data and to assess history of marijuana use and current use. The questionnaire included items related to marijuana use including age of initiation, use in the last month, frequency and quit attempts. We also collected data on the time of day that individuals usually used marijuana.

The interviews were conducted using an interview guide. Broad discussion categories included: history and pattern of use, the reasons for their use, what they knew about marijuana, the sources of that information as well as contextual factors related to their use. Open-ended questions were posed in relation to each of these topics, as required during the interviews. Many of these youth were at ease when talking about their use of marijuana and needed little prompting. When youth described the use of marijuana to help them feel better, participants were asked to elaborate further on their experiences.

The tape-recorded interviews took place in privacy within the school setting and lasted from 1 to 2 hours. Participants were offered a \$20 honorarium. Field notes were used to record impressions of responses to the interview

and the interviewer's assessment of the quality of the interview. In addition, field notes were maintained to record pertinent observations within the school and in the larger community (e.g., noting school policies regarding marijuana use at school and the presence of graffiti related to marijuana in close proximity of the school; visiting favourite outdoor settings where some indicated that they preferred to smoke marijuana along with hemp shops where they purchased pipes and bongs and other paraphernalia).

Data Analysis

All data including transcribed interviews and field notes were reviewed several times by the research team paying close attention to young people's descriptions of experiences with the use of marijuana to address uncomfortable feelings or health problems, and the circumstances that surrounded this use. Close readings of the interviews by the investigative team involved highlighting potentially important comments, raising questions about the data, and identifying prominent dimensions of participants' experiences. During team meetings, interview data were discussed and emergent categories were identified to capture experiences related to marijuana use. These categories were organized into a coding framework and used to code the data. All coding was completed by one of the authors who completed a majority of the interviews (BMM). To code the data, we used [29] the NVivo software program designed for qualitative analysis of textual data. The program was also used to retrieve data coded under each category for a more nuanced analysis by the investigative team. Through reflective questioning of these data and detailed comparisons, themes were identified and discussed in team meetings.

Results

The Context of Using Marijuana for Relief

The teens situated their use of marijuana for relief of health problems in the context of difficult life events and illness experiences marked by a lack of supportive family networks, unexpected and sometimes traumatic losses of close friends or family members, and difficulties at school. Many indicated that they had few people to turn to help them; for some their parents were having difficulty coping with their own situations of unemployment, substance use, and marriage breakdowns and offered little support. Those living in households with a parent and step-parent had difficulty coping with unresolved feelings towards their estranged biological parent. Finally, several teens who made frequent moves with their families experienced social isolation at school and were subject to being bullied and teased.

Experiences with the medical system to address their health problems consistently fell short of the teens' expecta-

tations; their problems were either not taken seriously or the solutions offered were not helpful. For example, youth who reported they had been prescribed drugs such as Ritalin, Prozac or sleeping pills, stopped using them because they did not like how these drugs made them feel or found them ineffective. Despite visits to doctors, prescribed treatments and, for a few, hospitalizations, many of these teens perceived that they did not receive the help they needed from doctors.

A final contextual feature to these teens' lives were their observations of others' use of marijuana to deal with difficult circumstances or symptoms, including, in a few cases, parents and other significant adults in their life. For example, one young man reported that his mother was using marijuana while receiving cancer treatment. As he observed, "It helped her sleep and calmed her down." Others described how they were given advice from other teens about how marijuana could "help." Together these circumstances created a context where teens routinely turned to marijuana to manage physical and psychological problems in their lives. Marijuana was readily available, used by others in their network, and was perceived to provide an effective solution not offered to them from the medical system.

Regular Relief: Patterns of Using Marijuana for Persistent Problems

Most of the participants who consistently used marijuana for relief, smoked it when alone, often several times a day. For some, their day began and ended with using marijuana; they smoked before leaving home for school and prior to going to bed. Some indicated that they needed to smoke marijuana during the school day to manage symptoms, and when this occurred it was often in the company of friends. A few participants smoked marijuana for relief in adult company that included relatives and "older" friends who supported their need to use marijuana to manage symptoms.

There were two patterns of marijuana use for relief: intermittent and chronic. With intermittent use, youth routinely relied on marijuana to deal with short-term problems such as stressful situations or limited periods of physical pain. One 14 year old male described non-daily use occurring whenever he had a "really bad day." In the case of chronic use, daily marijuana was used for the relief of identified conditions such as depression, ADHD and to routinely settle at night or manage sleeplessness. Young people's descriptions of marijuana use for relief were imbued with language common to using pharmaceuticals. A number of these youth indicated how they carefully titrated their intake; others described their use as "moderate," involving a "few puffs," or just a "certain amount." Through experience, they had learned to hone

ways of using the right amount of marijuana to achieve a state of relief. As one male elaborated, he regulated his intake by mixing his marijuana with tobacco so as to get "just enough" marijuana to relieve regular states of agitation and high levels of stress. Along with skills at monitoring their intake of marijuana, these youth confidently shared in-depth knowledge of the strength and associated effects of different strains of marijuana.

Explaining the Need to Use Marijuana for Relief

The young people in the sub-sample were particularly articulate in describing their "need" to use marijuana. They were adamant and confident that marijuana provided relief from their health problems. The decision to smoke marijuana was stated in a straight forward fashion (e.g., "I started it to make myself feel better") and justified because they had a "reason for it." Participants also framed their marijuana use in a positive manner; in so doing, gave credence to the claim that this was the right course of action. As one girl elaborated on her daily use, "Pot helps me be me." Several described unpleasant physical sensations such as feeling "jittery" associated with the absence of marijuana. For these youth, regular marijuana use allowed them relief from these unpleasant symptoms so that they were able to feel "normal." One 18-year old male who used marijuana everyday indicated, "If anything, it makes you more normal." Of note, he had first started to use marijuana at the age of 13, and smoked it regularly for 5 years typically 4 times a day.

For these youth, the purpose of smoking marijuana was not specifically about getting high or stoned, nor was marijuana used for "pleasure." In fact, participants tended to differentiate their own use from peers who were recreational users who smoked marijuana when they were "partying" or "socializing." As one 16-year old male described his use, "I don't get a strong sense of euphoria, I just calm down a bit, that's just how it is for me." However, there were a few instances when female participants did smoke "to get high" for the purpose of "escaping reality," a strategy used to remove themselves temporarily from the challenging circumstances that accompanied their daily lives. The participants also distinguished themselves from the "stoner" stereotype, whose preferred activities were watching movies or listening to heavy metal music while smoking marijuana.

Some explanations of using of marijuana to feel better were further bolstered with a focus on use for described "health" reasons. As one 16-year old female indicated, her daily use of marijuana was "more of a health thing, than to get high." She reflected on her history of "mild depression" and her difficulties with antidepressants that had resulted in insomnia and a loss of appetite. She suggested that these health issues would re-surface in the absence of

marijuana, thereby providing solid rationale for her continued use of marijuana. One male situated his marijuana use within a perspective that medications are used to help deal with problems.

I bet you if I had never been put on Ritalin at a younger age, I might not have had the same opinion of drugs growing up, you know, because I was taught growing up that you take drugs to help you out with your problems, you know. [18 years, non-daily use]

Often, marijuana was compared to other substances in a way that suggested marijuana was the best option, further supporting ongoing use of marijuana for relief purposes. Some constructed marijuana as a "natural" substance that was preferable and considered "safer" than many pharmaceutical alternatives. One 14-year old female discovered that marijuana was a better option than dealing with the side effects of pharmaceuticals stating, "Well, my body, I have to be careful what pills I take. I have bad reactions to some medications. My body rejects it and I get really sick." Interestingly, one 18-year old who smoked twice a day on 21 days during the last month, went as far to describe himself as a "healthy marijuana user" adding, "It's not good for you, but then again, neither is MacDonald's and a lot of other things." The health claims in these descriptions served to explain the ongoing use of marijuana for relief.

Painful Lives: Types of Symptoms and Distress Requiring Relief

In the interviews the teens directly linked their use of marijuana with the management of difficult feelings (including depression, anxiety and stress), sleep problems, problems with concentration and physical pain. Each of these will be described in the following sections.

Difficult Feelings

Although some teens described using marijuana to deal with instances of being angry, experiencing a significant disappointment (e.g., with exam results), being afraid, or to forget the past, the most frequent uses were associated with dealing with depression, and managing stress and anxiety.

Depression

Six participants indicated they were using marijuana specifically to deal with depression and several others reported knowing teens that were doing the same. Dealing with difficult personal circumstances was a common theme for this group of teens and was linked to the loss of significant people in their lives, a family history of depression, financial worries at home, "fights" with parents, abuse, and too much "shit" in their lives. Several reported receiving treatment for depression in the form of antide-

pressants and counseling, sometimes over extended periods, yet with little relief. For others, these options were not available in part because "nobody wanted to listen" to them. As a last resort, these teens had opted to try smoking marijuana. In a relatively short time, marijuana helped them to feel better about themselves, happier and more like the person they "wanted to be" as well as alleviate other problems associated with depression (poor appetite, difficulty concentrating, poor sleep).

Not all participants agreed about the use of marijuana for depression. One 16-year old male used marijuana to deal with his unhappiness surrounding the conflict between his mother and father, and worried that he might be using pot too frequently. He reasoned that being happy all of the time was not natural, and that there was nothing wrong with being sad and confused sometimes. As a result, he tried to limit using marijuana to weekends with friends. Others believed that marijuana should only be used for certain types of depression because of the possibility of becoming more depressed by smoking pot:

I think it depends on the level of depression that you have. If it's like depressed because you are sick, then pot is helping you. It's making you happier. But if you're depressed about killing yourself, I don't think that it's a good idea to smoke pot just because it could bring you down more. It's hard to say, though, it's different for every person, right? That just how it makes me feel. [Female, 17 years, daily use]

Stress and anxiety

The use of marijuana to manage stress and anxiety was described by 12 teens in our sample. Dealing with bullying at school, heavy demands of school work, taxing shifts at work, and just "giving as much as you can" along side difficult relationships with parents or guardians, and receiving threats from neighbors all took its toll on these youth. For some, these experiences contributed to high levels of stress and anxiety, and for others uncomfortable levels of anger – both were difficult to manage. Although some had friends they could turn to, marijuana provided an additional source of stress relief that was ready at hand.

Lots of people know me, know I do pot and they think that I'm a pot head but really the thing they don't realize is that I have a reason for it. It's for my stress and an antidepressant. I get really upset. It [pot] helps me feel better about myself, because you know people don't do that [help me], like my friend [name] can, but nobody else can. [Female, 14 years, non-daily use]

There was general agreement among the teens that marijuana calmed them down, and helped them feel "not so nervous" and "not so uptight about everything." One teen

recognized, however, that despite the fact that marijuana could be a very effective stress reliever, it might not work for everyone:

Well as far as pot goes, the good thing is that it's definitely a stress reliever, hands down. I know lots of people who would be just a complete wreck if they weren't smoking pot but then there's also people who are a complete wreck because they do smoke pot, so it's kind of a hard thing. [Male, 16 years, non-daily use]

Sleep problems

Nine teens in our sample described using marijuana to help them sleep. The "trouble" they had with sleeping was a constant problem that many had experienced for years. One 16-year old, who also experienced mild depression, indicated that she "stopped sleeping for two years." Not only did the problem affect their school performance, but it was deeply disturbing to them. As another female described,

I have a really hard time sleeping. I can lay there for about four to five hours, just laying there. And I just finally had it, and I just feel like screaming I don't want to wake anyone up. So I go downstairs and ask my gran or my brother [for some marijuana] or I have a roach or two sitting around. [16 years, non-daily use]

Although one teen indicated that she had spoken to her mother about her problems sleeping, others indicated that the adults in their lives did not offer any support.

I have trouble going to sleep and waking up...My mum wanted to get the doctor to put me on sleeping pills but he said at such a young age it would cause like an addiction to them...I've had these problems since elementary school...I just, I can't go to sleep at night and then I like to sleep during the day. [Female, 14 years, non-daily use]

Many teens turned to pot and found almost immediate benefits in helping them sleep. Likened to a "magic sleeping pill" by one young male, the teens found it calmed their "busy minds," helped them relax and fall asleep quickly.

Focus/concentration

Three teens reported using marijuana to improve their concentration. They explained that they had difficulty focusing at school and that this affected their school performance. As one male explained:

Personally, I'm a very fast paced guy and my mind is always rushing, hard to gather my thoughts. I think a lot faster than I can speak. I get distracted very easily.

In social studies last year, I would talk and wouldn't do any work. But if I had just a little bit of pot, I could really focus my work. I could sit there and I'd work all day and finish everything and have no homework and be done by the end of class. [16 years, non-daily use]

These young people believed they could "think better" when they used marijuana because it allowed them to focus their thinking, and, slow it down in a way that was preferable. All suggested that these cognitive changes were linked to improved school performance. One teen, who self-identified as having "attention deficit, hyperactive disorder" shared the difficulties he experienced on Ritalin. He began smoking pot when he was 12 years of age and still on Ritalin.

Usually my mind is in over gear, right? I'm usually going about a mile a minute and my hands are moving way too fast, and I'm really fidgety. But if I have a puff of marijuana in a moderate use, by moderate I mean one to three to four puffs, depending on the quality....being toned down a bit I find really helps me....If I try to do homework at home without smoking pot, I just can't focus. I'll be looking at my schoolwork and for me with my ADHD this is how it's always been for me. Like school was just a constant story of this scenario before I smoked marijuana. [17 years, non-daily use]

Physical Pain

Five teens indicated they used marijuana to obtain pain relief, and several others shared similar stories about other youth. One male used marijuana to deal with pain associated with rehabilitation after a muscle injury, another used marijuana following an accident where he sustained 3rd degree burns and yet another because of plates in his back due to a car injury. Others suggested that marijuana reduced muscle pain after a hard day of skiing and helped with headaches, and that girls used marijuana for menstrual cramps. One 17-year old male used it daily and explained that marijuana "numbs your systems or senses [and] relaxes your muscles."

Considering the Risks of Using Marijuana for Relief

In spite of experiencing personal benefits from using marijuana for relief, some participants wrestled with their use of marijuana. One girl noted her own problematic use of marijuana that had quickly evolved into relying on it to deal with the regular stress in her life. As she pondered, she commented knowingly that it would be preferable to use it only when her stress level was "really" high.

I mean I started it, and I'm doing it for the wrong reasons...I think if I cut back and only did it when I was *really* stressed out or something, then, you know, really cut back, I think it would be okay. [14 years, non-daily use]

Although knowing that it was "harmful" to her body, she added that she found it difficult to quit using marijuana. Most youth were aware of the health consequences associated with marijuana use in general and their own use in particular. They noticed physical symptoms such as decreased stamina and shortness of breath with physical activities, while others worried about weakened immune systems and how it affected their energy level. Some recognized that they were addicted to marijuana. One male who had been using marijuana for six years framed it as something that he would address at a later date. "I'm trying to get through school and then worry about my dependency issue with marijuana."

Others noted that their marijuana use was linked to difficulties that they were having at school. One male concluded, "I think it brings marks down in one way and sometimes you don't understand things maybe as easily." Others recognized how their use had affected their memory. For a number of the participants, their knowledge of the risks of smoking marijuana was limited and, at times, incorrect. For example, as one 14-year old male who had started smoking marijuana in the past year to relieve muscle pain noted, "It's bad for your lungs, just it's 400 times lower than tobacco."

In what appeared to be an effort to minimize their use in the face of health risks, the teens emphasized that they were not using marijuana "in excess." One 18-year old summed up six years of using marijuana by saying, "I don't feel that I have a problem," adding that "it doesn't really have that many side effects." Some suggested that the benefits of smoking marijuana outweighed the risks. As noted, for those with difficulties sleeping at night, not being able to function the following day when sleep deprived was agonizing; marijuana use at night was preferable and provided a solution to that quandary. However, one male pondered both sides of his use of marijuana in dealing with his depression and was less optimistic:

Well, in some ways, it's helped me and some ways it hasn't. It's good when it's there, but when it's not, it kind of makes me sad. So it's hard like to try to keep up with staying happy all the time. [18 years, daily use]

Several participants made reference to the contradictions that they saw in their world regarding other licit substances and used that argument to make sense of and praise the benefits of marijuana over the risks.

And the thing is that if it's already used, they're already growing it for people that need it for medical help, then like why not.... Like no one has ever overdosed on marijuana, but people die everyday from alcohol, everyday from cigarettes and everyday from vast

amounts of things that the government has legalized, but they just won't legalize marijuana for some reason. It's never killed anyone, never really hurt anyone, it saves people's lives and they could make a good amount of money from it and drop crime rates, why don't they do it? [Male, 14 years, non-daily use]

Discussion

The findings of this study provide one of the first in-depth descriptions of youths' use of marijuana for non-recreational purposes, adding to the growing body of research on the use of drugs to self-medicate among young people. Teens involved in regular and long-term use of marijuana for relief constructed their use of marijuana as essential to feeling better or "normal" in situations where they perceived there were few other options available to them. Unlike the spontaneity typically involved in recreational use, these youth were thoughtful and prescriptive with their marijuana use – carefully monitoring and titrating their use to optimize its therapeutic effect. The findings also point to important contextual factors that further support youth's use of marijuana for relief that extend beyond the availability of marijuana and dominant discourses that construct marijuana as a natural product with medicinal properties.

Of key importance in the findings are the unmet health needs of these youth. Health issues such as depression, insomnia, and anxiety were significant problems that interfered with these youths' ability to function at school, maintain relationships with family and friends, and feel that they could live a normal life. The level of distress associated with these health concerns, along with the lack of effective interventions by health care providers and family members appeared to leave them with few alternatives. Researchers have reported that when adolescents in rural communities experience barriers to seeking health care, they think they can take care of the problems themselves [30]. Similarly, our study participants believed that their best option was to assume responsibility for treating their problems by using marijuana. Unpleasant side effects with prescribed medications and long, ineffective therapies resulted in little hope that the medical system could be counted on as beneficial. In contrast, marijuana provided these youth with immediate relief for a variety of health concerns. Nevertheless, the regular use of marijuana put youth at risk. Cannabis use has been identified as a risk factor for mental illness such as psychosis, schizophrenia [21,31,32] and psychiatric symptoms such as panic attacks [33]. Teens who smoked marijuana at least once per month in the past year were found to be three times more likely to have suicidal thoughts than non-users [34], and there is evidence that exposure to cannabis may worsen depression in youth [35]. Marijuana use among youth has also been associated with other sub-

stance use and school failure [36]. What is interesting is that the findings of this study suggest that youth have little awareness of some of these risks; rather, some are using marijuana to counteract these very problems (e.g., depression, school failure). Teens' perceptions that their health concerns were not addressed suggest that more attention is needed to assess these issues and ensure that other options are available to them. Parents and health care providers need to make a concerted effort to not only understand the pressures and influences on youth [37], but also gain a better understanding of the effect of youths' health problems on their ability to engage in healthy lifestyle choices.

Underlying problems related to youth health concerns also need to be addressed. In many situations, the participants' symptoms appeared to be directly related to their life circumstances. Along with the challenges inherent in being an adolescent in today's complex world, some teens were also trying to deal with significant losses (death of a close friend or family member), extremely difficult family relationships, disappointments with friends, school and sports, and a fragile family and peer support network. The risk of substance use increases substantially when youth are attempting to deal with these kinds of situations in isolation. Although marijuana provided the youth with temporary relief, the underlying situation often went unattended – leading the teens into a regular pattern of use. Appropriate guidance and targeted support from counselors and health care providers must be sensitive to meeting the needs of youth as they work through such situations and life altering events. In addition, adults working with youth must find better ways to talk with young people about how they are coping with their health issues, including their marijuana use. Based on the experiences of youth in this study, there is a wide range of support that may benefit youth including counseling, stress management, social skills training, anger management, study skills, pain management, and sleep hygiene. The youth in this study had minimal access to these types of resources.

The influence of the policy environment in Canada related to medical marijuana cannot be dismissed. The youth in this study were familiar with medical marijuana and its sanctioned use among those with serious illnesses; some knew individuals in their social network who were medical marijuana users. In addition, we acknowledge that the availability of marijuana in the study settings provided teens with opportunities to try marijuana to relieve symptoms. In locales where it is more difficult to access marijuana and penalties for possession of marijuana are harsh, teens with similar symptoms may use other approaches.

Despite presenting themselves as being sophisticated users of marijuana, with a rich knowledge of marijuana

acquired through direct experience, conversations and observations of others, the youth in our study did not appear to be well informed about the therapeutic use of marijuana. Targeted education for youth regarding the risks of marijuana and its appropriate use as a therapeutic agent is warranted, including the risks of legal sanctions. However, as Tupper [38] has suggested regarding drug education, fear-based approaches are unlikely to be effective when the reality of youths' observations and experiences suggest that few serious consequences stand in direct contrast to the "facts" teachers often provide. Alternative approaches are required that acknowledge the complexity of the issues that inform understandings of marijuana. Tupper suggests that drug education be framed using the metaphor of "drugs as tools" to allow "more nuanced understandings of the benefits and harms of drugs, depending on who is using them, in what circumstances, and for what purpose" (p. 235). This approach may be useful in education focused on marijuana.

This study was conducted in three locations in the province of British Columbia (BC) Canada and as such may not be generalized to other contexts. The province of BC is known for its illicit marijuana production [39]. And, in general the BC public is tolerant of marijuana use and support decriminalizing recreational use. In other contexts, teens might turn to other substances such as alcohol. The findings of this study provide a snapshot of these teens' use of marijuana. Further research is required to examine how this therapeutic use evolves over time.

Conclusion

In summary, this study highlights youths' efforts to address their health problems and their experiences in using marijuana for relief. Marijuana may be perceived by some teens to be the only available alternative for those experiencing difficult physical or emotional problems when medical treatments have failed or when they lack access to appropriate health care. As has been noted in other studies of substance use [40], understanding why adolescents use particular substances is key in developing appropriate educational and intervention programs.

Re: REVISED Final Agency Decision: Petitions to Establish Additional Debilitating Medical Conditions under the New Jersey Medicinal Marijuana Program

Dear Petitioners:

On March 22, 2018, I issued a final agency decision in the matter of the Department of Health's (Department) Request for Petitions to establish additional deliberating medical conditions under the New Jersey Medicinal Marijuana Program (MMP). In this final decision, I added chronic pain related to a musculoskeletal disorder as a debilitating medical condition to the MMP. Included in this chronic pain category was opioid use disorder, for which the Department received a petition, because the withdrawal symptoms for this disorder can cause severe and agonizing pain and research evidences that the use of medical marijuana was not only an effective alternative treatment to the opioids that are commonly used to treat this disorder but also reduces the likelihood of a patient developing opioid use disorder. As explained in detail below, after further review of this petition against the opioid crisis that is plaguing our State and research suggesting that the use of medical marijuana in conjunction with medication-assisted therapy to treat this disorder may aid in the reduction of relapses and assist with the prevention of opioid overdose deaths, I am issuing this revised final decision to include opioid use disorder as a standalone deliberating medical condition under the MMP. With this decision, opioid use disorder patients are eligible for medical marijuana if they suffer from chronic, painful withdrawal symptoms or as an adjunct treatment to their current medication-assisted treatment regimen. Accordingly, this Revised Final Agency Decision replaces my March 22nd final agency decision.

This letter sets forth the basis, rationale and final decision in the matter of the Department of Health's (Department) Request for Petitions to establish additional deliberating medical conditions under the New Jersey Medicinal Marijuana Program (MMP). As explained in detail below, I am granting the petitions seeking to add chronic pain conditions that are related to musculoskeletal disorders, chronic pain conditions that are of a visceral origin, as well as Tourette's Syndrome, migraine, and anxiety as debilitating medical conditions under the MMP. Additionally, I am granting the petition seeking to add opioid use disorder to the MMP, with the condition that medical marijuana be prescribed in conjunction with medication-assisted therapy for the treatment of the disorder. However, I am denying the petitions seeking to add asthma and chronic fatigue syndrome to the MMP.

In reaching this decision, I considered the Request for Petitions, the petitions submitted in response to the Request, the MMP panel's recommendations, written and oral public comments

received regarding various petitions, as well as the requirements of the New Jersey Compassionate Use Medical Marijuana Act (the Act), N.J.S.A. 24:6I-1 et seq., and the regulations promulgated thereunder. The referenced materials are incorporated herein and made a part of this final decision.

The Request for Petitions

On July 5, 2016, the Department published the Request for Petitions in the New Jersey Register advising that from August 1, 2016 to August 31, 2016, it was accepting petitions to establish additional medical conditions as “debilitating” under the MMP. 48 N.J.R. 1395(a). The Request for Petitions stated that the Department was seeking petitions in accordance with the Act, which authorizes the Department to include additional debilitating medical conditions under the MMP.

In the Request for Petitions, the public was advised that submitted petitions were required to include the following information, pursuant to N.J.A.C. 8:64-5.3:

- (1) The extent to which the condition is generally accepted by the medical community and other experts as a valid, existing medical condition;
- (2) If one or more treatments of the condition, rather than the condition itself, are alleged to be the cause of the patient's suffering, the extent to which the treatments causing suffering are generally accepted by the medical community and other experts as valid treatments for the condition;
- (3) The extent to which the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting, or otherwise severely impair the patient's ability to carry on activities of daily living;
- (4) The availability of conventional medical therapies other than those that cause suffering to alleviate suffering caused by the condition and/or the treatment thereof;
- (5) The extent to which evidence that is generally accepted among the medical community and other experts supports a finding that the use of marijuana alleviates suffering caused by the condition and/or the treatment thereof; and
- (6) Letters of support from physicians or other licensed health care professional knowledgeable about the condition.

The Department also crafted a Petition Form that petitioners could use for their submissions. The form detailed the above-listed criteria, which each petitioner needed to provide in order for his or her submission to be accepted and considered.

In addition to publishing the request for petitions in the New Jersey Register, the Department also posted it on its website.

Completeness Review

At the close of the petition submission period, the Department received sixty-eight petitions. Thereafter, the Department reviewed each petition to determine whether it contained the information that was required for it to be accepted for consideration. From its review, the

Department determined that twenty-three petitions did not meet the criteria for consideration.¹ Accordingly, the Department denied these petitions under separate cover on December 7, 2016, pursuant to N.J.A.C. 8:64-5.3(b). The remaining forty-five petitions met the criteria for consideration and were accepted.

Statutory and Regulatory Criteria

The Act charges the Department with the responsibility of administering the State's MMP, including establishing a registry of qualifying patients and primary care givers. To qualify as a MMP patient, an individual must suffer from one of the debilitating medical conditions set forth in the Act. The Act defines a "debilitating medical condition" as:

- (1) one of the following conditions, if resistant to conventional medical therapy: seizure disorder, including epilepsy; intractable skeletal muscular spasticity; post-traumatic stress disorder; or glaucoma;
- (2) one of the following conditions, if severe or chronic pain, severe nausea or vomiting, cachexia, or wasting syndrome results from the condition or treatment thereof: positive status for human immunodeficiency virus; acquired immune deficiency syndrome; or cancer;
- (3) amyotrophic lateral sclerosis, multiple sclerosis, terminal cancer, muscular dystrophy, or inflammatory bowel disease, including Crohn's disease; [or]
- (4) terminal illness, if the physician has determined a prognosis of less than 12 months of life.

[N.J.S.A. 24:6I-3.]

In addition to the conditions listed in the Act, the Legislature authorized the Department to establish additional medical conditions as debilitating under the MMP. Ibid. Consistent with its statutory authority, the Department promulgated rules that outline the process for expanding the list of medical conditions that qualify as "debilitating" under the MMP. See N.J.A.C. 8:64-1.1 et seq. Pursuant to these rules, I am required to take into consideration the following factors in order to determine whether a condition should be added to the MMP as a "debilitating" medical condition that is likely to benefit from the use of medical marijuana to treat or alleviate the debilitating effect of the condition:

- (1) The extent to which the condition is generally accepted by the medical community and other experts as a valid, existing medical condition;
- (2) If one or more treatments of the condition, rather than the condition itself, are alleged to be the cause of the patient's suffering, the extent to which the treatments causing suffering are generally accepted by the medical community and other experts as valid treatments for the condition;
- (3) The extent to which the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or

¹ Legislation was enacted during the pendency of the petitions, which added post-traumatic stress disorder to the list of conditions that qualify as debilitating under the MMP. As a result, the petitions seeking to add this condition to the MMP were deemed moot and not forwarded to the Panel for consideration.

vomiting or otherwise severely impair the patient's ability to carry on activities of daily living;

(4) The availability of conventional medical therapies other than those that cause suffering to alleviate suffering caused by the condition and/or the treatment thereof;

(5) The extent to which evidence that is generally accepted among the medical community and other experts supports a finding that the use of marijuana alleviates suffering caused by the condition and/or the treatment thereof; and

(6) Letters of support from physicians or other licensed health care professionals knowledgeable about the condition.

[N.J.A.C. 8:64-5.3]

The MMP Review Panel Meetings, Public Comments and Panel Recommendations

On May 11, 2017, the MMP Review Panel, which is a panel assembled by the Department to review and make recommendations on petitions seeking to add conditions to the MMP, met to review and hear public comments on the forty-five accepted petitions. At the meeting, the Panel acknowledged that they reviewed the material submitted with the petitions and that they also conducted their own independent analysis and research for each condition. During the meeting, the Panel also advised that it grouped the petitioned conditions into seven categories, namely chronic pain related to musculoskeletal disorders, chronic pain of a visceral origin, Tourette's Syndrome, migraine, anxiety, asthma and chronic fatigue. After offering a panel discussion on each condition and hearing public comments from two individuals, both of whom expressed support for the MMP, the Panel voted on each petition. Based upon a majority vote of the members who were present at the meeting, the Panel recommended that chronic pain related to musculoskeletal disorders, chronic pain of a visceral origin, Tourette's Syndrome, migraine, and anxiety be approved as debilitating conditions under the MMP and recommended denial of asthma and chronic fatigue.

After the meeting, the Chairman of the Panel reduced the Panel's initial recommendations to writing and submitted it to me for consideration. In the initial recommendation letter, the Panel advised that it was recommending that I add chronic pain related to musculoskeletal disorders, chronic pain of a visceral origin, Tourette's Syndrome, migraine, and anxiety to the MMP because these conditions are debilitating, and medicinal marijuana was more likely than not to have the potential to be beneficial to treat or alleviate the debilitation associated with each condition.

As for asthma and chronic fatigue, the Panel recommended that these conditions not be added to the MMP because medical marijuana was not likely to have the potential to be beneficial to treat or alleviate the debilitation associated with the conditions.

After receiving the Panel's initial recommendation letter, it was posted on the Department's website for a 60-day public comment period to provide the public with an opportunity to submit written comments on the recommendations. At the time the comment period closed, the Department received approximately sixty comments, which were generally supportive of the MMP.

During the 60-day comment period, the Department's MMP Review Panel also convened a public hearing on September 18, 2017, which provided the public with an additional opportunity to comment on the recommendations. During this public hearing, the Panel heard from seven individuals. The comments provided by the commenters did not express any disagreement with the Panel's recommendations.

Upon the conclusion of the public comment period, the Panel reconvened for a final meeting on the petitions. At the meeting, which was held on October 26, 2017, the Panel further deliberated its recommendations on the petitioned conditions, taking into consideration the petitions, information submitted with the petitions, public comments, the factors outlined in N.J.A.C. 8:64-5.3, each member's own research or that done by others, as well as each member's education and training, in order to determine whether any changes should be made to the Panel's initial recommendations. In so deliberating, the Panel discussed each condition in turn and permitted additional public comment on the conditions. Based upon the Panel's extensive and thorough discussions, the majority of the Panel members present at the meeting voted to uphold their initial recommendations on the conditions. As such, the Panel's initial recommendations converted to the Panel's final recommendations to the Commissioner, pursuant to N.J.A.C. 8:64-5.3(f).

Findings and Decisions on the Petitions

For the reasons that follow, I am granting the petitions seeking to add chronic pain that is related to musculoskeletal disorders, chronic pain conditions that are of a visceral origin, as well as Tourette's Syndrome, migraine, opioid use disorder and anxiety under the MMP and denying the petitions seeking to include asthma and chronic fatigue syndrome under the MMP. In reaching my decision, I considered the statutory and regulatory criteria articulated above, the Panel's recommendations and their supporting materials, the petitions with supporting information, public comments, emerging research on medical marijuana and the transcripts of the Panel's meetings, which provides the Panel members' detailed discussions on each condition.

Granted Petitions

Chronic Pain associated with a Musculoskeletal Disorder

Based upon my independent review of the petitions, I am granting those seeking to add chronic pain associated with a musculoskeletal disorder to the MMP.² In coming to this

² Thirty-five of the petitions received by the Department concern various forms of chronic pain. After reviewing these petitions, the Panel determined that they fell into two categories: chronic pain associated with a musculoskeletal disorder and chronic pain of a visceral origin. Based upon my review of this matter, I find that the Panel made the appropriate categorizations of these petitions. Thus, I agree with the Panel that the chronic pain conditions sought to be added to the MMP should be generally labeled as chronic pain associated with a musculoskeletal disorder and chronic pain of a visceral origin, rather than the unique, individual conditions set forth in each chronic pain petition. The list of petitions that fall into each category are set forth in the Panel's recommendation letter, which is incorporated herein by reference. The only exception I have to the bundling of these petitions into the two chronic pain categories is the petition seeking to add opioid use disorder to the MMP, which I find should be granted as both a standalone disorder and as a condition that falls under the category of chronic pain associated with a musculoskeletal disorder.

conclusion, I reviewed this condition against the six regulatory criteria cited above and found that it meets the requirements for inclusion in the MMP.

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that chronic pain associated with a musculoskeletal disorder is a valid condition. According to the U.S. Department of Health and Human Services, Centers for Disease Control and Prevention's National Center for Health Statistics (NCHS), chronic pain associated with a musculoskeletal disorder is pain that persists beyond the usual course of an acute condition, which is typically three months or more or past the time for normal healing, and includes injury and inflammatory conditions "that cause pain in the body's joints; ligaments; muscles; nerves; tendons; and structures that support the limbs, neck, and back."³ Moreover, as noted by the Panel, the World Health Organization's International Classification of Diseases, as clinically modified by the NCHS (ICD-10-CM), uses unique alphanumeric codes to identify known diseases and other health problems and lists multiple codes for chronic pain.⁴ Given the fact that chronic pain associated with a musculoskeletal disorder has a common medical definition and maintains several ICD-10-CM codes, which entities covered by the Health Insurance Portability and Accountability Act must use for processing claims pursuant to rules promulgated by the U.S. Department of Health and Human Services, I find that chronic pain associated with a musculoskeletal disorder is a valid condition recognized by the medical community. See 45 C.F.R. 162.

Under the second factor, I must consider whether the treatments for the condition, if the treatments are causing the patient suffering, are generally accepted by the medical community and other experts as valid treatments for the condition. As set forth in the petitions and acknowledged by the Panel, the generally accepted treatments for chronic pain associated with a musculoskeletal disorder are opioids and non-steroid anti-inflammatory drugs (NSAIDs), both of which can have significant side effects. I agree. According to the Centers for Disease Control and Prevention (CDC), NSAIDs, such as ibuprofen, are a common treatment for chronic pain associated with a musculoskeletal disorder.⁵ The CDC also recognizes opioids, such as oxycodone and hydrocodone, as a common and medically accepted treatment for chronic musculoskeletal pain.⁶ Thus, I find that the treatments for chronic pain, namely NSAIDs and opioids, are recognized and accepted by the medical community and relate to a patient's suffering.

As for the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that chronic pain associated with a musculoskeletal disorder itself as well as the treatment for this condition cause severe suffering for patients inflicted with this condition. As the name suggests, a patient with chronic pain associated with a musculoskeletal disorder experiences just that - pain. Specifically, musculoskeletal chronic pain can cause widespread or localized pain that may worsen with movement, stiffness or achiness, fatigue, and/or muscle twitches.⁷ Thus, the condition itself is the main culprit for the suffering experienced by patients with this disorder. While

³See <https://www.cdc.gov/nchs/data/nhsr/nhsr098.pdf> (last visited March 13, 2018). See also <https://www.cdc.gov/drugoverdose/prescribing/guideline.html> (last visited March 13, 2018).

⁴ See ftp://ftp.cdc.gov/pub/Health_Statistics/NCHS/Publications/ICD10CM/2018/ (last visited March 13, 2018).

⁵ See https://www.cdc.gov/drugoverdose/pdf/nonopioid_treatments-a.pdf (last visited March 13, 2018).

⁶ See <https://www.cdc.gov/drugoverdose/opioids/index.html> (last visited March 13, 2018).

⁷ See <https://my.clevelandclinic.org/health/diseases/14526-musculoskeletal-pain> (last visited March 13, 2018).

chronic pain, in and of itself, causes extensive pain, the treatment for chronic pain associated with a musculoskeletal disorder can also cause significant suffering. Specifically, prolonged use of NSAIDs can cause gastritis, ulcerative disease, heartburn, nausea, vomiting and dizziness⁸. And, opioids can cause constipation, nausea, respiratory depression, dependency, opioid use disorder, sedation and dizziness.⁹ All of these side effects can prevent a patient from engaging in activities of daily living, thereby diminishing one's quality of life. Accordingly, I find that musculoskeletal chronic pain as well as the therapies to treat this condition cause severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. Unfortunately, the treatments for chronic musculoskeletal pain that cause the patient suffering, namely NSAIDs and opioids, are essentially the most viable conventional medical therapies offered for this condition, which was noted by the Panel. As such, I find that there is an absence of effective alternative medical therapies to the conventional therapies currently prescribed for chronic musculoskeletal pain that cause patients to suffer.

Regarding the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I agree with the Panel's conclusion that there is extensive research establishing that the use of medical cannabis can relieve the chronic pain associated with a musculoskeletal disorder. Specifically, there are several peer-reviewed publications in leading medical journals, including a review published by the National Academies of Sciences, Engineering, and Medicine in 2017, as well as a significant number of clinical trials, which found that the use of medical marijuana was effective in relieving chronic pain.¹⁰ As such, I find that there is general acceptance in the medical community that medicinal cannabis can alleviate the suffering caused by chronic musculoskeletal pain.

As for the final factor, which is whether there were letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of chronic musculoskeletal pain under the MMP, I find that the petitions were submitted with support from medical professionals.

Based upon the above analysis, I find that the condition of chronic pain related to a musculoskeletal disorder is "debilitating" and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the debilitating effect of this condition. As such, I find that chronic pain related to a musculoskeletal disorder should be added to the MMP.

Chronic Pain Conditions of a Visceral Origin

From my detailed review of the petitions, I am granting those seeking to add chronic pain conditions of a visceral origin to the MMP. In coming to this conclusion, I reviewed the petitions

⁸ See <https://my.clevelandclinic.org/health/drugs/11086-non-steroidal-anti-inflammatory-medicines-nsaids> (last visited March 13, 2018).

⁹ See Footnote 6.

¹⁰ See, e.g., The Health Effects of Cannabis and Cannabinoids: the Current State of Evidence and Recommendations for Research, National Academies Press (2017) (<http://nationalacademies.org/hmd/Reports/2017/health-effects-of-cannabis-and-cannabinoids.aspx>) (last visited March 13, 2018); Cannabinoids for treatment of chronic non-cancer pain; a systematic review of randomized trials, British Journal of Clinical Pharmacology (2001) (<https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3243008/>) (last visited March 13, 2018).

against the six regulatory criteria cited above and found that the condition meets the requirements for inclusion in the MMP.

For the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that chronic pain of a visceral origin is a valid condition. Chronic pain of a visceral origin is commonly defined by the medical community as pain that arises from the internal organs of the body and persists beyond the usual course of an acute condition, which is typically three months or more or past the time for normal healing.¹¹ Specifically, visceral pain is pain that results from the activation of nociceptors located in most viscera (internal organs of the body, specifically those within the chest (as the heart or lungs) or abdomen (as the liver, pancreas or intestines)) and the surrounding connective tissue.¹² Moreover, as noted by the Panel, there are multiple ICD-10-CM codes for chronic pain of a visceral origin, such as codes for pancreatitis, pain related to neurogenic bladder and bowel dysfunction, and irritable bowel syndrome. Because there is a common medical definition for chronic visceral pain as well as many ICD-10-CM codes for this condition, I find that chronic pain of a visceral origin is a valid and recognized medical condition.

As for the second factor, I must consider whether the treatments for the condition, if the treatments are causing the patient suffering, are generally accepted by the medical community and other experts as valid treatments for the condition. Like chronic musculoskeletal pain, chronic pain of a visceral origin is generally treated with opioids and NSAIDs, which, as I stated above, can have severe side effects. Indeed, the CDC advises that NSAIDs and opioids are the most common forms of treatment for chronic pain.¹³ Thus, I find that the treatments for chronic pain, namely NSAIDs and opioids, are recognized and accepted by the medical community as the treatments for chronic visceral pain and relate to a patient's suffering.

Regarding the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that both the chronic pain condition itself as well as the treatments for this condition cause severe suffering for patients stuck with this disorder. Specifically, visceral pain due to an obstruction of a hollow organ is poorly localized, deep, and cramping and may be referred to remote cutaneous sites.¹⁴ Visceral pain that is caused by an injury of organ capsules or other deep connective tissues may be more localized and sharp.¹⁵ As such, the actual condition is the main cause for the suffering experienced by patients with this disorder. Although chronic pain itself causes severe pain, the treatment for this condition can also result in significant suffering. As I outlined above, prolonged use of NSAIDs can cause gastritis, ulcerative disease, heartburn, nausea, vomiting and dizziness. And, opioids can cause constipation, nausea, respiratory depression, dependency, opioid use disorder, sedation and dizziness. So, the condition itself as well as the side effects from the medications used to treat this condition can prevent a patient from engaging

¹⁴ See footnote 12.

¹⁵ Ibid.

in activities of daily living and eviscerate one's quality of life. Accordingly, I find that both the condition of chronic pain as well as the therapies to treat it cause severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. Unfortunately, the treatments for chronic pain that cause the patient suffering, which are NSAIDs and opioids, are the only viable conventional medical therapies offered for this condition.¹⁶ Therefore, I find that there is a lack of medically-accepted, alternative medical treatments to the conventional therapies currently recommended for chronic pain of this nature.

As for the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, the Panel concluded that there is comprehensive research demonstrating that the use of medicinal cannabis can alleviate the pain associated with chronic pain. As stated above, there are peer-reviewed publications in leading medical journals, including a review published by the National Academies of Sciences, Engineering, and Medicine in 2017, and a number of clinical trials that found that the use of medical marijuana was effective in relieving chronic pain. As such, I find that the medical community has generally accepted the use of medicinal marijuana as a likely effective treatment for alleviating the suffering caused by chronic pain.

As for the final factor, which is whether there were letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of chronic visceral pain under the MMP, I find that the petitions were submitted with support from medical professionals.

Based upon the above analysis, I find that the condition of chronic pain of a visceral origin is "debilitating" and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the debilitating effect of this condition. As such, I find that chronic pain of a visceral origin should be added to the MMP.

Tourette's Syndrome

After a careful review of the petition seeking to add Tourette's Syndrome (TS) to the MMP, I have decided to grant this petition. In formulating this determination, I reviewed the condition against the six regulatory criteria cited above and found that it meets the requirements for inclusion in the MMP.

Under the first factor, I must determine whether the condition is generally accepted in the medical community as a valid medical condition. I find that TS meets this requirement. Specifically, TS is commonly defined by the medical community as a neurological disorder characterized by repeated involuntary movements (motor tics) and uncontrollable vocal sounds (vocal tics), with symptoms usually manifesting before the age of eighteen.¹⁷ Moreover, a CDC study found that "1 of every 360 (0.3%) children 6 – 17 years of age in the United States have been diagnosed with TS based on parent[al] report[s]," with boys being "three to five times more

¹⁶ Ibid.

¹⁷ See <http://www.merckmanuals.com/professional/pediatrics/neurologic-disorders-in-children/tic-disorders-and-tourette-syndrome-in-children-and-adolescents> (last visited March 13, 2018).

likely to have TS than girls.”¹⁸ Accordingly, I find that TS is a valid and recognized medical condition.

Regarding the second factor, I must consider whether the treatments for the condition, rather than the condition itself, are causing the patient's suffering and the extent to which the treatments causing the patient suffering are generally accepted by the medical community and other experts as valid treatments for the condition. According to the petition and as acknowledged by the Panel, the generally accepted treatments for TS are medication and behavioral treatments, which can help manage the tics.¹⁹ As noted by the Panel, there is no one primary medication to treat TS and, as a result, there is a varying approach to how it is addressed.²⁰ Most medications prescribed for TS have not been approved by the U.S. Food and Drug Administration (FDA) for treating tics and the medications that are approved fall into the category of anti-psychotics, which can have serious adverse side effects that include weight gain, stiff muscles, tiredness, restlessness, and social withdrawal.²¹ As such, I find that the treatments for the symptoms of TS are recognized and accepted by the medical community as the treatments for this condition and relate to a patient's suffering.

As for the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that both TS itself as well as co-occurring conditions and the treatments for this condition cause severe suffering for patients inflicted with this condition. While the tics caused by TS clearly impair a patient's ability to carry on his or her activities of daily living, the co-occurring conditions that arise with this disorder can be equally if not more devastating to the patient. According to the National Institute of Neurological Disorders and Stroke, many individuals with TS experience additional neurobehavioral problems that often cause more impairment than the tics themselves. These include inattention, hyperactivity and impulsivity (attention deficit hyperactivity disorder — ADHD), problems with reading, writing, and arithmetic, and obsessive-compulsive symptoms such as intrusive thoughts/worries and repetitive behaviors.²² Thus, TS itself along with its co-occurring conditions negatively impact a patient's quality of life. Additionally, as I noted above, the pharmacological treatments for TS can cause serious side effects that negatively impact an individual's quality of life. As recognized by the Panel, TS is difficult to treat and very debilitating.²³ I concur. As such, I find that both the condition of TS as well as the therapies to treat it cause severe suffering.

Under the fourth factor, I must analyze the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. Unfortunately, the only FDA-approved therapies for TS are anti-psychotic medications. While these medications have an 80% rate of tic suppression, which was noted by the Panel, the medications have serious side effects that can include weight gain and social withdraw. And, although behavioral therapy is a treatment that teaches people with TS

²³ In Re: Medicinal Marijuana Review Panel Transcript. 54:11. October 25, 2017.

ways to manage their tics, it is not a cure for tics. As such, the conventional therapies for TS, which are pharmaceutical and behavioral treatment, may not fully suppress or manage tics and the presence of TS may severely impair the patient's ability to carry on activities of daily living. Accordingly, I find that there is a lack of medically-accepted, alternative medical therapies to the conventional therapies currently prescribed for TS that cause suffering for some patients.

Regarding the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I agree with the Panel's conclusion that there is research establishing that the use of medical cannabis can relieve the symptoms associated with TS. Evidence on the use of cannabis for effective symptomatic treatment of movement disorders, including TS, dates to the late 1990s with the work of Dr. Kirsten Müller-Vahl of the Hannover Medical School in Hannover, Germany.²⁴ Dr. Müller-Vahl's studies demonstrated improvements in global functioning and tic severity scores with cannabis use. Specifically, Dr. Müller-Vahl conducted a clinical survey among sixty-four TS patients of whom seventeen had reportedly consumed cannabis and approximately 82% of these patients reported a reduction in symptoms.²⁵ Subsequent studies of single cases confirmed that administration of 10mg of tetrahydrocannabinol (THC), which is one of the active chemical compounds in cannabis, led to an 80% reduction in tics and a simultaneous increase in the attention of patients.²⁶ And, a randomized, placebo-controlled six-week trial of up to 10mg THC per day confirmed the previous findings.²⁷ Furthermore, case reports have suggested that cannabis can reduce tics and that the therapeutic effects of cannabis might be due to the anxiety-reducing properties of marijuana rather than to a specific anti-tic effect.²⁸ Moreover, several states, such as Minnesota and Illinois, have approved medical marijuana specifically for the treatment of TS. Even more, a recent systematic review and meta-analysis published in the Journal of the American Medical Association (JAMA) in 2015 suggests there is some evidence that cannabinoids may improve symptoms of TS.²⁹ While the 2015 JAMA review suggests that marijuana may only have a minimal effect on relieving the symptoms of TS, the fact that the study evidenced some relief, even with the limited number of clinical trials available on the medical benefits of marijuana due to the legal restrictions surrounding cannabis, shows promise that marijuana is effective for this condition. As such, I find that the totality of the above research exhibits a general consensus in the medical community that marijuana is likely to alleviate some of the suffering caused by TS.

As for the final factor, which is whether there were letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of TS under the MMP, I find that the petition was submitted with support from medical professionals.

Based upon the above analysis, I find that the condition of TS is "debilitating" and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the

debilitating effect of this condition. As such, I find that Tourette's Syndrome should be added to the MMP.

Migraine

After a thorough review of the petitions, I am granting those seeking to add migraine to the MMP. In coming to this conclusion, I reviewed these petitions against the six regulatory criteria cited above and found that the condition meets the requirements for inclusion in the MMP.

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that migraine meets this criterion. According to the Merck Manual, migraine is an episodic primary headache disorder.³⁰ Symptoms typically last four to seventy-two hours and may be severe.³¹ Pain is often unilateral, throbbing, worsen with exertion, and accompanied by symptoms such as nausea and sensitivity to light, sound, or odors. Auras occur in about 25% of patients, usually just before but sometimes after the headache.³² And, there are approximately 28 million individuals living with migraines in the United States.³³ As such, I find that migraine is a valid and recognized medical condition.

Under the second factor, I must consider whether the treatments for the condition, rather than the condition itself, are causing the patient's suffering and the extent to which the treatments causing the patient suffering are generally accepted by the medical community and other experts as valid treatments for the condition. As stated in the petitions and recognized by the Panel, the generally accepted treatments for migraines are NSAIDs, triptans, opioids and/or ergots (ergot alkaloids), all of which can have significant side effects.³⁴ Specifically, prolonged use of NSAIDs can cause gastritis, ulcerative disease, heartburn, nausea, vomiting and dizziness.³⁵ Side effects of triptans include nausea, dizziness, drowsiness and muscle weakness.³⁶ Furthermore, triptans should not be used by those who have a past history of, or risk factors, for heart disease, high blood pressure, high cholesterol, angina, peripheral vascular disease, impaired liver function, stroke or diabetes.³⁷ Ergots may worsen nausea and vomiting related to migraines, and it may also lead to medication-overuse headaches.³⁸ And, as outlined above, opioids have serious side effects including addiction and nausea.³⁹ Thus, I find that the treatments for migraine, namely NSAIDs, triptans, opioids and ergots, can cause a patient to suffer and are accepted by the medical community as the treatments for this condition.

³⁵ See <https://my.clevelandclinic.org/health/drugs/11086-non-steroidal-anti-inflammatory-medicines-nsaids> (last visited March 13, 2018).

³⁶ See <http://www.headaches.org/2007/10/25/triptans/> (last visited March 13, 2018).

³⁷ *Ibid.*

³⁸ See <https://www.drugs.com/mcd/migraine> (last visited March 13, 2018).

³⁹ See footnote 6.

As for the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that both the migraine condition itself as well as the treatments for this condition cause severe suffering for patients. As stated above, the condition itself causes intense pain, nausea and sensitivity to light, sound, or odors. In fact, the pain and sensitivity may become so intense that the patient may have no other option than to rest in a dark, quiet room until the migraine passes.⁴⁰ Thus, the migraine condition causes severe suffering.

The same holds true for migraine treatments. The side effects caused by the treatments for migraines can be equally if not worse than the symptoms produced by this condition. Specifically, the treatments, which include opioids and triptans, can cause nausea, dizziness, and muscle weakness and may even cause rebound symptoms that are more intense than the original onset of the migraine.⁴¹ Thus, the migraine condition as well as side effects accompanying the treatment for this condition impair or even prevent a patient from engaging in activities of daily living, thereby diminishing one's quality of life. With this, I find not only that the migraine condition in and of itself causes a patient severe suffering but that the therapies to treat it also cause significant suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. The treatments for migraine that cause the patient suffering, namely NSAIDs, triptans, opioids and ergots, are the conventional medical therapies offered for this condition. Furthermore, as noted by the Panel, the conventional therapies are ineffective for some patients, leaving them with a decreased ability to function and a decreased quality of life. Alternatives such as biofeedback, ice packs, acupuncture, aromatherapy, adequate sleep, smoking cessation, avoiding any food and environmental triggers are available and may alleviate migraine symptoms.⁴² However, these alternative treatments usually do not treat all of the symptoms associated with a migraine and do not necessarily alleviate the patient's suffering caused by the migraine. Therefore, patients that are not responsive to conventional or alternative therapies may suffer constant unrelenting pain, which produces mental and physical debilitation. As such, I find that there are serious limitations with the medically-accepted, alternative medical therapies and the conventional therapies currently prescribed for migraine.

Regarding the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I agree with the Panel's conclusion that there is extensive research establishing that the use of medical cannabis can relieve the pain associated with migraine. There are studies which found that the use of medical marijuana was effective in decreasing the frequency of migraine headaches and relieving migraine pain.⁴³ Most notably, a recent study recommended that prospective studies

⁴² *Ibid.* See also <https://migraine.com/complimentary-and-alternative-therapies/> (last visited March 13, 2018).

⁴³ Ethan B. Russo, Clinical Endocannabinoid Deficiency Reconsidered: Current Research Supports the Theory in Migraine, Fibromyalgia, Irritable Bowel, and Other Treatment-Resistant Syndromes, *Cannabis and Cannabinoid Research*, 20a6, 1,1, 154. See <https://www.liebertpub.com/doi/10.1089/can.2016.0009> (last visited March 13, 2018).

should be conducted to explore a cause-and-effect relationship and the use of different strains, formulations, and doses of marijuana to better understand the effects of medical marijuana on migraine headache treatment and prophylaxis.⁴⁴ A majority of the Panel agreed that a review of the literature suggests that marijuana might alleviate some of the symptoms caused by a migraine with less side effects than commonly accepted medical treatment. Based upon this research, I find that there is generally accepted evidence in the medical community that medicinal cannabis can alleviate the suffering caused by migraine.

As for the final factor, which is whether there were letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of migraine under the MMP, I find that the petitions were submitted with support from physicians and an advanced practice nurse. Indeed, one petition was submitted by a board certified anesthesiologist. Thus, I find that this requirement is met.

Based upon the above analysis, I find that the condition of migraine is “debilitating” and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the debilitating effect of this condition. As such, I find that migraine should be added to the MMP.

Anxiety

Based upon my independent review of the petitions, I am granting those seeking to add anxiety to the MMP. In coming to this conclusion, I reviewed these petitions against the six regulatory criteria cited above and found that the condition meets the requirements for inclusion in the MMP.

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that anxiety satisfies this criteria. Specifically, the American Psychiatric Association defines anxiety and anxiety disorders as conditions characterized by excessive fear and behavioral disturbances.⁴⁵ Anxiety results from anticipation of a future threat and may be associated with symptoms of muscle tension, vigilance in preparation for future danger, and overly cautious or avoidant behaviors.⁴⁶ Additionally, there are multiple ICD-10-CM codes for anxiety disorders.⁴⁷ Because anxiety maintains a common definition in the medical community and has ICD-10-CM codes, I find that anxiety is a valid and recognized medical condition.

Under the second factor, I must consider whether the treatments for the condition, rather than the condition itself, are causing the patient’s suffering and the extent to which the treatments causing the patient suffering are generally accepted by the medical community and other experts as valid treatments for the condition. From my review of this condition, the generally accepted treatments for anxiety are dependent on the symptoms and the severity of the particular disorder. Mild and moderate forms of anxiety may not require a pharmacologic intervention, but may necessitate other forms of treatment, such as meditation, mindfulness, breathing techniques as well as psychotherapy (counseling) or cognitive therapy.⁴⁸ The most common classes of

⁴⁴ See <https://www.ncbi.nlm.nih.gov/pubmed/26749285> (last visited March 13, 2018).

⁴⁵ See <https://dsm.psychiatryonline.org/doi/abs/10.1176/appi.books.9780890425596.dsm05> (last visited March 13, 2018).

⁴⁶ *Ibid.*

⁴⁷ See ftp://ftp.cdc.gov/pub/Health_Statistics/NCHS/Publications/ICD10CM/2018/ (last visited March 13, 2018).

⁴⁸ See <https://adaa.org/finding-help/treatment#> (last visited March 14, 2018).

medications used to combat anxiety disorders are antidepressants, anti-anxiety drugs, and beta-blockers.⁴⁹ Antidepressants are safe and effective but they may be risky for children, teens, and young adults.⁵⁰ Antidepressants also come with a “black box” warning – the FDA’s strongest warning - advising that some people may have suicidal thoughts or make suicide attempts while taking the medication.⁵¹ The most common anti-anxiety medications are called benzodiazepines. As noted by the Panel, the common side effects of benzodiazepines include headache, confusion, tiredness, and in some cases nightmares and memory impairments.⁵² And, benzodiazepines carry a risk of dependence and addiction.⁵³ Furthermore, the FDA notes that the number of patients who were prescribed both an opioid analgesic and benzodiazepine increased by 41% between 2002 and 2014.⁵⁴ As a result, the FDA requires black box warnings and patient-focused Medication Guides for prescription opioid analgesics, opioid-containing cough products, and benzodiazepines to inform the patient about the serious risks associated with using these medications at the same time.⁵⁵ Thus, I find that the treatments for anxiety are recognized and accepted by the medical community as the treatments for this condition and relate to the suffering of the patient.

As for the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that both the anxiety condition itself as well as the treatments for this condition cause severe suffering for patients. Specifically, anxiety may lead to problems that negatively impact an individual's activities of daily living and quality of life and may lead to suicide and depression. Anxiety disorders can also cause significant distress or interfere with social, occupational, and other areas of functioning. In fact, an estimated 31.1% of U.S. adults experience an anxiety disorder at some time in their lives.⁵⁶ Medications, in some instances, may exacerbate the symptoms and are associated with debilitating side effects that can prevent a patient from engaging in activities of daily living, thereby diminishing one's quality of life. Accordingly, I find that both the condition of anxiety as well as the therapies to treat it cause severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. As discussed above, mild and moderate forms of anxiety may be treated with meditation, mindfulness, breathing techniques as well as counseling or cognitive therapy that can be effective. Progression to medication therapy may be initiated; however, in both instances, one must consider the therapeutic response. Failure to respond to therapies or side effects associated with treatments may result in significant impacts on quality of life. As such,

⁴⁹ *Ibid.*

⁵⁵ *Ibid.*

⁵⁶ See <https://www.nimh.nih.gov/health/statistics/any-anxiety-disorder.shtml> (last visited March 13, 2018).

I find that there is an absence of medically-accepted, alternative medical therapies to the conventional therapies currently prescribed for migraine that cause suffering.

Regarding the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I find that cannabis is generally accepted as an effective treatment for anxiety. The Panel discussed medical evidence that cannabis may exacerbate anxiety symptoms or that an effect related to cannabis may be associated with anxiety, such as dependence and cravings. Literature suggests that individuals with anxiety sensitivity may be more likely to turn to cannabis as a mechanism for coping with stress, which may in turn lead to problematic use behaviors.⁵⁷ However, the Panel further discussed a review published by the National Academies of Sciences, Engineering, and Medicine in 2017, which found that there is limited evidence that cannabidiol is an effective treatment for the improvement of anxiety symptoms, which was assessed by a public speaking test utilizing individuals with social anxiety disorders.⁵⁸ On balance, the Panel recommended adding anxiety as an allowable condition under the MMP as research suggests that it could be helpful to some patients with this condition. I agree. While marijuana may not be effective for all anxiety sufferers, there is research evidencing that it may be helpful to some, especially those with social anxiety disorders. Thus, I find that there is acceptance in the medical community that marijuana is likely to relieve the suffering associated with some anxiety conditions. However, like any medical condition, the use of medical marijuana to treat anxiety must be explored by the medical professional treating the patient to determine whether it is the best and most appropriate course of treatment for the patient.

As for the final factor, which is whether there were letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of anxiety under the MMP, I find that the petitions were submitted with support from medical professionals.

Based upon the above analysis, I find that the condition of anxiety is “debilitating” and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the debilitating effect of this condition. As such, I find that anxiety should be added to the MMP.

Opioid Use Disorder

From my independent review of the petitions, I am granting the petition that seeks to add opioid use disorder to the MMP. In coming to this conclusion, I reviewed this condition against the six regulatory criteria cited above and find that it meets the requirements for inclusion in the MMP, with the condition that physicians prescribing medical marijuana for this disorder do so in conjunction with their patient’s medication-assisted treatment, instead of as a singular treatment for the disorder.

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that opioid use disorder is a valid condition. According to the U.S. Department of Health and Human Services, Centers for Disease Control

⁵⁷ Anxiety Sensitivity and Distress Intolerance as Predictors of Cannabis Dependence Symptoms, Problems, and Craving: The Mediating Role of Coping Motives. Farris SG, Metrik J, Bonn-Miller MO, Kahler CW, Zvolensky MJ. *J Stud Alcohol Drugs*. 2016 Nov;77(6):889-897.

⁵⁸ The Health Effects of Cannabis and Cannabinoids: the Current State of Evidence and Recommendations for Research, National Academies Press (2017); Cannabinoids for treatment of chronic non-cancer pain; a systematic review of randomized trials, *British Journal of Clinical Pharmacology* (2001).

and Prevention, opioid use disorder is “[a] problematic pattern of opioid use that causes significant impairment or distress.”⁵⁹ Additionally, there are multiple ICD-10-CM codes for opioid use disorder.⁶⁰ Because opioid use disorder has a common medical definition and maintains several ICD-10-CM codes, I find that opioid use disorder is a valid condition recognized by the medical community.

Under the second factor, I must consider whether the treatments for the condition, if the treatments are causing the patient suffering, are generally accepted by the medical community and other experts as valid treatments for the condition. As noted in the petition, the generally accepted treatment for opioid use disorder is medication-assisted treatment (MAT), which includes methadone, naltrexone, and buprenorphine (suboxone). I agree. As stated by the U.S. Department of Health and Human Services, Substance Abuse and Mental Health Services Administration (SAMHSA), MAT is the “gold standard” for treatment of opioid use disorder.⁶¹ According to SAMHSA, MAT consists of FDA-approved medications, namely methadone, buprenorphine or naltrexone, in combination with behavioral therapies, “to provide a whole-patient approach to the treatment of substance use disorders.”⁶² Side effects from MAT medications include insomnia, headaches, abdominal pain, body aches and vomiting, to name a few.⁶³ Thus, I find that the treatment for opioid use disorder, specifically MAT medications, is recognized and accepted by the medical community. And, while I agree that MAT medications are an effective treatment for opioid use disorder, there are serious side effects that come with this treatment. Accordingly, I also find that MAT medications can cause a patient’s suffering.

As for the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient’s ability to carry on activities of daily living, I find that opioid use disorder itself as well as the treatment for this condition cause severe suffering for patients inflicted with this condition. It is without question that opioid use disorder causes severe suffering for an individual stricken with this condition. According to the U.S. Department of Health and Human Services, Office of the Surgeon General, “[o]pioid addiction typically involves a pattern of: (1) intense intoxication, (2) the development of tolerance, (3) escalation in use, and (4) withdrawal signs that include profound negative emotions and physical symptoms, such as bodily discomfort, pain, sweating, and intestinal distress.”⁶⁴ With increased use, the individual not only must take the opioid to avoid the severe withdrawal side effects, but the individual will also experience intense cravings for the opioid and preoccupation with using the opioid.⁶⁵ As such, an individual living with opioid use disorder can experience suffering that ranges from severe psychosocial impairment to overdosing and even death.⁶⁶ With these side effects, a patient is unable to engage

⁵⁹See <https://www.cdc.gov/drugoverdose/opioids/terms.html> (last visited January 17, 2019).

⁶⁰ See ftp://ftp.cdc.gov/pub/Health_Statistics/NCHS/Publications/ICD10CM/2018/ (last visited January 17, 2019).

⁶¹ See https://addiction.surgeongeneral.gov/sites/default/files/Spotlight-on-Opioids_09192018.pdf (last visited January 17, 2019).

⁶² See *Ibid.*

⁶³ See <https://medlineplus.gov/druginformation.html> (last visited January 17, 2019).

⁶⁴ See https://addiction.surgeongeneral.gov/sites/default/files/Spotlight-on-Opioids_09192018.pdf (last visited January 17, 2019).

⁶⁵ *Ibid.*

⁶⁶ *Ibid.*

in activities of daily living, thereby diminishing his or her quality of life. Thus, the condition itself causes the patients with this disorder to suffer immensely.

While opioid use disorder, in and of itself, causes extensive suffering, the treatment for the disorder can also cause significant suffering. Specifically, MAT medications can cause headaches, vomiting, body aches and insomnia.⁶⁷ All of these side effects can prevent a patient from engaging in activities of daily living, thereby diminishing one's quality of life. Accordingly, I find that opioid use disorder as well as the medications used to treat this condition cause severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. Unfortunately, the treatment for opioid use disorder that causes the patient suffering, specifically MAT medications, is the most effective and viable conventional medical therapy offered for this condition. As such, I find that there is an absence of effective alternative medical therapies to the conventional therapies currently prescribed for opioid use disorder that cause patients to suffer.

Regarding the fifth factor, which is whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I find that there is sufficient evidence that the use of medical marijuana may relieve the suffering related to opioid use disorder when it is used in conjunction with MAT. There is a recent publication by the Cannabis and Cannabinoid Research Journal that sets forth emerging evidence that the use of medical cannabis in conjunction with MAT has the potential to "ease opioid withdrawal symptoms, reduce opioid consumption, ameliorate opioid cravings, prevent opioid relapse, improve [opioid use disorder] treatment retention, and reduce overdose deaths."⁶⁸ However, the publication notes that these findings are preliminary and that additional research, which is hampered by the federal government's designation of marijuana as a Schedule I drug, should be conducted on this promising form of treatment for opioid use disorder.⁶⁹ While I acknowledge that there is little research on the effectiveness of medical marijuana, either alone or in conjunction with MAT, as a treatment for opioid use disorder, given the current opioid epidemic consuming our great State, the citizens of New Jersey suffering from this horrible disorder simply cannot wait for the removal of the political barriers that are preventing research on this promising treatment in order to receive a medication that may ultimately save their lives.

Moreover, as declared under Executive Order No. 219 (2017), "[t]he abuse of and addiction to opioid drugs is a public health crisis in New Jersey, necessitating the marshalling of all appropriate resources to combat its harmful effects on the citizens of our State." This crisis is further evidenced by the staggering number of deaths resulting from opioid overdoses that occur each year in New Jersey. In fact, overdose deaths have more than doubled since 2013. In 2013, there were 1,336 drug-related deaths; in 2016, that number increased to 2,221.⁷⁰ For 2018, the

⁶⁷ See Footnote 6.

⁶⁸ See Wiese B, Wilson-Poe AR (2018) Emerging evidence for cannabis' role in opioid use disorder, Cannabis and Cannabinoid Research 3:1, 179–189, DOI: 10.1089/can.2018.0022.

⁶⁹ *Ibid.*

⁷⁰ See <https://www.njcares.gov/>

number of deaths is projected to jump to a staggering 3,163.⁷¹ With opioid overdose deaths climbing at such an alarming rate, I am compelled to find that the research to date on the beneficial use of medical cannabis as an adjunct to MAT for the treatment of opioid use disorder is sufficient evidence that this form of treatment may alleviate the suffering relating to the disorder and prevent overdose deaths. Indeed, I cannot ignore these disturbing numbers and allow more of our citizens to succumb to this disorder when there is at least some research suggesting that the use of medical marijuana in conjunction with MAT may be an effective treatment for opioid use disorder and ultimately prevent a patient's demise. As such, in giving effect to Executive Order 219's call to garner all possible resources to combat the opioid crisis, I find that the available research I have reviewed establishes sufficient evidence that the use of medical marijuana may relieve the suffering related to opioid use disorder when it is used in conjunction with MAT.

As for the final factor, which is whether there were letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of opioid use disorder under the MMP, I find that the petitions were submitted with support from medical professionals.

Based upon the above analysis, I find that the condition of opioid use disorder is "debilitating" and that medical marijuana is more likely than not to be potentially beneficial to treat or alleviate the debilitating effect of this condition when it is used in conjunction with MAT. As such, I find that opioid use disorder, as a standalone condition, should be added to the MMP.

Denied Petitions

Asthma

After carefully reviewing the petition seeking to include asthma as a debilitating condition under the MMP, and in accordance with the Panel's recommendation, I am denying the request. In coming to this conclusion, I reviewed the petition against the six regulatory factors cited above and found that the condition fails to meet the requirements for inclusion in the MMP.

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that asthma meets this requirement. The CDC defines asthma as a chronic lung disease⁷² that "causes repeated episodes of wheezing, breathlessness, chest tightness, and nighttime or early morning coughing."⁷³ Moreover, the Department recognizes asthma as a chronic medical condition with approximately 600,000 adults and 167,000 children suffering from this condition in New Jersey.⁷⁴ Thus, I find that asthma is generally accepted by the medical community as a valid medical condition.

Under the second factor, I must consider whether the treatments for the condition, if the treatments are causing the patient suffering, are generally accepted by the medical community and other experts as valid treatments for the condition. In the petition, the petitioner asserts that the use of albuterol to treat asthma causes an individual to experience an increased heart rate and shakiness and that the use of corticosteroids to treat asthma can cause the patient to become

⁷¹ *Ibid.*

⁷² See https://www.cdc.gov/asthma/stateprofiles/asthma_in_nj.pdf (last visited March 13, 2018).

⁷³ See <https://www.cdc.gov/asthma/default.htm> (last visited March 13, 2018).

⁷⁴ See <http://www.nj.gov/health/fhs/chronic/asthma/in-nj/> (last visited March 13, 2018).

addicted to the drug. While corticosteroids and bronchodilators, such as albuterol, are generally accepted treatments for asthma, I do not find that the average patient suffers from the use of these medications. As stated by the Panel, there are several treatments for asthma that are not only effective but also provide minimal side effects. Specifically, asthma is generally treated with inhaled, oral and intravenous corticosteroids and bronchodilators.⁷⁵ Common side effects associated with the use of corticosteroids include acne, weight gain and upset stomach.⁷⁶ However, these side effects rarely occur with the short-term use of these medications, such as when they are used for acute asthma episodes.⁷⁷ While the use of corticosteroids is accepted by the medical community as valid treatments for asthma, I do not find that these treatments cause the vast majority of patients to experience suffering from their use.

The same holds true for bronchodilators. While bronchodilators can cause nervousness or shakiness, headache, throat or nasal irritation, muscle aches and, in rare instances, a rapid heart rate or heart palpitations, these side effects can be greatly reduced and even eliminated by changing the delivery method of the medication and/or reducing the dosage.⁷⁸ Although these side effects could potentially cause a patient to suffer, they can be effectively decreased and even eliminated through medication management. As such, I find that the treatments for asthma do not cause an average asthma patient to experience suffering.

As for the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that asthma can cause severe suffering. Specifically, when asthma is not well-controlled, it can severely impair a patient's ability to engage in his or her activities of daily living, such as limiting the patient's physical activity, cause sleep disturbances and can even result in death. Accordingly, I find that asthma can cause a patient to experience severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. While asthma cannot be cured, it can be well-controlled with self-management education, adequate pharmacological management, and avoidance of exposure to environmental triggers.⁷⁹ Specifically, asthma is commonly and effectively treated with bronchodilators and corticosteroids, which are widely available to patients and have little side effects.⁸⁰ Thus, I find that the conventional medical treatments for asthma are effective and easily attainable by patients.

Regarding the fifth factor, which whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I agree with the Panel's conclusion that there are no reliable clinical trials or research supporting the proposition that medical cannabis is an effective treatment for asthma. While the petitioner points

⁷⁵ See <https://www.mayoclinic.org/diseases-conditions/asthma/diagnosis-treatment/drc-20369660> (last visited March 13, 2018).

⁷⁶ See <https://my.clevelandclinic.org/health/diseases/16864-treating-the-inflammation-of-asthma> (last visited March 13, 2018).

⁷⁷ *Ibid.*

⁷⁸ See <https://www.mayoclinic.org/diseases-conditions/asthma-attack/expert-answers/albuterol-side-effects/faq-20058088> (last visited March 13, 2018).

⁷⁹ See <https://www26.state.nj.us/doh-shad/topic/Asthma.html> (last visited March 13, 2018).

⁸⁰ See Footnote 62.

to a study published in the New England Journal of Medicine in 1973, which suggests that marijuana dilates the airway for a short period of time, the study did not evaluate the effect marijuana has on patients suffering from asthma. In fact, the study utilized thirty-two male subjects with no serious medical conditions and advised that “further investigation is required to determine . . . the effects of marijuana smoking and oral THC on the airway of asthmatic subjects.” As such, I find that this study does not support the proposition that marijuana is an effective treatment for asthma.

Even more, physicians with the American Thoracic Society recently published an article in the American Journal of Respiratory and Critical Care Medicine advising that marijuana can worsen existing lung conditions and specifically noted that “marijuana smoke can cause an asthma attack leading to hospitalization and even death.”⁸¹ Thus, the medical community appears to be opposed to the use of marijuana as a treatment for asthma. Because the petitioner failed to point to any evidence demonstrating that the medical community accepts medical marijuana as a treatment for asthma, and neither I nor the Panel found any reliable trials or research in support of this, I find that the medical community is not in favor of using medicinal cannabis to alleviate the suffering associated with asthma.

As for the final factor, which is whether there are letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of asthma under the MMP, I find that the petition only referenced the 1973 New England Journal of Medicine article and did not include any letters of support from healthcare professionals. While the journal article was authored by three physicians, I do not find that this lone article from 1973 on the general effects of marijuana on the airway constitutes support from a medical professional for the inclusion of asthma to the MMP. Additionally, there were no public comments from medical professionals supporting the inclusion of asthma under the MMP. Thus, I find that there is a lack of support from physicians or other health care professionals for this condition to be added to the MMP.

Based upon the foregoing, I find that asthma can be debilitating if uncontrolled, but that marijuana is not likely to be a beneficial treatment for this condition or alleviate the debilitating effect of this condition. Indeed, as noted by the Panel, inhalation of smoke is a known trigger for asthma exacerbation and, as a result, smoking marijuana may actually increase the suffering of asthma patients rather than alleviate the suffering associated with this condition⁸². And, while I acknowledge that medicinal marijuana is available in non-smokable forms, I am not convinced that there is credible support for its use in treating asthma. Unless and until there is sufficient research and evidence demonstrating that the use of marijuana can be beneficial for an asthma patient, I find that asthma should not be added to the MMP.

Chronic Fatigue Syndrome

From my detailed review of the petition seeking to include chronic fatigue syndrome as a debilitating condition under the MMP, and in accordance with the Panel’s recommendation, I have concluded that the petition should be denied. In coming to this conclusion, I reviewed the petition

⁸¹ Drake MD, Matthew G. and Slatore MD, Christopher G. “Smoking Marijuana and the Lungs.” Am. J. Respir. Crit. Care Med., Vol. 195, P5-6 (2017).

⁸² Ibid.

against the six regulatory factors cited above and found that the condition fails to meet the requirements for inclusion in the MMP.

Regarding the first factor, which is whether the condition is generally accepted in the medical community as a valid medical condition, I find that chronic fatigue syndrome meets this criteria. According to the CDC, chronic fatigue syndrome, also known as myalgic encephalomyelitis, is a “long-term illness that affects many body systems.”⁸³ In addition to extreme fatigue, which may worsen with physical or mental activity, but does not improve with rest, an individual with this condition may experience insomnia, depression, joint and muscle pain and memory impairments.⁸⁴ In fact, there is an estimated 836,000 to 2.5 million individuals affected with this condition in the United States.⁸⁵ Thus, I find that chronic fatigue syndrome is a valid medical condition.

Under the second factor, I must consider whether the treatments for the condition, if the treatments are causing the patient suffering, are generally accepted by the medical community and other experts as valid treatments for the condition. Unfortunately, there is neither a cure nor an FDA-approved treatment for chronic fatigue syndrome.⁸⁶ As a result, treatment is largely palliative as the treatment is tailored to relieve the symptoms experienced by each individual patient. For example, a patient experiencing depression as a result of chronic fatigue syndrome could be treated with an anti-depressant and a patient experiencing muscle and joint pain could be prescribed an NSAID to relieve the pain.⁸⁷ Moreover, the symptoms of chronic fatigue are oftentimes treated with nutritional supplements and complementary therapies, such as massage, meditation, tai chi and acupuncture, which may be helpful in increasing the patient’s energy level and decreasing his or her pain.⁸⁸ But, these are not treatments for the actual condition but rather treatments for the symptoms associated with the condition. As such, I find that there is no treatment generally accepted in the medical community for this disease that causes suffering.

However, I do find that the above therapies prescribed by healthcare professionals to treat the **symptoms** associated with chronic fatigue syndrome are accepted by the medical community. While I find that the treatments for chronic fatigue symptoms are medically acceptable, the specific treatment prescribed depends on the type and severity of the symptoms presented and can range from anti-depressants and NSAIDs, which can have severe side effects for some patients and thereby cause suffering, to massage therapy and acupuncture, which have little to no side effects. Because there is a vast array of treatment options for chronic fatigue symptoms and no two patients are treated the same, I am unable to conclude that chronic fatigue patients generally suffer from the treatments they receive for their symptoms. However, individuals with severe forms of chronic fatigue syndrome may suffer from the treatments used to alleviate their symptoms.

⁸³ <https://www.cdc.gov/me-cfs/index.html> (last visited March 13, 2018).

⁸⁴ <https://www.mayoclinic.org/diseases-conditions/chronic-fatigue-syndrome/symptoms-causes/syc-20360490> (last visited March 13, 2018).

⁸⁵ Wright Clayton, MD, Ellen, “Beyond Myalgic Encephalomyelitis/Chronic Fatigue Syndrome An IOM Report on Redefining an Illness.” JAMA (2015).

⁸⁶ <https://www.cdc.gov/me-cfs/treatment/index.html> (last visited March 13, 2018).

⁸⁷ <https://www.cdc.gov/me-cfs/index.html> (last visited March 13, 2018).

⁸⁸ *Ibid.*

As for the third factor, which is whether the condition itself and/or the treatments thereof cause severe suffering, such as severe and/or chronic pain, severe nausea and/or vomiting or otherwise severely impair the patient's ability to carry on activities of daily living, I find that chronic fatigue syndrome can cause severe suffering. Specifically, some individuals suffering from chronic fatigue syndrome can experience severe pain, gross memory loss and even such extreme fatigue that the patient is house-bound or even bed-bound, all of which greatly impacts a patient's ability to engage in activities of daily living and maintain a quality life. Accordingly, I find that chronic fatigue syndrome can cause a patient to experience severe suffering.

Under the fourth factor, I must evaluate the availability of conventional medical therapies, other than those that cause suffering, to alleviate the patient's suffering caused by the condition and/or the treatment thereof. While chronic fatigue cannot be cured and there is no approved treatment for the condition, there is a wide array of pharmacological therapies available for alleviating the symptoms associated with this condition. Specifically, chronic fatigue symptoms can be effectively managed for some patients with NSAIDs, anti-depressants and sleep-aids, depending on the severity and type of symptoms presented. However, depending upon the patient, the pharmacological treatments for chronic pain symptoms may be effective but may also cause the patient to suffer from side effects. Thus, I find that there are available conventional medical therapies to alleviate a chronic fatigue patient's suffering, but those treatments may cause suffering for some patients.

Regarding the fifth factor, whether there is generally accepted evidence in the medical community that the use of marijuana alleviates suffering relating to the condition, I agree with the Panel's conclusion that there are no reliable clinical trials or research supporting the proposition that medical cannabis is an effective treatment for chronic fatigue syndrome. While the petitioner points to studies suggesting that medical marijuana can alleviate an individual's pain, which is potentially one symptom a patient inflicted with chronic fatigue syndrome may experience, the studies fail to articulate that marijuana is an effective treatment for the condition of chronic fatigue syndrome as a whole. Because the petitioner failed to point to any evidence demonstrating that the medical community accepts medical marijuana as a treatment for the actual condition of chronic fatigue syndrome, and neither I nor the Panel found any credible clinical evidence in support of this, I find that there is a lack of support in the medical community for the use of medicinal cannabis to alleviate the suffering associated with chronic fatigue syndrome.

As for the final factor, which is whether there are letters from physicians or other licensed health care professionals knowledgeable about the condition supporting the inclusion of chronic fatigue under the MMP, I find that the petition only referenced the above-mentioned studies reflecting on the effectiveness of medical marijuana to treatment pain and did not include any letters of support from healthcare professionals to have chronic fatigue added to the MMP. Additionally, there was an absence of public comments from medical professionals supporting the inclusion of chronic fatigue under the MMP. Thus, I find that there is a lack of support from physicians or other health care professionals for this condition to be added to the MMP.

Based upon the above analysis, I find that chronic fatigue syndrome can be debilitating for some patients, but that medical marijuana is not likely to be a potentially beneficial treatment for the debilitating effect of this condition or the alleviation of the symptoms associated with this condition. Indeed, as noted by the Panel, this condition has been researched for years and there is yet to be found a solid elucidation of the etiology of this condition or the treatments that are

effective for it.⁸⁹ Because there are still so many unknowns with this condition and there is no clinical evidence suggesting that marijuana would be beneficial as a treatment, I find that chronic fatigue syndrome should not be added to the MMP at this time.

Conclusion

Based upon the foregoing, I am adding chronic pain associated with musculoskeletal disorders, chronic pain of a visceral origin, as well as Tourette's Syndrome, migraine, anxiety and opioid use disorder (with the condition that medical marijuana be prescribed in conjunction with medication-assisted therapy for the treatment of the disorder) to the MMP. However, asthma and chronic fatigue syndrome will not be added to the MMP.

In order to provide patients with relief as soon as possible from the suffering they are experiencing from these debilitating conditions, I am immediately adding chronic pain associated with musculoskeletal disorders, chronic pain of a visceral origin, Tourette's Syndrome, migraine, anxiety and opioid use disorder to the MMP in advance of rule promulgation. While I am including these conditions under the MMP, please note that this decision is not intended to be a blanket endorsement for every patient inflicted with a condition falling under the MMP to utilize medicinal marijuana as a treatment. As with any condition, the course of treatment must be determined by a medical professional after a thorough evaluation and discussion with the patient regarding the benefits and possible negative effects of the recommended therapy. Accordingly, I encourage patients to discuss the possibility of utilizing medical marijuana as a treatment for their debilitating conditions with the medical professionals treating them. I hope that this decision brings needed relief to those suffering with these conditions.

This is a final agency decision. You have the right to appeal this final agency decision within 45 days to the New Jersey Superior Court, Appellate Division, Richard J. Hughes Justice Complex, P.O. Box 006, Trenton, New Jersey 08625-0006.

Therapeutic Benefits of Cannabis: A Patient Survey

Charles W. Webb MD and Sandra M. Webb RN, BSN

Abstract

Clinical research regarding the therapeutic benefits of cannabis ("marijuana") has been almost non-existent in the United States since cannabis was given Schedule I status in the Controlled Substances Act of 1970. In order to discover the benefits and adverse effects perceived by medical cannabis patients, especially with regards to chronic pain, we hand-delivered surveys to one hundred consecutive patients who were returning for yearly re-certification for medical cannabis use in Hawai'i.

The response rate was 94%. Mean and median ages were 49.3 and 51 years respectively. Ninety-seven per cent of respondents used cannabis primarily for chronic pain. Average pain improvement on a 0-10 pain scale was 5.0 (from 7.8 to 2.8), which translates to a 64% relative decrease in average pain. Half of all respondents also noted relief from stress/anxiety, and nearly half (45%) reported relief from insomnia. Most patients (71%) reported no adverse effects, while 6% reported a cough or throat irritation and 5% feared arrest even though medical cannabis is legal in Hawai'i. No serious adverse effects were reported.

These results suggest that Cannabis is an extremely safe and effective medication for many chronic pain patients. Cannabis appears to alleviate pain, insomnia, and may be helpful in relieving anxiety. Cannabis has shown extreme promise in the treatment of numerous medical problems and deserves to be released from the current Schedule I federal prohibition against research and prescription.

Introduction

Research into the therapeutic benefits of cannabis has been severely limited by the federal Schedule I classification, which essentially prohibits any ability to acquire or to provide cannabis for studies investigating possible therapeutic effects. Limited studies have been done in Canada and in Europe, as well as several in California.

Hawai'i is one of twenty states (plus the District of Columbia) which allow certifications for use of medical cannabis. The authors have been certifying patients for use of medical cannabis in Hawai'i for more than four years. In an attempt to discover the perceived benefits and adverse effects of medical cannabis, we conducted a survey of medical cannabis patients.

Methods

Sample Selection

Between July of 2010 and February of 2011, we hand-delivered questionnaires to one hundred consecutive patients who had been certified for the medical use of cannabis for a minimum of one year and were currently re-applying for certification.

Survey Design and Administration

The subjects were verbally instructed to complete the questionnaire in the office at the time of re-certification or were provided a stamped and addressed envelope so they could complete the questionnaire at home. All patients were instructed to remain anonymous and to answer the questions as honestly as possible.

A universal pain scale was used to assess pain before and after treatment (0 = no pain, 10 = worst pain ever). Open-ended questions were asked to ascertain the following:

- (1) "Any adverse effects you have had from using medical cannabis?"
- (2) "Does medical cannabis help you with any other problems? If so, what?"

The purpose of the last question was to explore benefits outside the parameters of the state of Hawai'i's medical cannabis qualifying conditions.

Results

The overall response rate was 94%. The mean age was 49.3 years and the median age was 51. No data was collected on sex or race/ethnicity. Almost all respondents (97%) used medical cannabis primarily for relief of chronic pain.

Average reported pain relief from medical cannabis was substantial. Average pre-treatment pain on a zero to ten scale was 7.8, whereas average post-treatment pain was 2.8, giving a reported average improvement of 5 points. This translates to a 64% average relative decrease in pain.

Other reported therapeutic benefits included relief from stress/anxiety (50% of respondents), relief of insomnia (45%), improved appetite (12%), decreased nausea (10%), increased focus/concentration (9%), and relief from depression (7%). Several patients wrote notes (see below) relating that cannabis helped them to decrease or discontinue medications for pain, anxiety, and insomnia. Other reported benefits did not extend to 5% or more of respondents.

Six patients (6%) wrote brief notes relating how cannabis helped them to decrease or to discontinue other medications. Comments included the following: "Medical cannabis replaced my need for oxycodone. Now I don't need them at all." "I do not need Xanax anymore." "In the last two years I have been able to drop meds for anxiety, sleep, and depression." "I've cut back 18 pills on my morphine dosage."

A majority (71%) reported no adverse effects, while 6% reported a cough and/or throat irritation and 5% reported a fear of arrest. All other adverse effects were less than 5%. No serious adverse effects were reported.

Discussion

According to the Institute of Medicine, chronic pain afflicts 116 million Americans and costs the nation over \$600 billion every year in medical treatment and lost productivity.¹ Chronic pain is a devastating disease that frequently leads to major depression and even suicide.² Unfortunately, the therapeutic options for chronic pain are limited and extremely risky.

Spurred by efforts to encourage physicians to become more pro-active in treating chronic pain, US prescription opioids (synthetic derivatives of opium) have increased ten-fold since 1990.³ By 2009 prescription opioids were responsible for almost half a million emergency department visits per year.⁴ In 2010 prescription opioid overdoses were responsible for well over 16,000 deaths.⁵ A 2010 article in the *New England Journal of Medicine* addressing this problem is aptly titled “A Flood of Opioids, a Rising Tide of Deaths.”³ Drugs such as OxyContin[®] are so dangerous that the manufacturer’s boxed warning states that “respiratory depression, including fatal cases, may occur with use of OxyContin, even when the drug has been used as recommended and not misused or abused.”⁶ Clearly safer analgesics are needed.

The Hippocratic Oath reminds to “first, do no harm.” It cannot be over-emphasized that there has never been a death from overdose attributed to cannabis.⁷ In fact, no deaths whatsoever have been attributed to the direct effects of cannabis.⁷ Cannabis has a safety record that is vastly superior to all other pain medications.

Many physicians worry that cannabis smoke might be as dangerous as cigarette smoke; however, epidemiologic studies have found no increase in oropharyngeal or pulmonary malignancies attributable to marijuana.⁸⁻¹⁰ Still, since smoke is something best avoided, medical cannabis patients are encouraged to use smokeless vaporizers which can be purchased on-line or at local “smoke-shops.” In states that (unlike Hawai‘i) allow cannabis dispensaries, patients can purchase “vapor pens,” analogous to e-cigarettes and fully labeled regarding doses of THC and other relevant cannabinoids.

Tests have proven that smoke-free vaporizers deliver THC as well or even more efficiently than smoking, and that most patients prefer vaporizers over smoking.¹¹ Like smoking, vaporizers allow patients to slowly titrate their medicine just to effect, analogous to IV patient-controlled analgesia (PCA) that has been so successful in hospital-based pain control. This avoids the unwanted psychoactive side-effects often associated with oral medication such as prescription Marinol[®] (100% THC in oil) capsules which tend to be slowly and erratically absorbed and are often either ineffectually weak or overpoweringly strong.^{12,13} Because inhaled cannabis is rapid, reliable, and titratable, most patients strongly prefer inhaled cannabis over Marinol[®] capsules.¹⁴

While the relative safety of cannabis as medication is easily established, the degree of efficacy is still being established. The reported pain relief by patients in this survey is enormous. One reason for this is that patients were already self-selected for success: they had already tried cannabis and found that it worked for them. For this sample, the benefits of cannabis outweighed any negative effects. The study design may therefore lend itself to over-estimating the benefits and under-estimating the negative side-effects if extrapolated to the general population.

Another reason that the reported pain relief is so significant is that cannabis has been proven effective for many forms of

recalcitrant chronic pain. A University of Toronto systematic review of randomized controlled trials (RCT’s) examining cannabinoids in the treatment of chronic pain found that fifteen of eighteen trials demonstrated significant analgesic effect of cannabinoids and that there were no serious adverse effects.¹⁵

While opioids are generally considered to have little benefit in chronic neuropathic pain, several RCT’s have shown that cannabinoids can relieve general neuropathic pain,¹⁶ as well as neuropathic pain associated with HIV and with multiple sclerosis (MS).^{17,18} One study found that cannabis had continuing efficacy at the same dose for at least two years.¹⁹

Even low dose inhaled cannabis has been proven to reduce neuropathic pain. In a randomized, double-blind, placebo-controlled crossover trial involving patients with refractory neuropathic pain, Ware, et al, found that therapeutic blood levels of THC (mean 45 ng/ml achieved by a single inhalation three times a day) were much lower than those necessary to produce a cannabis euphoria or “high”(> 100 ng/ml).¹⁹

Cannabis is relatively non-addicting, and patients who stop using it (eg, while traveling) report no withdrawal symptoms. One author (Webb C.) worked for 26 years in a high volume emergency department where he never witnessed a single visit for cannabis withdrawal symptoms, whereas dramatic symptoms from alcohol, benzodiazepine, and/or opioid withdrawal were a daily occurrence.

So why is cannabis still held hostage by the DEA as a Schedule I substance? On June 18, 2010, the Hawai‘i Medical Association passed a resolution stating in part that:

“Whereas, 1) Cannabis has little or no known withdrawal syndrome and is therefore considered to be minimally or non-addicting; and

Whereas, 2) Cannabis has many well-known medical benefits (including efficacy for anorexia, nausea, vomiting, pain, muscle spasms, and glaucoma) and is currently recommended by thousands of physicians; and

Whereas 3) Cannabis has been used by millions of people for many centuries with no history of recorded fatalities and with no lethal dosage ever discovered; and

Whereas, Cannabis therefore fulfills none of the required three criteria (all of which are required) to maintain its current restriction as a Schedule I substance...

The Hawai‘i Medical Association recommends that Medical Cannabis be re-scheduled to a status that is either equal to or less restrictive than the Schedule III status of synthetic THC (Marinol[®]), so as to reduce barriers to needed research and to humanely increase availability of cannabinoid medications to patients who may benefit.”²⁰

Medical cannabis remains controversial mainly because the federal government refuses to recognize cannabis as an accepted medication. To this we would echo the words of Melanie Thernstrom in her excellent book *The Pain Chronicles*,² “How could treating pain be controversial?” one might ask, “ Why wouldn’t it be treated? Who are the opponents of relief?”

Conclusions

Cannabis is an extremely safe and effective medication for many patients with chronic pain. In stark contrast to opioids and other available pain medications, cannabis is relatively non-addicting and has the best safety record of any known pain medication (no deaths attributed to overdose or direct effects of medication). Adverse reactions are mild and can be avoided by titration of dosage using smokeless vaporizers.

More research needs to be pursued to discover degrees of efficacy in other areas of promise such as in treating anxiety, depression, bipolar disorder, autism, nausea, vomiting, muscle spasms, seizures, and many neurologic disorders. Patients deserve to have cannabis released from its current federal prohibition so that scientific research can proceed and so that physicians can prescribe cannabis with the same freedom accorded any other safe and effective medications.

Conflict of Interest

None of the authors identify a conflict of interest.

Authors' Biography:

Dr. Webb graduated from Dartmouth Medical School (BS Medicine) and from UC San Francisco School of Medicine (MD 1974). General Residency US Public Health Hospital (San Francisco) and Highland Hospital (Oakland). Emergency Medicine Physician 1975-2006 (Colorado), Urgent Care Physician 2007-present (Kailua Kona). Sandra Webb RN, since 1979 (emergency and radiology nurse). Dr. Webb and nurse Webb have been certifying patients for medical use of cannabis since 2009.
