Medical Cannabis Registry

PETITION TO ADD A DEBILITATING MEDICAL CONDITION IN 2020

Instructions

1. ALL items on the form MUST be completed.
2. Petitions and any supporting documents may be submitted as follows:
 - a. Email to: medicalmarijuana@doh.hawaii.gov before the close of business (4:30PM) on **Thursday, April 30, 2020**. Please use the subject line: Petition to Add New Condition. Note that the DOH will not make public any information that is protected pursuant to Chapter 92F, HRS, the Uniform Information Practices Act.
 - b. Postal mail to: 4348 Waialea Avenue, #648, Honolulu, Hawaii 96816. Mailed petitions must be received by **Thursday, April 30, 2020**.
 - c. Hand delivered to: Kinau Hale at 1250 Punchbowl Street, Honolulu, Hawaii 96813 before the close of business (4:30PM) on **Thursday, April 30, 2020**. Hand delivered petitions must be left with the security guard and addressed to the Medical Cannabis Registry Program **ATTN: Petition to Add New Condition**.
3. For best results, complete and thorough petitions that include substantiated and reputable research have the best chance of succeeding. DOH recommends that you do the following for items #2- #8 on the petition form:
 - a. Please cite research, published evidence, or findings using the standard American Medical Association (AMA) format for each piece of research, published evidence, or findings that you reference in your submittal or at a minimum the following:
Author's Name; Title of Article; Name of Publication; Date of Publication; Volume/Section/Chapter/Page/Line as applicable; and URL (if applicable).
 - b. Please attach a PDF copy of the cited material to your submittal. These documents will NOT be returned.
 - c. Please be sure to indicate the specific section, page(s), lines, etc., of the attachment that you want reviewed/considered as evidence.
4. To view a list of current conditions click here: [Current Debilitating Medical Conditions](#)

Petitioner

Name

I am a Physician/APRN
 Potentially qualifying patient (a person who has been diagnosed with the medical condition for which the petition is being made)

Street Address

City

State

Email

I prefer the following and give my consent for all notifications about my petition to be by:

- Mailing address
 Email address
 Both mailing and email addresses

If I have indicated communication via email, and if for any reason email communication is not successful (i.e. email provided bounces or is kicked back to DOH), then I further understand that communication will be by regular U.S. postal service to the mailing address that I have provided. I also take full responsibility for any inaccurate email or U.S. postal mail address provided.

Petitioner Content

(1) State the specific medical condition or its treatment for which the petition is being made.

Insomnia

(2) State the reason(s) why the medical condition or its treatment should be added to the list of qualifying debilitating medical conditions for which medical cannabis may be used. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Insomnia is a widespread, serious and debilitating condition, to which the current traditional treatments are dangerous (alcohol, ambien) or have a low success rate (relaxation, exercise, glass of milk). Patients with other qualifying conditions report that cannabis helps with insomnia. As cannabis is non toxic and highly effective for insomnia, insomnia should be added to the list of qualifying conditions for those people who do not currently have a qualifying condition.

Institute of Medicine (US) Committee on Sleep Medicine and Research; Colten HR, Altevogt BM, editors.

Washington (DC): [National Academies Press \(US\)](#); 2006.

It is estimated that 50 to 70 million Americans chronically suffer from a disorder of sleep and wakefulness, hindering daily functioning and adversely affecting health and longevity. There are around 90 distinct sleep disorders; most are marked by one of these symptoms: excessive daytime sleepiness, difficulty initiating or maintaining sleep, and abnormal events occurring during sleep. The cumulative long-term effects of sleep loss and sleep disorders have been associated with a wide range of deleterious health consequences including an increased risk of hypertension, diabetes, obesity, depression, heart attack, and stroke. **After decades of research, the case can be confidently made that sleep loss and sleep disorders have profound and widespread effects on human health.**

(REF #99) The National Academy of Sciences Institute of Medicine, in its 1999 report on marijuana, found that many serious and debilitating conditions had the symptom of insomnia and that medical marijuana was able to safely treat insomnia by inducing sleep.

Page 83 of the pdf:

The most commonly reported effects of smoked marijuana are a sense of well-being or euphoria and increased talkativeness and laughter alternating with periods of introspective dreaminess followed by lethargy and **sleepiness** (see reviews by Adams and Martin, 1996,¹ Hall and Solowij,⁵⁹ and Hall et al. ⁶⁰).

Page 164:

Victims of spinal cord injury reporting at IOM workshops noted that smoking marijuana reduces their muscle spasms, their nausea, and **the frequency of their sleepless nights.**

(REF #40) The National Academies of Sciences, Engineering, and Medicine reviewed all marijuana research conducted and published from 1999-2016 and published a comprehensive report on cannabis and health.

National Academies of Sciences, Engineering, and Medicine 2017. *The Health Effects of Cannabis and Cannabinoids: The Current State of Evidence and Recommendations for Research*. Washington, DC: The National Academies Press.

<https://doi.org/10.17226/24625>

<https://www.nap.edu/catalog/24625/the-health-effects-of-cannabis-and-cannabinoids-the-current-state>

Page 13:

There is moderate evidence that cannabis or cannabinoids are effective for:

Improving short-term sleep outcomes in individuals with sleep disturbance associated with obstructive sleep apnea syndrome, fibromyalgia, chronic pain, and multiple sclerosis (cannabinoids, primarily nabiximols) (4-19)

A safety profile of Medical Marijuana can be found in the first year report of the Minnesota medical marijuana program. The Minnesota Department of Health surveyed 1500+ medical marijuana patients enrolled in the program.

(REF #11) <https://www.health.state.mn.us/people/cannabis/about/firstyearreport.html>

Adverse Side Effects: At this point, the safety profile of the medical cannabis products available through the Minnesota program seems quite favorable. Approximately 20-25% of enrolled patients report negative physical or mental side effects of some kind, with the majority – around 60% - reporting only one and 90% reporting three or fewer. The vast majority of adverse side effects, around 90%, are mild to moderate in severity. An assessment of the 30 patients reporting severe side effects, meaning “interrupts usual daily activities,” found no apparent pattern of patient age, medical condition, or type of medical cannabis used. The most common adverse side effects are dry mouth, drowsiness, and fatigue. Fortunately, up to the present no serious adverse events (life threatening or requiring hospitalization) have been reported.

Medical Marijuana's mild to moderate side effects of dry mouth, drowsiness and fatigue are easily tolerated by the vast majority of patients. Fatigue means being tired, and is the desired effect for people who suffer from insomnia and wish to feel tired so they can sleep.

(REF #77) <https://www.mass.gov/files/documents/2019/07/09/MBHS-full-report-final.pdf>

<https://www.mass.gov/report/massachusetts-department-of-public-health-marijuana-research>

The Marijuana Baseline Health Study (MBHS)

A legislative mandate required the Massachusetts [Department of Public Health \(DPH\)](#) to conduct a baseline study to investigate marijuana use in Massachusetts. The report published confirms the consensus that marijuana use improves sleep and treats insomnia for a large percentage of people.

Page 148:

Results from this survey suggest that respondents appear to be treating a wide range of medical conditions, and often more than one at a time. **The top 5 medical conditions being treated were** anxiety (60% or all respondents), chronic pain (46%), **insomnia (43%)**, depression (42%), and stress (41%), and the average number of conditions being treated by medical marijuana is 4.7.

The CDC says "Insufficient Sleep Is a Public Health Problem". <https://www.cdc.gov/features/dssleep/index.html>

The National Department of Transportation estimates drowsy driving to be responsible for 1,550 fatalities and 40,000 nonfatal injuries annually in the United States.

https://one.nhtsa.gov/people/injury/drowsy_driving1/Drowsy.html

A lack of sleep among the U.S. workforce is costing approximately \$411 billion and losing 1.2 million working days per year, a new study has found.

<http://fortune.com/2016/11/30/sleep-productivity-rand-corp-411-billion/>

The most widely prescribed medication for insomnia is Ambien, which can cause its users to sleep walk, sleep drive, sleep eat and other actions while unconscious.

http://www.huffingtonpost.com/2014/01/15/ambien-side-effect-sleepwalking-sleep-aid_n_4589743.html

Ambien, a drug that can make people sleepwalk and get into cars and drive - causing numerous accidents and deaths, is Schedule 4. Marijuana is Schedule 1. Ambien was first discovered in the early 1980s and used for insomnia in France in 1988, USA in 1992.

<http://www.emedexpert.com/facts/zolpidem-facts.shtml>

The choice for relief of insomnia is between an FDA approved "BLACK BOX" drug that is 30 years old and still has unknown side effects, or medical marijuana which has been used safely and effectively by humans for thousands of years by every country inhabited by humans on the entire planet.

Comparing medical marijuana to other insomnia medications shows that medical marijuana has less side effects, no toxicity and is safer.

Benadryl is another FDA approved treatment commonly used to treat Insomnia:

Overall driving performance was the poorest after taking diphenhydramine, and participants were most drowsy after taking diphenhydramine (before and after testing). *The authors concluded that diphenhydramine clearly impairs driving performance, and may have an even greater impact than does alcohol on the complex task of operating a motor vehicle.*

<https://one.nhtsa.gov/people/injury/research/job185drugs/diphenhydramine.htm>

While the study of marijuana and driving is clear: <http://blog.caranddriver.com/marijuana-doesnt-pose-significant-risk-in-car-crashes-nhtsa-says/>

<https://one.nhtsa.gov/people/injury/research/job185drugs/cannabis.htm>

Which reports on a study by NHTSA:

When factoring age, sex, and race, there was no "significant increased risk of crash involvement" due to marijuana use.

http://www.nhtsa.gov/staticfiles/nti/pdf/812117-Drug_and_Alcohol_Crash_Risk.pdf

A general consensus has developed from population-based studies that approximately 30% of a variety of adult samples drawn from different countries report one or more of the symptoms of insomnia.

<https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1978319/>

(REF #8) In 1889, Dr Ed Birch published case reports of patients and documented that cannabis was a “well known remedy for insomnia” in the Lancet journal.

I prescribed the cannabis simply with a view to utilising a well-known remedy for insomnia, but it did much more than procure sleep.

As evidenced by the included medical marijuana patient surveys in other states and countries, adults are using medical marijuana to treat this disease. Patients will continue to use medical marijuana to treat symptoms whether or not you approve this condition. Approving this condition to the list of Qualifying Conditions in the Hawaii Medical Cannabis Program has the only effect of protecting sick people from arrest or penalty. These patients are currently breaking the law by using a safe and non-toxic plant that they can grow themselves. The alternative are prescriptions that cost thousands of dollars per month, that the FDA approves even if it is toxic and poisons and kills many Americans each year.

(3) Describe the **extent to which** the medical condition is generally accepted by the medical community as a valid, existing medical condition. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Insomnia is a common and serious debilitating medical condition, accepted by the medical community, affecting millions in the US each year. Veterans suffer from debilitating insomnia in percentages more than the general population.

(REF #68) <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5930488/>

Insomnia in Military Veterans

Chronic Insomnia Disorder is a common behavioral sleep disorder clinically defined as dissatisfaction with sleep quantity or quality marked by complaints of difficulty falling or staying asleep, waking up earlier than desired, or sleep that is non-restorative and the cause of significant daytime impairment. Such problems are not related to other medical or sleep disorders, exist despite adequate opportunity and environment for sleep, and are endorsed three or more nights per week for three months or longer ([American Psychiatric Association, 2013](#)). Insomnia and/or insomnia-like symptoms are present in 27–54% of military personnel and veterans ([Hoge, W. et al., 2008](#); [Mysliwiec, McGraw, Smith, Trapp, & Roth, 2013](#)), rates that are two to three times higher than in the general U.S. adult population ([Ford, Cunningham, Giles, & Croft, 2015](#); [Roth, 2007](#)). The rate of incident insomnia cases in military personnel saw a 19-fold increase from 2000 to 2009 ([Mysliwiec et al., 2013](#)). The prevalence of insomnia among Veterans Health Administration (VHA) users is expected to continue to rise as many troops who served after September 11, 2001 continue to retire from military service and begin accessing VHA healthcare in the coming years ([Campbell, Shattuck, Germain, & Mysliwiec, 2015](#)).

Consequences of Insomnia

Persistent insomnia can lead to poor health outcomes and chronic conditions ([Fernandez-Mendoza & Vgontzas, 2013](#); [Taylor et al., 2007](#)), exacerbate symptoms of traumatic brain injury ([Macera, Aralis, Rauch, & MacGregor, 2013](#)), reduce overall quality-of-life ([Katz & McHorney, 2002](#)), and increase risk for morbidity and premature mortality ([Dew et al., 2003](#); [Kripke, Garfinkel, Wingard, Klauber, & Marler, 2002](#)). Chronic sleep problems can also negatively impact day-to-day outcomes including task performance ([Pilcher & Huffcutt, 1996](#)), stress coping ([Hamilton, Delwyn, & Karlson, 2007](#)), and management of chronic health conditions ([Ahn, Jiang, Smith, & Ory, 2014](#)).

Function, Performance and Health Management

Chronic insomnia impairs function and performance across cognitive, emotional, social, and physical domains ([Killgore, Balkin, & Westensten, 2006](#); [Killgore et al., 2008](#); [Pilcher & Huffcutt, 1996](#)). Adequate functioning in these areas enables veterans to adapt to and cope with daily hassles and reintegration stressors noted earlier. However, impairments in one or more domains can reduce ability to cope with acute and ongoing stressors. As a result, functional performance and independence decline, thereby decreasing the likelihood of successful reintegration into civilian life ([Institute of Medicine, 2013](#); [Pilcher & Huffcutt, 1996](#)).

Many of these aforementioned impairments can also reduce a veteran's capacity to cope with health-related stressors, a concept of particular interest to clinicians and health services researchers within the VHA. Medically complex patients, defined as individuals with two or more chronic conditions, who are challenged by managing such conditions ([Shippee, Shah, May, Mair, & Montori, 2012](#)), represent a growing subgroup of veterans utilizing VHA healthcare ([Yoon, Schott, Phibbs, & Wagner, 2011](#); [Yu et al., 2003](#)). Medical complexity is often marked by a cycle of ongoing acute and chronic health-related stressors. Patients cycle through these stressors and strive to achieve and maintain a balance between workload demands (i.e. management of chronic diseases) and physical and psychological resources ([Zullig et al., 2016](#)). Successful balance and management of stressors is bolstered by high physical and psychological reserve and capacity ([Zullig et al., 2016](#)). These new models of complexity support the idea that capacity is malleable and can be impacted by resources, behaviors, and events on individual and community levels. Although sleep problems, including insomnia, are gaining more attention within the VHA, sleep patterns and behaviors are not explicitly addressed in these models.

Mental Health

Insomnia symptoms are common among veterans with mental health disorders. In one study, more than three-quarters reported difficulty falling or staying asleep and just over one-half reported being at least moderately distressed about sleep that was restless or disturbed ([Ulmer et al., 2015](#)). Although this research sample was designed to over-recruit veterans with mental health symptoms, this same study drew attention to the notably high prevalence of sleep difficulties in veterans without a mental health diagnosis, including approximately seventy percent who met clinical criteria for poor sleep quality, defined as a score of five or greater on the Pittsburgh Sleep Quality Index ([Buysse, Reynolds, Monk, Berman, & Kupfer, 1989](#)).

The high rate of sleep problems among veterans without mental health diagnoses is alarming given that research with veteran and non-veteran populations has found that chronic sleep problems predict incident mental health diagnoses ([Baglioni et al., 2011](#); [Breslau, Roth, Rosenthal, & Andreski, 1996](#); [D. Ford & Kamerow, 1989](#); [Perlis et al., 2006](#)) and suicidal ideation ([Pigeon, Britton, Ilgen, Chapman, & Conner, 2013](#); [Pigeon, Piquart, & Connor, 2012](#)) as well as persistence of existing mental health problems, including depression ([Pigeon, Unutzer, & Perlis, 2008](#)), and increased risk for readmission to a partial hospitalization psychiatry program ([Koffel, Thuras, Chakravorty, Germain, & Khawakaja, 2015](#)). In a large study of OEF/OIF service members, researchers found that military personnel with predeployment insomnia symptoms had greater odds of developing depression, anxiety, and PTSD at follow-up ([Gehrman et al., 2013](#)). Another longitudinal study found that insomnia measured at four months post-deployment was a significant predictor of depression and PTSD at 12-months post-deployment ([Wright et al., 2011](#)).

<https://medlineplus.gov/insomnia.html>

What other problems can insomnia cause?

Insomnia can cause daytime sleepiness and a lack of energy. It also can make you feel anxious, depressed, or irritable. You may have trouble focusing on tasks, paying attention, learning, and remembering. Insomnia also can cause other serious problems. For example, it could make you may feel drowsy while driving. This could cause you get into a car accident.

(4) Describe the symptoms and other physiological or psychological effects experienced by an individual suffering from the medical condition or its treatment and **the extent to which** these symptoms and physiological or psychological effects are debilitating. Note: "Debilitating" generally means impairing the ability of a person to accomplish activities of daily living. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

(REF #66) <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1978319/>

Roth T. (2007). Insomnia: definition, prevalence, etiology, and consequences. *Journal of clinical sleep medicine : JCSM : official publication of the American Academy of Sleep Medicine*, 3(5 Suppl), S7–S10.

Due to its chronicity, insomnia is associated with substantial impairments in an individual's quality of life. In several studies, insomniacs reported decreased quality of life on virtually all dimensions of the 36-item Short Form Health Survey of the Medical Outcomes Study (SF-36), which assesses 8 domains: (1) physical functioning; (2) role limitation due to physical health problems (role physical); (3) bodily pain; (4) general health perceptions; (5) vitality; (6) social functioning; (7) role limitations due to emotional health problems (role emotional); and (8) mental health.^{16–18} One study compared SF-36 results in groups of mild and severe insomnia patients with groups of patients diagnosed with depression or congestive heart failure (CHF).¹⁹ Severe insomnia patients had numerically greater loss of function than patients with CHF in reported pain, emotional effects, and mental health effects. Additionally, insomnia patients also reported more physical problems than patients with depression.¹⁹

Research has shown that among the daytime consequences of insomnia, the increased occurrence of accidents poses the greatest health risk. Insomniacs are 2.5 to 4.5 times more likely than controls to have an accident.^{20,21} In a sample of 8,625 community respondents in France, Léger et al. reported that 8% of insomniacs and 1% of non-insomniacs had an industrial accident in the past 12 months.²² Work productivity is also compromised among insomniacs due to work-related problems (ie, higher rates of absenteeism, decreased concentration, and difficulty performing duties). Kuppermann and colleagues²³ found that individuals reporting a current sleep problem were more likely than good sleepers to have decreased job performance and to have been absent from work in the last month due to health problems. Simon and VonKorff²⁴ evaluated insomnia in a staff-model health maintenance organization population (N=1,962). After adjusting for age, gender, and chronic disease, days of restricted activity due to illness and days spent in bed were about twice as common among insomniacs compared with non-insomniacs. Additionally, mean total health care expenditures were 60% higher in the insomnia group relative to the controls.

Population- and clinic-based studies have demonstrated a high rate of psychiatric comorbidities in patients with chronic insomnia. In fact, insomnia is more frequently associated with psychiatric disorders than any other medical illness.²⁵ For example, in the Epidemiologic Catchment Area study, 40% of insomniacs had a comorbid psychiatric disorder compared with 16.4% of those with

no sleep complaints.⁸ Additionally, depression and anxiety are the most common comorbid psychiatric disorders in insomniacs. It has traditionally been assumed that insomnia is secondary to the psychiatric disorder; however, given the chronicity of insomnia, it is possible that in some, if not most, cases the insomnia precedes the psychiatric disorder. In fact, it is possible that insomnia represents a significant risk for the development of a subsequent psychiatric disorder. In a large-scale European population-based study (N=14,915), it was found that insomnia more often preceded rather than followed incident cases of a mood disorder.²⁶ This effect is even more pronounced for relapses of the mood disorder, where in 56.2% of cases, insomnia symptoms preceded symptoms of a mood disorder relapse. In contrast, in chronic insomnia patients with a comorbid anxiety disorder, the first occurrence of anxiety or a relapse preceded insomnia in most instances.

To further understand the relation of sleep and psychiatric disorders, several longitudinal studies have examined the evolution of psychiatric disorders among insomnia patients. These studies used follow-up periods ranging from 1 to 40 years, with the majority using a 1- to 3-year follow-up period. In all of these studies, insomnia has been found to confer a substantial risk for the development of a depressive disorder.^{27,28} Typically, the relative risk was approximately 5 (range 2–40), and in all cases it was statistically significant. While some studies also reported an increased risk for anxiety or drug abuse, neither of these was consistently found. Finally, longitudinal studies in subjects with affective disorders show that depressed patients who experience improvements in sleep will also experience a more rapid antidepressant response; while those patients whose insomnia persists will have a short time to relapse.^{29,30} What is clearly needed are clinical trials to assess the impact of insomnia therapy on incidence of depression as well as the time to relapse in depressed patients who are in remission.

The question then arises as to whether insomnia causes depression, vice versa, or both. The close association of insomnia with depression is likely related to common underlying pathophysiological mechanisms for sleep and mood regulation that make the individual vulnerable to both conditions. Data have shown that both the diagnosis of insomnia and the severity of the sleep disturbance are related to overactivation of the hypothalamic-pituitary-adrenal (HPA) axis and the hypersecretion of cortisol.³¹ Recent evidence suggests that there may be some neuroendocrine and clinical similarities between insomnia and depression. Corticotropin-releasing factor (CRF) dysregulation has been implicated in the pathogenesis of psychiatric disorders such as depression³² as well as in the mediation of hyperarousal seen in primary insomnia.³³ This abnormality might represent the common risk factor, and therefore, it is quite possible that both disorders would respond to the same therapeutic intervention (eg, corticotropin-releasing hormone antagonists).

(5) If one or more treatments for the medical condition, rather than the condition itself, are alleged to be the cause of a person's suffering, describe **the extent to which the treatments causing suffering are generally accepted by the medical community as valid treatments for the medical condition.** For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

This petition is for the medical condition of insomnia, not the treatment of insomnia.

The prescription medication treatment of insomnia causes zombie like side effects when awake, and sleepwalking effects when asleep.

(REF #69) <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4689974/>

Residual medication effects—such as feelings of being drowsy, groggy, or sluggish the next day, difficulty concentrating/remembering, or sleeping too much—were reported by approximately four out of every five individuals currently using prescription sleep medication. Overall, findings showed significant burden experienced by patients reporting residual sleep medication effects relative to those not reporting such effects.

Though patients with and without perceived residual effects suffered a similar number of nights with sleep problems (falling

asleep, staying asleep, waking before the alarm, or any problem), the experience of residual effects was associated with an average of one more day per week of “unrestful sleep.” One potential explanation is that the residual effects of the sleep medication itself are responsible for the difference, though this is only speculation; the present analysis was not designed to identify the cause. Patients reporting residual effects were also less satisfied with their medications. Moreover, there were clear relationships between increasingly severe residual symptoms and decreased satisfaction, as well as increasingly severe residual symptoms and greater work and activity impairment, and greater sleep-related interference in home management, ability to work, and social relationships. Though respondents reporting residual effects indicated they experienced more psychiatric symptomatology and other comorbidities than those not experiencing such effects, the relationships between functioning and residual symptom severity remained significant after these and other relevant covariates were accounted for.

...

Ultimately, patients who experience residual sleep medication effects represent a group with significant impairment of workplace, home, and social life activities; as the perceived severity of the residual symptoms increases, so does the burden. Thus, thorough medical and psychosocial/behavioral assessment of individuals experiencing residual effects is recommended (especially for the elderly). Also, improved management of insomnia would be beneficial. Behavioral and cognitive interventions have essentially no side effects and have been shown to lead to long-lasting, sustained improvements in sleep symptoms and parameters over 6 months to 24 months [28]. However, the degree of sleep medication use in this sample demonstrates that many may prefer, or need, pharmacotherapy for insomnia, highlighting a need for medications with fewer residual symptoms. The development of sleep medications with reduced residual effect profiles will be important for treatment of this patient population.

(REF #69)

Of the hypnotics, benzodiazepines and non benzodiazepine hypnotics with longer half-lives tend to produce residual impairment or “hang over,” particularly with middle-of-the-night dosing and regular use [17, 18]. Residual effects of hypnotics include sedation, cognitive impairment, motor incoordination, ataxia, dizziness, and gastrointestinal upset. In the elderly, the use of sedating drugs is dangerously associated with increased fall risk [19].

Meanwhile, the use of some antidepressants to treat insomnia has been associated with increased suicidal ideation, increased mania / hypomania in patients with bipolar disorder, and exacerbation of restless legs syndrome [20]. Further, the use of anticonvulsants (e.g., pregabalin) can produce daytime sedation, dizziness, and cognitive impairment [13]. Finally, the use of antipsychotics has been correlated with exacerbation of restless legs syndrome and increased mortality, particularly in elderly individuals [11]. From the standpoint of concern for public safety, insomnia treatments have been shown to impair next-day driving and increase the risk of motor vehicle accidents, particularly in women [21].

Ambien and other sleep medications have side effects of amnesia, sleep walking, sleep driving, sleep eating, sleep sex, and other activities done while unconscious. This pharmaceutical treatment is generally accepted by the medical community as a treatment for insomnia.

(6) Describe the availability of conventional medical therapies other than those that cause suffering to alleviate symptoms caused by the medical condition or its treatment. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Treatments include lifestyle changes, counseling, and medicines:

- Lifestyle changes, including [good sleep habits](#), often help relieve acute (short-term) insomnia. These changes might make it easier for you to fall asleep and stay asleep.
- A type of counseling called cognitive-behavioral therapy (CBT) can help relieve the anxiety linked to chronic (ongoing) insomnia
- Several medicines also can help relieve your insomnia and allow you to re-establish a regular sleep schedule

<https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2924526/>

First line pharmacotherapy

These drugs carry the highest level of evidence supporting efficacy and safety.

Benzodiazepines

Benzodiazepines are frequently prescribed to treat insomnia. These hypnotics reduce latency to sleep onset and total awakenings by increasing total sleep duration. Benzodiazepines enhance the effect of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) by increasing the affinity of GABA for its receptor. Benzodiazepines non-selectively bind to an allosteric site and affect the GABA-A receptor complex to allow a greater number of chloride ions to enter the cell when GABA interacts with the receptor and therefore enhance the inhibitory action of GABA. This accounts for their sedative, anxiolytic, myorelaxant, and anticonvulsant properties. Five benzodiazepines (estazolam, flurazepam, quazepam, temazepam, and triazolam) have an FDA-approved indication for the management of insomnia. Dose, distinguishing pharmacokinetic properties (absorption rate, distribution, and elimination half-life), and risk-benefit ratio should be considered when selecting the most appropriate medication. The lowest effective dose should be used to minimize side effects, and long-acting benzodiazepines with active metabolites should be avoided in the elderly.

Major side effects of short-acting benzodiazepines include rebound insomnia and anterograde amnesia. Intermediate- and longer-acting benzodiazepines are less effective for inducing sleep, but are indicated for sleep maintenance and decreasing nocturnal awakenings.^[44] Long-acting medications are best indicated for people with insomnia as well as concomitant daytime anxiety. Accumulation of active metabolites is problematic in elderly patients and in those patients with impaired liver function as it can cause confusion and cognitive dysfunction. Benzodiazepines are contraindicated in patients with acute alcohol intoxication with depressed vital signs, a history of substance abuse, and during pregnancy.

Benzodiazepines should be used cautiously in patients with chronic pulmonary insufficiency or untreated sleep apnea. They are frequently used in mood disorders but a worsening of the dysphoric symptoms and precipitation of suicide has been noted in depression, while hypomania or frank mania and paradoxical hyper-excited states can also occur.^[42] However, long-term use (beyond 4 weeks) is associated with dependence, discontinuation syndrome, difficulty in new learning abilities, and blunting of emotions.^[45]

Non-benzodiazepine hypnotics

Non-benzodiazepine hypnotics include zopiclone, zolpidem, and zaleplon.

Zopiclone

Zopiclone is a non-benzodiazepine hypnotic of the cyclopyrrolone class. It is effective for reducing sleep latency and nocturnal awakenings and increasing total sleep time. Zopiclone delays the onset of rapid eye movement (REM) sleep but does not reduce consistently the total duration of (REM) periods. Rebound effects have been reported but are minimal. The incidence of adverse effects is low at recommended doses (3.75–7.5 mg).^[46]

Zolpidem

Zolpidem is a non-benzodiazepine hypnotic of the imidazopyridine class. It exhibits hypnotic effects with minimal myorelaxant, anticonvulsant, and anxiolytic properties, as it preferentially binds with the GABA-A receptor complexes with an alpha-1 subtype. Zolpidem is effective for reducing sleep latency and nocturnal awakenings and increasing total sleep time. Rebound effects are minimal. Common side effects include drowsiness, dizziness, and headache.[\[47\]](#)

Zaleplon

Zaleplon, like zolpidem, belongs to the imidazopyridine class of non-benzodiazepine hypnotics. The pharmacology of these two drugs is similar; however, zaleplon has an ultra-brief duration of effect.[\[48\]](#) It is effective for reducing time to sleep onset, but is not as effective for reducing nighttime awakenings or increasing total sleep time. No next-day sedation or rebound insomnia is documented with zaleplon at recommended doses (5–10 mg).

Eszopiclone

Eszopiclone, which is the active stereoisomer of zopiclone, acts as an agonist at benzodiazepine (BNZ) receptors. Well absorbed orally, about 3 mg of eszopiclone is equivalent to 10 mg of diazepam.[\[49\]](#) Although FDA approved for the management of chronic insomnia, there have been several reports of adverse effects like headaches, day-time drowsiness, loss of coordination, GI effects, decreased sexual desire, painful menstruation, and breast enlargement in males, leading a major reviewer to comment that the risk-benefit ratio should be weighed carefully due to the possible adverse effects such as cancer, infection, and death.[\[50\]](#)

Ramelteon

A melatonin agonist, it acts by selectively binding to the melatonin receptors (MT1, MT2) in the suprachiasmatic nucleus (SCN). It has also recently been approved for the treatment of insomnia and is the only non-scheduled prescription drug available in the United States for the treatment of insomnia. It has been shown to be effective in the elderly.[\[51\]](#)

No specific agent within this group is recommended as preferable to the others in a general sense; each has been shown to have positive effects on sleep latency, total sleep time (TST), and/or wake after sleep onset (WASO) in placebo-controlled trials.[\[52-55\]](#)

Second line pharmacotherapy

These drugs have moderate level of evidence supporting their efficacy and tolerability.

Antidepressants

Tricyclic antidepressants (TCAs) such as amitriptyline, doxepin, and nortriptyline are effective for inducing sleep and improving sleep continuity.[\[56\]](#) These agents should be used at their lowest effective dose to minimize anticholinergic effects and to minimize cardiac conduction prolongation, especially in the elderly. The overdose potential of TCAs is greater than with other hypnotic agents, and daytime sedation can be significant.

Trazodone

Trazodone is a potent sedating antidepressant. Trazodone improves sleep continuity and is an attractive option in persons prone to substance abuse, as addiction or tolerance is not a problem.[\[57\]](#) Trazodone is also used in conjunction with stimulating antidepressants such as some SSRIs and bupropion in depressed patients with insomnia. Adrenergic blockade can result in oversedation and orthostatic hypotension, especially in elderly patients. The risk of priapism, a condition of painful, prolonged erection in men, is rare. Other antidepressants used include *Mirtazapine* due to its sedative properties. Evidence for their efficacy when used alone is relatively weak and hence no specific agent within this group is recommended as preferable to the others in this group.[\[58-61\]](#)

Antihistamines

Antihistamines are found in many over-the-counter (OTC) sleep aids. These agents are effective for mild insomnia; however, next-day sedation may be a problem. Antihistamines commonly cause psychomotor impairment and anticholinergic effects. Tolerance may also develop with repeated use and evidence for their efficacy and safety is very limited.[\[62\]](#)

Alternative medications

These are drugs with variable evidence and are useful only in individual cases.

Valerian is a perennial plant that appears to increase GABA concentrations in animal studies, but its exact mechanism is not known. Valerian should not be used for the acute management of insomnia because its hypnotic effect is delayed for 2–4 weeks. Valerian appears to be well tolerated; however, it can cause headache and daytime sedation[63] and is currently still being evaluated.[64]

Other herbs used to promote sleep include skullcap, passion flower, California poppy, and Lemon balm.[65] Melatonin and L-tryptophan are two other molecules undergoing evaluation for the treatment of chronic insomnia.[66] There is currently very little evidence for their use.[67] Indiplon, a novel GABA_A potentiator, till recently being studied,[68] has now been abandoned due to its toxicity.

This week the Food and Drug Administration (FDA) announced that several prescription sleep medications now have to carry a “**black box**” **warning** alerting consumers of the potential for serious or life-threatening side effects. This is the agency's most prominent **warning** for medications. May 2, 2019

<https://www.healthline.com/health-news/why-fda-issued-a-black-box-warning-for-sleep-aids-such-as-ambien>

(7) Describe **the extent to which** evidence supports a finding that the use of cannabis alleviates symptoms caused by the medical condition or its treatment. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

1. <http://doi.org/10.1002/cbdv.200790150>

Sativex patients and their caregivers have remarked to their physicians how the medicine had transformed their lives through its ability to allow them more restful sleep, increase their daytime level of function, and markedly improve their quality of life. Its addition to the pharmacopoeia may be welcomed by patients, families, and physicians.

2. <https://harmreductionjournal.biomedcentral.com/articles/10.1186/1477-7517-2-18>

Approximately three quarters of participants (71%) claimed to have experienced a return of their symptoms or condition on stopping cannabis, especially: pain (53% of those who claimed a return of symptoms), depression or anxiety (30%), insomnia (11%), spasm (10%) and nausea/vomiting or lack of appetite (9%).

Positive ratings were ("great" or "good" relief) were also typical for its ability to relieve specific symptoms (Table 3). In addition, several other symptoms were noted, primarily insomnia (13% used for insomnia; of these 82% derived "great" relief).

3. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3998228/>

Ninety-seven per cent of respondents used cannabis primarily for chronic pain. Average pain improvement on a 0–10 pain scale was 5.0 (from 7.8 to 2.8), which translates to a 64% relative decrease in average pain. Half of all respondents also noted relief from stress/anxiety, and nearly half (45%) reported relief from insomnia. Most patients (71%) reported no adverse effects, while 6% reported a cough or throat irritation and 5% feared arrest even though medical cannabis is legal in Hawai'i. No serious adverse effects were reported.

These results suggest that Cannabis is an extremely safe and effective medication for many chronic pain patients. Cannabis appears to alleviate pain, insomnia, and may be helpful in relieving anxiety. Cannabis has shown extreme promise in the treatment of numerous medical problems and deserves to be released from the current Schedule I federal prohibition against research and prescription.

4. <http://doi.org/10.1016/j.smr.2007.12.004>

Several studies have shown that acute administration of THC decreases sleep latency,³⁸ and is associated with reports of greater ease in getting to sleep

5. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3929256/>

In addition, sleep improvement appears to be a primary motivator for coping-oriented use. Additional research is needed to examine the health consequences of this pattern of cannabis use and whether alternative sleep promoting interventions (e.g. CBT-I) could reduce the reliance on cannabis for adequate sleep among those with PTSD.

6. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3673028/>

Mental health disorders were the next largest group of diagnoses made (22.9%), followed closely by sleep disorders (21.3%).

Non-prescription therapies tried by applicants seeking medicinal marijuana allowances included physical therapy (48.6%), chiropractic services (37.2%), surgery (21.9%), psychological counseling (20.7%), and acupuncture (19.6%). Thus, these data do not suggest that applicants immediately seek marijuana recommendations as the first strategy to deal with their symptoms. In many cases, these individuals tried more traditional forms of medicine.

7. <https://www.ncbi.nlm.nih.gov/pubmed/26195653>

While further research into cannabinoid treatment effects on PTSD symptoms is required, the evaluated evidence indicates that substantial numbers of military veterans with PTSD use cannabis or derivative products to control PTSD symptoms, with some patients reporting benefits in terms of reduced anxiety and insomnia and improved coping ability.

8. [http://www.thelancet.com/journals/lancet/article/PIIS0140-6736\(00\)30567-0/fulltext](http://www.thelancet.com/journals/lancet/article/PIIS0140-6736(00)30567-0/fulltext)

I prescribed the cannabis simply with a view to utilizing a well-known remedy for insomnia, but it did much more than procure sleep.

9. <https://www.ncbi.nlm.nih.gov/pubmed/12185373>

In a survey of 15 chronic pain patients who admitted to using cannabis medicinally pain, sleep and mood were most frequently improved, while doses used were modest.

Small doses of smoked cannabis may improve pain, mood and sleep in some patients with chronic pain.

10. <http://doi.org/10.1213/ANE.0b013e3181c76f70>

Thirty-one subjects were enrolled and 29 completed the trial (26 women, mean age 49.5 yr). Although sleep was improved by both amitriptyline and nabilone, nabilone was superior to amitriptyline (Insomnia Severity Index difference = 3.2; 95% confidence interval = 1.2-5.3). Nabilone is effective in improving sleep in patients with FM and is well tolerated. Low-dose nabilone given once daily at bedtime may be considered as an alternative to amitriptyline.

11. <http://www.health.state.mn.us/topics/cannabis/about/firstyearreport.html>

At this point, the safety profile of the medical cannabis products available through the Minnesota program seems quite favorable. Approximately 20-25% of enrolled patients report negative physical or mental side effects of some kind, with the majority – around 60% - reporting only one and 90% reporting three or fewer. The vast majority of adverse side effects, around 90%, are mild to moderate in severity. An assessment of the 30 patients reporting severe side effects, meaning “interrupts usual daily activities,” found no apparent pattern of patient age, medical condition, or type of medical cannabis used. The most common adverse side effects are dry mouth, drowsiness, and fatigue. Fortunately, up to the present no serious adverse events (life threatening or requiring hospitalization) have been reported.

12. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4845302/>

Studies examining the effect of cannabis on objective sleep measurements obtained either by an experienced observer rating sleep by polysomnography (PSG) largely confirm the subjective reports. For instance, an observer-rated study showed that administration of 10, 20, or 30 mg of THC decreased total time to fall asleep, and a PSG study showed both shorter sleep latency (SL), and decreased time awake after sleep onset (WASO).

13. <https://www.ncbi.nlm.nih.gov/pubmed/28749704>

At Time 1, 25% of students reported using at least one substance (alcohol, marijuana, or over-the-counter medications) for sleep aid in the past two weeks.

14. <https://www.ncbi.nlm.nih.gov/pubmed/4337346/>

Although subjective effects of oral THC are reported to appear within 30 to 60 minutes, the increment in Stage 4 sleep suggests that the onset of drug action occurred about 3 hours after ingestion. These observations indicate the insensitivity of the latency to sleep onset measure to any initial hypnotic properties of THC, since subjects were asleep well before the drug could have taken effect. The decrease in time spent awake after sleep onset and the increase in Stage 4 sleep, however, could be interpreted as indicating, respectively, less disturbed and "deeper" sleep, thereby empirically supporting the attribution of sedative properties to THC.

15. <http://doi.org/10.1016/j.neuropharm.2011.08.013>

Patients with post-traumatic stress disorder (PTSD) frequently complain of having sleep disturbances, such as insomnia and rapid eye movement (REM) sleep abnormality. Cannabidiol (CBD), a psycho-inactive constituent of marijuana, reduces physiological non-REM (NREM) sleep and REM sleep in normal rats, in addition to generating its anxiolytic effect.

16. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5101100/>

Cannabidiol oil, an increasingly popular treatment of anxiety and sleep issues, has been documented as being an effective alternative to pharmaceutical medications. This case study provides clinical data that support the use of cannabidiol oil as a safe treatment for reducing anxiety and improving sleep in a young girl with posttraumatic stress disorder.

17. <https://www.ncbi.nlm.nih.gov/pubmed/24095000>

Patients reported using cannabis to treat multiple symptoms, with sleep, pain, and anxiety being the most common. Cannabis was perceived to provide effective symptoms relief across medical conditions. Patterns of use were also consistent across medical conditions. Notable differences were observed with regard to modes of access.

18. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4758425/>

Marijuana was customarily used to treat insomnia and as an antiemetic before the onset of specific therapies in the 1930s.

19. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1654142/>

Cannabis, in herbal form, is widely used as self-medication by patients with diseases such as HIV/AIDS and multiple sclerosis suffering from symptoms including pain, muscle spasticity, stress and insomnia.

21. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3068013/>

Even less attention has focused on inhaled "street" cannabis. Data show that 36%–43% of patients with MS have at some time smoked cannabis. The figure for current use, 14%–18%, is more modest, but indicates that a substantial minority of patients with MS find cannabis helpful for relief from pain, spasticity, insomnia, bladder problems, tremors, and emotional distress.

22. <https://www.ncbi.nlm.nih.gov/pubmed/15184623/>

The symptoms reported by medical cannabis users to be most effectively relieved were stress, sleep, mood, stiffness/spasm, and pain.

23. <http://doi.org/10.1016/j.jns.2008.06.037>

The VAS evaluation of self-reported clinical modifications after cannabis medicinal use showed a wide range of improvement that was mainly perceived in sleep disturbances, pain, tremor, and muscle spasms

24. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4578915/>

Many people suffering from PTSD often have interrupted sleep, with many seeking medical marijuana as a means of helping them treat their sleep issues

25. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4157067/>

Our survey reports that cannabidiol-enriched cannabis is behaviorally well tolerated and may have beneficial effects on cognition and mood. Many parents reported that their children experienced better sleep, increased alertness, and better mood while taking cannabidiol-enriched cannabis. These beneficial side effects are rarely reported with pediatric use of other AEDs (anti epileptic drugs).

26. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5312634/>

Finally, preliminary clinical trials suggest that high-dose oral CBD (150–600 mg per day) may exert a therapeutic effect for epilepsy, insomnia, and social anxiety disorder. Nonetheless, such doses of CBD have also been shown to cause sedation.

27. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5165161/>

In addition, we have assessed the role of the cannabinoid system and marijuana constituents in neuroprotection as well as considered other beneficial effects of marijuana. Marijuana has been shown to improve nonmotor symptoms of PD such as depression, pain, sleep, and anxiety. Moreover, components of cannabis have been demonstrated to have neuroprotective effect due to their anti-inflammatory, antioxidative, and antiexcitotoxic properties.

Effect of Cannabinoids on Sleep Disorders

Sleep disorders are common in PD patients and negatively affect the quality of life. The reported prevalence ranges from 25% to 98% and this wide variation could be due to differences in study design and diagnostic tools used [297]. The causes of the sleep disturbances in PD are multifactorial and include neurodegeneration and the medications used to treat motor symptoms of PD [298]. Various sleep disorders including rapid eye movement sleep behavior disorder, insomnia, sleep fragmentation, excessive daytime sleepiness, restless legs syndrome, and obstructive sleep apnea have been described in PD patients [2 99 , 300].

Cannabidiol, the major nonpsychotic component of marijuana, has been reported to improve rapid eye movement sleep behavior disorder in PD patients [68 , 6 9]. Marijuana has also been shown to improve nonmotor symptoms of PD including sleep [65]. In clinical trials involving 2000 patients with various pain conditions, nabiximols has been demonstrated to improve subjective sleep parameters [3 01]. Thus, marijuana could be used to enhance the quality of life of PD patients by alleviating sleep disorders and pain.

28. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4604191/>

The 1854, the US Dispensary listed cannabis to treat neuralgia, depression, pain, muscle spasms, insomnia, tetanus, chorea, insanity, and other disorders.

29. <https://www.ncbi.nlm.nih.gov/pubmed/26317379>

367 medical marijuana patients in Arizona were surveyed.

145 patients reported using medical marijuana for treatment of Insomnia.

31 patients reported using medical marijuana for treatment of Sleep Apnea.

General relief from Insomnia symptoms was 82.7% and 58.1% for Sleep Apnea

Relief by medical marijuana compared to other medications was 77.4% for Insomnia and 85% for Sleep Apnea.

Less frequent use of other medications was 81.9% for Insomnia and 66.6% for Sleep Apnea.

30. <https://www.ncbi.nlm.nih.gov/pubmed/28189912>

In regards to conditions, pain-related conditions were the most common, reported by 53% of participants (n = 144; chronic pain 36%; (n = 98), arthritis 12% (n = 32), headache 5% (n = 14)). The second most prominent class was mental health (eating disorder, PTSD & psychiatric disorder), reported by 15% (n = 41). Other prominent conditions included gastrointestinal disorders (11%, n = 29), insomnia (7%, n = 18) and multiple sclerosis (4%, n = 11).

In regards to symptoms; the most highly endorsed were chronic pain (73%, n = 197), stress (60%, n = 162), insomnia (57%, n = 155), depression (46%, n = 126) and headache (32%, n = 87). Gastrointestinal (GI) issues also featured prominently, with 29% (n = 79) citing appetite loss and another 29% (n = 79) nausea. Cannabis was perceived to be very effective at symptom relief, with 95% (n = 257) reporting that it “often” or “always” helped alleviate their symptoms.

31. <http://doi.org/10.1111/j.1742-1241.2004.00271.x>

Over the period 1998–2002, 3663 questionnaires were distributed, and 2969 were returned (81% response rate).

14 patients reported using medical marijuana to treat Insomnia for (1–8) years.

Overall Effectiveness. Of 948 reported users, 648 (68%) reported that cannabis made their symptoms overall much better, 256 (27%) said a little better, 36 (4%) said no difference and eight subjects said a little worse (four subjects) or much worse (four subjects).

Effectiveness Compared to Other Medications. When asked how cannabis compared to other medications overall, 412 of 916 subjects (45%) said it worked much better than prescribed medications, 261 (28%) said it was somewhat better and 45 (5%) said it was about the same; only 27 subjects said that prescription medicines worked better than cannabis (18 somewhat better and nine much better). One hundred and seventy-one (19%) subjects said it was impossible to tell.

Side Effects Compared to other Medications. When asked to compare the undesirable effects of cannabis to those of prescribed medicines, 872 subjects responded, of whom six found that cannabis produced much worse side effects, 23 found somewhat worse side effects and 54 said the side effects were about the same. Two hundred and sixty-four (30%) subjects stated that side effects of prescribed medicines were somewhat worse and 294 (34%) said they were much worse. Two hundred and thirty-one (26%) stated that it was impossible to tell.

Effects on Other Medication Use. Of the 909 subjects responding to this question, 374 stated that their use of cannabis had changed their use of other medications, while 521 said it had not. Fourteen were not coded.

Return of Symptoms on Stopping. Of the 876 subjects responding, 673 said their symptoms returned or got worse when they stopped using cannabis, and 203 denied any worsening on stopping cannabis.

32. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4277530/>

Most of the respondents (from the clinic and online groups) reported that cannabis improved their mood, pain, muscle spasms, and sleep .

33. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2683812/>

Sleep problems

Nine teens in our sample described using marijuana to help them sleep. The "trouble" they had with sleeping was a constant problem that many had experienced for years. One 16-year old, who also experienced mild depression, indicated that she "stopped sleeping for two years." Not only did the problem affect their school performance, but it was deeply disturbing to them.

As another female described,

"I have a really hard time sleeping. I can lay there for about four to five hours, just laying there. And I just finally had it, and I just feel like screaming I don't want to wake anyone up. So I go downstairs and ask my gran or my brother [for some marijuana] or I have a roach or two sitting around." [16 years, non-daily use]

Although one teen indicated that she had spoken to her mother about her problems sleeping, others indicated that the adults in their lives did not offer any support.

"I have trouble going to sleep and waking up... My mum wanted to get the doctor to put me on sleeping pills but he said at such a young age it would cause like an addiction to them. ..I've had these problems since elementary school...I just, I can't go to sleep at night and then I like to sleep during the day." [Female, 14 years, non-daily use]

Many teens turned to pot and found almost immediate benefits in helping them sleep. Likened to a "magic sleeping pill" by one young male, the teens found it calmed their "busy minds," helped them relax and fall asleep quickly.

34. <https://www.ncbi.nlm.nih.gov/pubmed/11210205>

This article reports on an exploratory study of medical cannabis users. Interviews were completed with 50 self-identified medical cannabis users recruited through notices in newspapers and on bulletin boards. They reported using cannabis for a variety of conditions including HIV-AIDS-related problems, chronic pain, depression, anxiety, menstrual cramps, migraine, narcotic addiction as well as everyday aches, pains, stresses and sleeping difficulties .

35. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3480566/>

There are no studies on marijuana for treating RLS, but there is considerable anecdotal evidence from patients as to its effectiveness. Typically, only 1 or 2 puffs of a marijuana cigarette or vaporizer is sufficient to relieve RLS symptoms. It is not clear how long the relief lasts, as most patients use this at bedtime, but they do report the very rapid disappearance of their symptoms, which then helps them fall asleep.

36. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4537525/>

These findings suggest that tolerance to the somnolent effects of THC may have occurred, but results should be considered preliminary due to design limitations.

37. <https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5053383/>

A 57-year-old, married male patient reporting fibromyalgia for 5 years, and osteoarthritis, torn shoulder tendon, and spinal stenosis for over 20 years was referred to our clinic. His initial in-clinic recorded pain score was 8/10 on a numerical rating scale. The patient also had a history of severe obesity, sleep apnea, restless legs syndrome, and anxiety. Signs of neuropathic pain included widespread allodynia and positive DN4 score. At the time of meeting, the patient was taking several prescribed pain medications, including Percocet 5/325 mg as needed and Oxyneo 40 mg daily. Physiotherapy, corticosteroid injections, codeine, and a number of anti-inflammatory medications were unsuccessful at achieving adequate analgesia. The patient was inexperienced with cannabis, except for intermittent use on weekends.

The patient was prescribed 1.5 g per day of a strain of cannabis containing 5% THC and 8% CBD to be administered by a vaporizer. After 2 weeks of trial, the patient reported a lack of success, and a strain of 12% THC was added to the other strain, with instructions to mix the strains in equal parts. At 60 days of follow-up, the patient's pain was lowered to a weekly average of 3/10 on a numerical rating scale, and he lowered his use of Percocet from four pills per day to three pills per week, on average.

38. <https://www.ncbi.nlm.nih.gov/pubmed/15118485>

It would appear that the cannabinoids, THC and CBD, when given in the doses and in the combinations used in the present study, are unlikely to have adverse clinical effects on sleep. THC would appear to be a sedative compound, whereas CBD would appear to have some alerting properties. The distinct activity of these compounds suggests that they could be complementary in clinical practice. The alerting activity of CBD may be particularly useful in the concomitant administration of THC and CBD when the therapeutic activity of both compounds is sought.

99. <https://www.nap.edu/catalog/6376/marijuana-and-medicine-assessing-the-science-base>

Victims of spinal cord injury reporting at IOM workshops noted that smoking marijuana reduces their muscle spasms, their nausea, and the frequency of their sleepless nights.

40. <https://www.nap.edu/catalog/24625/the-health-effects-of-cannabis-and-cannabinoids-the-current-state>

There is moderate evidence that cannabis or cannabinoids are effective for:

- Improving short-term sleep outcomes in individuals with sleep disturbance associated with obstructive sleep apnea syndrome, fibromyalgia, chronic pain, and multiple sclerosis (cannabinoids, primarily nabiximols) (4-19)

(8) Provide any information, studies, or research reports regarding any beneficial or adverse effects from the use of cannabis in patients with the medical condition. For best results, please cite research, published evidence, or scientific findings AND attach a PDF copy to your submittal. Indicate specific lines, page, section. Please use standard AMA format as outlined in the instructions.

Minnesota has undertaken the most comprehensive research on the medical cannabis patients in its medical cannabis program. Including surveys by both the patients and their physicians. Tracking which medical cannabis products they purchase, use and

continue using to treat each qualifying condition.

The Minnesota Department of Health publishes reports of the medical cannabis patients and how medical marijuana helps them with insomnia and sleep problems. In its first year of reports, the Minnesota DOH published patient comments about the beneficial effects of the medical marijuana.

<https://www.health.state.mn.us/people/cannabis/about/firstyearreport.html>

(REF #94) <https://www.health.state.mn.us/people/cannabis/docs/about/appendixa.pdf>

☞**My insomnia is so much better**,my muscle spasms have calmed down some,I have an appetite now,my muscle pain has lowered quite a bit to the point I can get some things down around the house,I was walking with a cane but I am no longer at this point...I believe my balance over all is better at this moment in time.

☞With my cancer diagnoses and treatment, I've found relief while taking the cannabis!!! **I get relief from pain, relief from nausea, relief from insomnia.**

Further reports in the following years also track which patients under each condition report benefits of medical marijuana on insomnia and sleep problems.

<https://www.health.state.mn.us/people/cannabis/about/omcreport.html>

<https://www.health.state.mn.us/people/cannabis/about/cohort.html>

(REF #93) https://www.health.state.mn.us/people/cannabis/docs/about/cohort/2015_2016_benefitspse.pdf

The patient self-evaluation is required for patients to complete prior to each medical cannabis purchase. It includes questions to assess symptom severity, some of which are administered to all patients (standard set of 8 symptom measures) and some of which are tailored to symptoms for a given condition (condition-specific symptom measures). Since symptom data is collected prior to each patient's first medical cannabis purchase, symptom changes can be assessed over time and compared to baseline (baseline = patient responses to symptom questions just prior to their first medical cannabis purchase)

These reports are useful to show that medical marijuana patients find a greater than 30% reduction in depression symptoms, and a large percentage of patients continue to maintain that reduction of depression for 4 months.

Of patients included on the standard 8 symptom analysis (n = 1512), more than half experienced moderate to severe symptoms at baseline on all measures except for vomiting(32%).Of patients experiencing moderate to severe symptoms at baseline, anywhere between 36% and 60% achieved at least a 30% reduction in symptom severity (symptom improvement) within 4 months of their first medical cannabis purchase. The lowest proportion of patients reporting symptom improvements in the initial 4-month period were for pain (36%) and fatigue (40%) symptoms, while the greatest proportion of patients reporting symptom improvements were for vomiting (60%), depression (57%), and nausea (56%) symptoms.

(REF #92) https://www.health.state.mn.us/people/cannabis/docs/about/cohort/2016_2017_benefitspse.pdf

(REF #91) https://www.health.state.mn.us/people/cannabis/docs/about/cohort/c2015_2017_benefitspse.pdf

MDOH publishes Adverse Side Effects reports. I urge you to read them all as it shows how small the number of adverse side effects reports are.

<https://www.health.state.mn.us/people/cannabis/about/cohort.html>

May 26, 2020

Aloha,

My name is Marghee Maupin and I am a board certified family Nurse Practitioner in Hawaii with over 30 years of experience. In the course of my practice, I have treated patients who utilize medical cannabis as an alternative treatment option for multiple health conditions. I have observed, (per patient report), that medical cannabis reduces the symptoms and severity of anxiety, insomnia and depression.

These three diagnosis present commonly as the top conditions that my patient's report medical cannabis has helped them with.

I have discussed, observed and documented the side effects of medical cannabis with my patient's and I have compared the side effects with traditional pharmaceuticals. Generally, I have found medical cannabis to have fewer and more manageable side effects than pharmaceutical formulations.

I am writing this letter as a letter of support to add Anxiety, Insomnia and Depression into the Hawaii Medical Cannabis program.

Please contact me at my office if you require any information.

Sincerely,

A handwritten signature in black ink that reads "M Maupin NP". The signature is fluid and cursive, with the initials "NP" written in a slightly larger, more distinct font at the end.

May 26, 2020

Dear Review Board,

My name is Dr. Saqib Nakadar, and I am a licensed physician practicing internal medicine. I am writing this letter in support of adding Insomnia to the medical cannabis program. Based on my 10 years of experience treating patients who have chosen to try medical cannabis after trying and failing with traditional prescription and therapy treatments, my patients have reported great success in reducing the severity of Insomnia using medical cannabis.

Dr. Saqib Nakadar D.O.

ASSOCIATION OF CANNABIS SPECIALISTS
SCIENCE. EDUCATION. REGULATION. COMPASSION.

May 27, 2020

Dear Madam/Sir:

I write to you to support the petitions before you to include anxiety, depression, and insomnia as qualifying conditions for medical cannabis treatment in Hawai'i.

I am a cannabis medicine specialist. I went to Harvard Medical School and trained in Internal Medicine at the Brigham & Women's Hospital in Boston. I have been in practice for over 25 years, the last nearly decade exclusively focused on cannabis medicine. I am president of the Association of Cannabis Specialists – an international professional organization, and I am an Instructor of Medicine at Harvard Medical School.

In Massachusetts, where I live and practice, we do not have qualifying conditions per se. We are afforded the freedom to treat patients who have any condition that is medically appropriate to treat with cannabis. I think this is an ideal approach that returns the ability and responsibility to follow the science and medical best practices to the physicians who are best able to judge that medical necessity.

The literature on medical cannabis specifically for the indications of anxiety, depression, and insomnia is clear. These studies have been presented by the petitioner and I would be happy to address any questions about these that you may have. Cannabis can be very effectively used to treat all three of these problems.

Dosing is the critical element dividing success or failure, particularly for these specific conditions. As with any medication, cannabis can be used successfully or it can be misused. Cannabis can be used in conjunction with many conventional medications to achieve better benefit than with either alone. I have personally treated thousands of patients with these specific illnesses, and the results are impressive.

As a practical matter, to improve the outcomes for patients in HI, I would suggest greater requirement of clinicians to be specific about dosing and delivery methods, and absolute adherence by the dispensary agents to a clinician's treatment plan.

777 Concord Ave. Ste 104
Cambridge, MA 02138

800-645-0807
www.cannabis-specialists.org

Please refer to the Association of Cannabis Specialists' website and the document entitled [A Federal Framework of Regulation for Medical Cannabis Use](#) which can equally well be applied to states' programs.

I, and the medical literature, strongly support the addition of anxiety, depression, and insomnia to the list of conditions clinicians are able to treat with medical cannabis in HI. I urge you to add these conditions to the approved list.

Sincerely,

Jordan Tishler MD
President, CMO inhaleMD
President, Association of Cannabis Specialists
Instructor of Medicine, Harvard Medical School

James Berg, MD

Barefootmd@gmail.com

Aloha,

I am licensed medical doctor from the Big Island of Hawaii, board certified in both Family Medicine and Integrative Medicine. I have been in practice for over thirty years treating my clients with a reasonable balance between medical and natural approaches to healing. I co-direct a school of natural medicine called the *Barefoot Doctors' Academy*, a nonprofit organization operating continuously since 1983, devoted to natural approaches to community medicine. In my career, I have been on the clinical teaching faculty of two medical schools, three traditional oriental medical colleges, two massage schools, and lecturer on scientifically oriented natural medicine. I am writing this letter of support to [REDACTED] three petitions submitted to the Hawaii Department of Health which adds depression, anxiety and insomnia to the medical qualification permitted for medical cannabis certification.

According to my records, I have taken care of over 6,000 patients in Hawaii who have used cannabis legally. I have taken their testimony, examined them, and followed up with many of them at least annually for the past 15 years. I have seen the medical cannabis program go through many changes, and would especially like to thank the Department of Health for their kind and skillful transformation of the Medical Cannabis Program since they took the helm from the Narcotics Enforcement Division. They have worked out many of the administrative kinks and have sincerely honored the clinical necessity of cannabis. A few years ago, they expanded the list of medical qualifications, and recognized Post Traumatic Stress Disorder as a qualification. That was the first psychological condition allowed to that date.

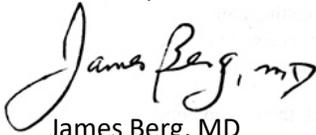

There are many conditions that cannabis is helpful for, but there are three conditions that cannabis is especially helpful for, yet even after twenty years of the program, depression, anxiety and insomnia remain off the qualification list. Cannabis has been labeled in the past as an "euphoric agent" because it relaxes people and helps them feel good. These days we call these kinds of medicines, "antidepressants" and "anti-anxiety medicines". Let me say emphatically, that I recognize that cannabis can cause the very same negative effects in some people. In my experience, at least 90% of my clients already know how cannabis helps their condition. They come and explain to me, their doctor, how it has helped them, and they seek certification so they can use this medicine legally. I want to testify that of all the conditions I have heard the greatest praise for the benefits of cannabis from my clients over the past fifteen years, it has been for this medicine's help with sleep, anxiety and depression. Keeping them off the list seems medically ethical at this point.

[REDACTED] has laid out in detail, various scientific studies giving evidence beyond my anecdotal testimony for these three ailments. I want to support his petition. As a Medical Cannabis Specialist, I witness the answers to these studies every day in my practice. I believe that depression, anxiety and insomnia are the conditions *most helped* by cannabis. I hear, patient after patient, testifying to me how they can finally sleep the night through simply by sucking on a medicated lozenge; How one puff can avert a panic attack; How they finally feel bright spirited and motivated. Cannabis has been a true blessing for many of my patients with insomnia, anxiety or depression, who have been qualified by another condition that the state recognizes. Unfortunately, that list excludes those without severe pain, nausea, muscle spasms, etc.

Yet they still have a severe problem that they know is helped by cannabis. That is self-evident in their experience. We do not need more studies to prove to them that they slept the night through, or didn't escalate into a panic attack, or that they actually feel happy for the first time in a long time. They know it helps with minimal side effects and that is proof enough to them.

In this case, science and politics needs to catch up with the clinical experience. As a practicing physician, I have seen medical cannabis be used far more safely than any pharmaceutical anti-depressant, anti-anxiety med, or sleeping pill commonly prescribed for insomnia, depression and anxiety. One day, I predict that cannabis, or an analogue, will be the medical standard for the first line of attack for mild to moderate depression, anxiety and insomnia. I speak for these sincere patients who already know that cannabis helps them. Please recognize these patient's needs and add depression, anxiety and insomnia onto the list of recognized qualifications for medical cannabis certification.

Sincerely,

A handwritten signature in black ink that reads "James Berg, MD". The signature is written in a cursive, flowing style.

TILL HANSEN, M.D.

24 N. Church Street, Suite 403, Wailuku, HI 96793

Telephone: (808) 242-5856 • Fax (808) 242-5949

Email: hawaiiendoc@yahoo.com

Aloha,

I am licensed medical doctor on Maui, board certified in both Internal Medicine and Endocrinology. I have been in practice for over thirty years, 25 in Hawaii. I am writing this letter of support of three petitions submitted to the Hawaii Department of Health which adds depression, anxiety and insomnia to the medical qualification permitted for medical cannabis certification.

A few years ago, the list of medical qualifications was expanded to recognized Post Traumatic Stress Disorder (PTSD). Note that PTSD is a disorder that can manifest with anxiety, depression and sleeplessness. There are many conditions that cannabis is helpful for, but there are three conditions that cannabis is especially helpful for, yet even after twenty years of the program, depression, anxiety and insomnia remain off the list of qualifying conditions.

██████████ has laid out in detail, from various evidence-based scientific sources and studies giving evidence that cannabis is helpful for these three ailments. I want to support his petition. I have been evaluating patients for their 329 cards for over 3 years and have done hundreds of renewals. Virtually 100% of patients have been helped. All use cannabis for the indications they listed but have also found that coincidentally medical marijuana helps with anxiety, depression and insomnia.

In fact, I believe that because of the better safety profile cannabis should be the first-line drug for these conditions. Most anxiolytics are habit forming. Anti-depressants have a warning: "May Cause Suicide". Hypnotics, like Ambien, are also habit forming and are used in combination with alcohol to simulate Rohypnol ("roofie") by rapists. Using cannabis as a safe first-line option will be a paradigm shift for many health care providers, but the approval of these conditions by the DOH will go a long way to legitimizing this point of view.

So far, in my decades as a physician, I have much more harm done with alcohol, hypnotics, opiates and anti-depressants and anxiolytics than with cannabis. In fact, as an urgent care, ER, hospital and ICU physician (before starting my Endocrine practice), I have never attended a single patient due to cannabis.

Please recognize these patient's needs and add depression, anxiety and insomnia onto the list of recognized qualifications for medical cannabis certification. Please call if you have any questions, 808-242-5856.

Thank you for your kind attention,

Till Hansen, M.D.

5/25/20

To whom it may concern:

I am writing this letter in support of [REDACTED] three petitions submitted to the Hawaii Department of Health, which adds depression, anxiety, and insomnia to the medical qualifications permitted for medical cannabis certification.

The mind and body are connected. The effects of insomnia, depression, and anxiety upon the physical well-being of an individual are significant and well documented. Current pharmaceutical interventions for these conditions can have severe side effects and risks. There is scientific evidence to support the use of medical cannabis for these disorders—a medicine with far less potential for addiction or abuse.

After witnessing the knee jerk, draconian response to the opioid crisis, I am concerned for that moment in time when someone realizes that a severe hypnotics problem also exists. I need to know that when severe restrictions are placed on hypnotics, my patients will have a safe and legal alternative. Medical cannabis is that alternative.

I have learned that if you close one door for a patient to escape their pain—they will find another. If you close or restrict the pharmaceutical options, they WILL find other ways to relieve their suffering. The inclusion of the three diagnoses recommended by [REDACTED] for the use of medical cannabis will provide a far safer option for these vulnerable patients.

Richard Podolny M.D.

Insomnia: Definition, Prevalence, Etiology, and Consequences

Thomas Roth, PhD

Sleep Disorders and Research Center, Henry Ford Hospital Detroit, MI

DEFINITION OF INSOMNIA

The term insomnia is used in a variety of ways in the medical literature and popular press. Most often, insomnia is defined by the presence of an individual's report of difficulty with sleep. For example, in survey studies, insomnia is defined by a positive response to either question, "Do you experience difficulty sleeping?" or "Do you have difficulty falling or staying asleep?" In the sleep literature, insomnia is sometimes used as a term to describe the presence of polysomnographic evidence of disturbed sleep. Thus, the presence of a long sleep latency, frequent nocturnal awakenings, or prolonged periods of wakefulness during the sleep period or even frequent transient arousals are taken as evidence of insomnia.¹ Thus, insomnia has been thought of both as a symptom and as a sign. However, for the purpose of this paper, the term insomnia will be used as a disorder with the following diagnostic criteria: (1) difficulty falling asleep, staying asleep or nonrestorative sleep; (2) this difficulty is present despite adequate opportunity and circumstance to sleep; (3) this impairment in sleep is associated with daytime impairment or distress; and (4) this sleep difficulty occurs at least 3 times per week and has been a problem for at least 1 month.

What qualifies insomnia to be considered a disorder? A disorder is a condition associated with negative consequences, and importantly, these consequences are not a normal result of the condition but rather the result of some sort of pathological response. In the present discussion, the consequences of insomnia can not merely be the normal consequence of sleep loss.

Disclosure Statement

Dr. Roth has received research support from Aventis, Cephalon, GlaxoSmithKline, Neurocrine, Pfizer, Sanofi, SchoeringPlough, Sepracor, Somaxon, Syrex, Takeda, TransOral, Wyeth, and Xenoport; is a consultant for Abbott, Accadia, Acoglix, Actelion, Alchemers, Alza, Ancil, Arena, AstraZeneca, Aventis, BMS, Cephalon, Cypress, Dove, Elan, Eli Lilly, Evotec, Forest, GlaxoSmithKline, Hypnion, Jazz, Johnson & Johnson, King, Ludbeck, McNeil, MedicNova, Merck, Neurim, Neurocrine, Neurogen, Novartis, Orexo, Organon, Orginer, Prestwick, Proctor and Gamble, Pfizer, Purdue, Restiva, Roche, Sanofi, ShoeringPlough, Sepracor, Servier, Shire, Somaxon, Syrex, Takeda, TransOral, Vanda, Vivometrics, Wyeth, Yamanuchi, and Xenoport; and has participated in speaking engagements supported by Sanofi and Takeda.

PREVALENCE OF INSOMNIA

Estimates of the prevalence of insomnia depend on the criteria used to define insomnia and more importantly the population studied. A general consensus has developed from population-based studies that approximately 30% of a variety of adult samples drawn from different countries report one or more of the symptoms of insomnia: difficulty initiating sleep, difficulty maintaining sleep, waking up too early, and in some cases, non-restorative or poor quality of sleep.² Conclusions from the NIH State-of-the-Science Conference held in June 2005 indicate that the addition of a diagnostic requirement that includes perceived daytime impairment or distress as a function of the insomnia symptoms results in approximately 10% prevalence of insomnia.³ Finally, the application of more stringent diagnostic criteria, such as the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)*,⁴ which includes the additional requirements that insomnia symptoms persist for at least 1 month and do not exclusively occur in the presence of another sleep disorder, mental disorder, or the direct physiological effects of a substance or medical condition, yields current prevalence estimates of approximately 6%.⁵

Several well-identified risk factors for insomnia were reported by the State-of-the-Science Conference in June 2005.³ Age and gender are the most clearly identified demographic risk factors, with an increased prevalence in women and older adults. While the cause of this increased risk in the elderly is not well defined, it may be due to the partial decline in functionality of sleep control systems that may contribute to insomnia in this older population. Importantly, the presence of comorbid medical conditions is also a significant contributor to the increased prevalence of insomnia in the elderly. Additionally, in women, insomnia is more prevalent with both the onset of menses and menopause.⁶ Comorbid medical disorders,⁷ psychiatric disorders,⁸ and working night or rotating shifts⁹ all represent significant risks for insomnia. It is important to recognize that these factors do not independently cause insomnia, but rather they are precipitants of insomnia in individuals predisposed to this disorder. In fact, chronic illnesses are a significant risk for insomnia. It is estimated that the majority of people with insomnia (approximately 75%-90%) have an increased risk for comorbid medical disorders,⁷ such as conditions causing hypoxemia and dyspnea, gastroesophageal reflux disease, pain conditions, and neurodegenerative diseases. Importantly, a variety of primary sleep disorders as well as circadian rhythm disorders are frequently comorbid with and often lead to insomnia. Among the primary sleep disorders, restless legs syn-

drome (RLS),¹⁰ periodic limb movement disorders (PLMD), and sleep-related breathing disorders (snoring, dyspnea, sleep apnea) often present with an insomnia symptom.¹¹ This is especially true among the elderly. Among younger individuals, difficulty falling asleep is often associated with a phase delay syndrome. However, in the elderly, phase advance syndrome results in reports of difficulty initiating sleep, maintaining sleep, and experiencing early morning awakenings.¹²⁻¹⁴

The most common comorbidities associated with insomnia are psychiatric disorders. It is estimated that 40% of all insomnia patients have a coexisting psychiatric condition.^{8,15} Among these psychiatric disorders, depression is the most common, and insomnia is a diagnostic symptom for depressive and anxiety disorders.¹¹

CONSEQUENCES OF INSOMNIA

Due to its chronicity, insomnia is associated with substantial impairments in an individual's quality of life. In several studies, insomniacs reported decreased quality of life on virtually all dimensions of the 36-item Short Form Health Survey of the Medical Outcomes Study (SF-36), which assesses 8 domains: (1) physical functioning; (2) role limitation due to physical health problems (role physical); (3) bodily pain; (4) general health perceptions; (5) vitality; (6) social functioning; (7) role limitations due to emotional health problems (role emotional); and (8) mental health.¹⁶⁻¹⁸ One study compared SF-36 results in groups of mild and severe insomnia patients with groups of patients diagnosed with depression or congestive heart failure (CHF).¹⁹ Severe insomnia patients had numerically greater loss of function than patients with CHF in reported pain, emotional effects, and mental health effects. Additionally, insomnia patients also reported more physical problems than patients with depression.¹⁹

Research has shown that among the daytime consequences of insomnia, the increased occurrence of accidents poses the greatest health risk. Insomniacs are 2.5 to 4.5 times more likely than controls to have an accident.^{20,21} In a sample of 8,625 community respondents in France, Léger et al. reported that 8% of insomniacs and 1% of non-insomniacs had an industrial accident in the past 12 months.²² Work productivity is also compromised among insomniacs due to work-related problems (ie, higher rates of absenteeism, decreased concentration, and difficulty performing duties). Kuppermann and colleagues²³ found that individuals reporting a current sleep problem were more likely than good sleepers to have decreased job performance and to have been absent from work in the last month due to health problems. Simon and VonKorff²⁴ evaluated insomnia in a staff-model health maintenance organization population (N=1,962). After adjusting for age, gender, and chronic disease, days of restricted activity due to illness and days spent in bed were about twice as common among insomniacs compared with non-insomniacs. Additionally, mean total health care expenditures were 60% higher in the insomnia group relative to the controls.

Population- and clinic-based studies have demonstrated a high rate of psychiatric comorbidities in patients with chronic insomnia. In fact, insomnia is more frequently associated with psychiatric disorders than any other medical illness.²⁵ For example, in the Epidemiologic Catchment Area study, 40% of insomniacs had a comorbid psychiatric disorder compared with 16.4% of those with no sleep complaints.⁸ Additionally, depression and anxiety are the

most common comorbid psychiatric disorders in insomniacs. It has traditionally been assumed that insomnia is secondary to the psychiatric disorder; however, given the chronicity of insomnia, it is possible that in some, if not most, cases the insomnia precedes the psychiatric disorder. In fact, it is possible that insomnia represents a significant risk for the development of a subsequent psychiatric disorder. In a large-scale European population-based study (N=14,915), it was found that insomnia more often preceded rather than followed incident cases of a mood disorder.²⁶ This effect is even more pronounced for relapses of the mood disorder, where in 56.2% of cases, insomnia symptoms preceded symptoms of a mood disorder relapse. In contrast, in chronic insomnia patients with a comorbid anxiety disorder, the first occurrence of anxiety or a relapse preceded insomnia in most instances.

To further understand the relation of sleep and psychiatric disorders, several longitudinal studies have examined the evolution of psychiatric disorders among insomnia patients. These studies used follow-up periods ranging from 1 to 40 years, with the majority using a 1- to 3-year follow-up period. In all of these studies, insomnia has been found to confer a substantial risk for the development of a depressive disorder.^{27,28} Typically, the relative risk was approximately 5 (range 2-40), and in all cases it was statistically significant. While some studies also reported an increased risk for anxiety or drug abuse, neither of these was consistently found. Finally, longitudinal studies in subjects with affective disorders show that depressed patients who experience improvements in sleep will also experience a more rapid antidepressant response; while those patients whose insomnia persists will have a short time to relapse.^{29,30} What is clearly needed are clinical trials to assess the impact of insomnia therapy on incidence of depression as well as the time to relapse in depressed patients who are in remission.

The question then arises as to whether insomnia causes depression, vice versa, or both. The close association of insomnia with depression is likely related to common underlying pathophysiological mechanisms for sleep and mood regulation that make the individual vulnerable to both conditions. Data have shown that both the diagnosis of insomnia and the severity of the sleep disturbance are related to overactivation of the hypothalamic-pituitary-adrenal (HPA) axis and the hypersecretion of cortisol.³¹ Recent evidence suggests that there may be some neuroendocrine and clinical similarities between insomnia and depression. Corticotropin-releasing factor (CRF) dysregulation has been implicated in the pathogenesis of psychiatric disorders such as depression³² as well as in the mediation of hyperarousal seen in primary insomnia.³³ This abnormality might represent the common risk factor, and therefore, it is quite possible that both disorders would respond to the same therapeutic intervention (eg, corticotropin-releasing hormone antagonists).

PATHOPHYSIOLOGY OF INSOMNIA

Insomnia is thought to be a disorder of hyperarousal experienced throughout the entire day. This hyperarousal may exhibit itself as a state of hypervigilance during the day and difficulty initiating and maintaining sleep at night.^{34,35} This arousal is currently explained by both cognitive and physiological models of insomnia. The cognitive model suggests that worry and rumination about life stresses disrupt sleep, creating acute episodes of insomnia, especially in initiating sleep and returning back to sleep

after an awakening.³⁶ Then, once an individual begins to experience sleep difficulties, worry and rumination shift from life events to worries about sleep itself and about the daytime consequences of not getting enough sleep. This negatively-toned cognitive activity is further fueled if a sleep-related threat is detected or a sleep deficit is perceived.

In parallel with the cognitive models, another model of the evolution of insomnia proposes that hyperarousal is primarily due to physiologic or neurophysiologic factors. Physiological arousal has been evaluated through measurements of the whole body metabolic rate, heart rate variability, neuroendocrine measures, and functional neuroimaging. Whole body metabolic rate may be measured by oxygen consumption (VO₂). Recent studies compared good sleepers with patients diagnosed with insomnia. The insomnia patients exhibited significantly higher metabolic rates (measured at intervals across the 24-hour day) than the healthy controls. Heart rate variability may provide a measure of arousal in that it is regulated by both sympathetic and parasympathetic nervous system activities. A 36-hour study³⁷ found that average heart rates were increased and variability was decreased in all stages of sleep in insomnia patients compared to healthy normal sleepers.

The neuroendocrine system may also provide evidence of arousal as demonstrated by chronic activation of the stress response system. Several studies measuring 24-hour urinary free cortisol excretion have found high levels in poor sleepers.^{38, 39} Urinary free cortisol levels have also been positively correlated with total wake time, and urinary catecholamines have been correlated with stage 1 sleep percentage and wake time after sleep onset.^{38, 40} Plasma measures of cortisol and adrenocorticotropic hormone (ACTH) have been evaluated in insomnia patients and healthy normal sleepers. Although the evidence is somewhat mixed, primary insomniacs appear to have higher levels of these compounds in their plasma, with the most significant differences seen in the evening and the first half of the night.^{38,39,41} Both the urinary and plasma measures of cortisol and ACTH suggest that the HPA axis is associated with the pathology of chronic insomnia.

Finally, positron emission tomography (PET) has been used to assess cerebral glucose metabolism, an indirect measure of whole brain metabolism, in patients with insomnia.⁴² Compared to healthy subjects, patients with insomnia exhibited greater cerebral glucose metabolism during waking and non-rapid eye movement (REM) sleep states. Furthermore, the insomnia patients demonstrated smaller reductions in relative metabolism from waking to non-REM sleep in wake-promoting regions of the brain. These findings suggest interacting neural networks involved in the inability to fall asleep, which include a general arousal system, an emotion-regulating system, and a cognitive system.

CONCLUSION

Chronic insomnia is highly prevalent and affects approximately 30% of the general population. Insomnia impairs cognitive and physical functioning and is associated with a wide range of impaired daytime functions across a number of emotional, social, and physical domains. Compared with good sleepers, people with persistent sleep disturbances are more prone to accidents, have higher rates of work absenteeism, diminished job performance, decreased quality of life, and increased health care utilization. Various risk factors associated with increased prevalence of chronic insomnia include older age, female gender, and comorbid medical and psy-

chiatric conditions. Approximately 40% of adults with insomnia also have a diagnosable psychiatric disorder—most notably depression. A comorbid psychiatric disorder such as depression or anxiety may be a consequence of—as well as a risk factor for—disrupted sleep. Recent research suggests that insomnia and depression share common pathological processes that make individuals vulnerable to both conditions—specifically, abnormal regulation of CRF. CRF regulation has been extensively implicated in the pathogenesis of depression, and hyperactivity of the HPA axis and CRF neurons could account for the hyperarousal and sleep disturbances associated with chronic insomnia. Studies that improve the knowledge of the neurobiological mechanisms controlling regulation of sleep homeostasis, circadian rhythms, physiological hyperarousal, genetics, stress, and cognition are needed to adequately evaluate the causes and mechanisms of insomnia. Effective pharmacologic and behavioral interventions to treat insomnia rely on accurate neurobehavioral and neurobiological information.

CASE REPORT

Zolpidem-Induced Sleepwalking, Sleep Related Eating Disorder, and Sleep-Driving: Fluorine-18-Fluorodeoxyglucose Positron Emission Tomography Analysis, and a Literature Review of Other Unexpected Clinical Effects of Zolpidem

Romy Hoque, M.D.; Andrew L. Chesson, Jr., M.D.

Sleep Disorders Center; Department of Neurology, Louisiana State University School of Medicine, Shreveport, LA

Zolpidem is a hypnotic which acts at the GABA_A receptor and is indicated for short-term insomnia. Sleep related disorders including somnambulism, sleep related eating and sleep-driving have been reported with zolpidem. A 51-year-old insomniac who used zolpidem 10 mg nightly starting at 44 years of age is described. A few weeks after starting zolpidem she began walking, eating, and had one episode of driving while asleep. Episodes of sleep related eating, sleepwalking, and sleeptalking occurred 3 nights per week, 1 to 2 h after sleep onset. After her evaluation, the patient's zolpidem was gradually discontinued, and all sleep related activities immediately ceased. An 18F-FDG-PET was obtained 2 months after discontinuation of zolpidem. The following day, FDG was administered 1 h after oral administration of

10 mg zolpidem, and then a second PET was performed. We report the results and a review of the literature regarding other unintended effects seen with zolpidem use.

Keywords: Zolpidem, fluorine-18-fluorodeoxyglucose positron emission tomography, sleep related eating disorder, sleepwalking, sleep-driving

Citation: Hoque R; Chesson AL. Zolpidem-induced sleepwalking, sleep related eating disorder, and sleep-driving: fluorine-18-fluorodeoxyglucose positron emission tomography analysis, and a literature review of other unexpected clinical effects of zolpidem. *J Clin Sleep Med* 2009;5(5):471-476.

Sleepwalking or somnambulism, is a parasomnia consisting of a series of complex behaviors usually initiated during arousals from slow wave sleep and commonly culminate in walking with an altered state of consciousness and impaired judgment.¹ Sleep related eating disorder (SRED) consists of recurrent episodes of involuntary eating during arousals from sleep.¹ Parasomnias such as sleepwalking, SRED, and sleep-driving can coexist and are rare side effects of zolpidem. In a 2005 National Institutes of Health consensus statement for the treatment of chronic insomnia in adults zolpidem was considered a hypnotic with limited risk.² Two post-marketing studies of zolpidem reported sleepwalking incidences of 7 of 1972 patients (0.3%)³ and 1 of 96 patients (1%).⁴ We present a patient with zolpidem-induced sleepwalking, SRED, and sleep-driving. A fluorine-18-fluorodeoxyglucose positron emission tomography (18F-FDG-PET) was obtained one month after discontinuation of zolpidem. A second 18F-FDG-PET was acquired the following day, 1 h after oral administration of zolpidem 10 mg (Figure 1). The cerebral glucose metabolism rates of the 2 studies were then compared, using statistical parametric mapping analysis. We also review the literature regarding unintended effects of zolpidem use.

CASE REPORT

The patient is a 51-year-old African American woman with past medical history of hypertension, mild obstructive sleep apnea, hyperlipidemia, and depression. Previous diagnostic polysomnogram revealed an apnea-hypopnea index of 10 events/h. Medications included paroxetine 20 mg once a day, extended release metoprolol 25 mg twice per day, and simvastatin 40 mg once a day. History for alcohol, tobacco, or illicit drug use was negative. The patient reported no personal or family history of sleepwalking or other parasomnias. The patient did not have a history of daytime eating disorder. At age 44 the patient was started on non-extended release zolpidem 10 mg at bedtime for insomnia. A few weeks after starting zolpidem, she began sleep related walking, eating, and one episode of driving.

Episodes of sleepwalking, SRED, and sleeptalking occurred 3 nights per week, 1-2 h after sleep onset. The patient would speak incoherently using short phrases with her eyes closed and would then open her eyes when questioned by her husband. She would also leave her bedroom to go to her kitchen where she would eat a loaf of bread, cold cereal, or leftover food. The following morning she would have abdominal fullness, find her kitchen messy, and have complete amnesia for the event. The patient would also leave her home and walk on her front porch or on her front lawn. As a preventive measure, she installed nocturnal alarms on her doors to wake her or her family from sleep if she opened one. Other reported events included one occasion of urination in the hallway, and one episode when the patient drove her automobile 10 miles from her home and

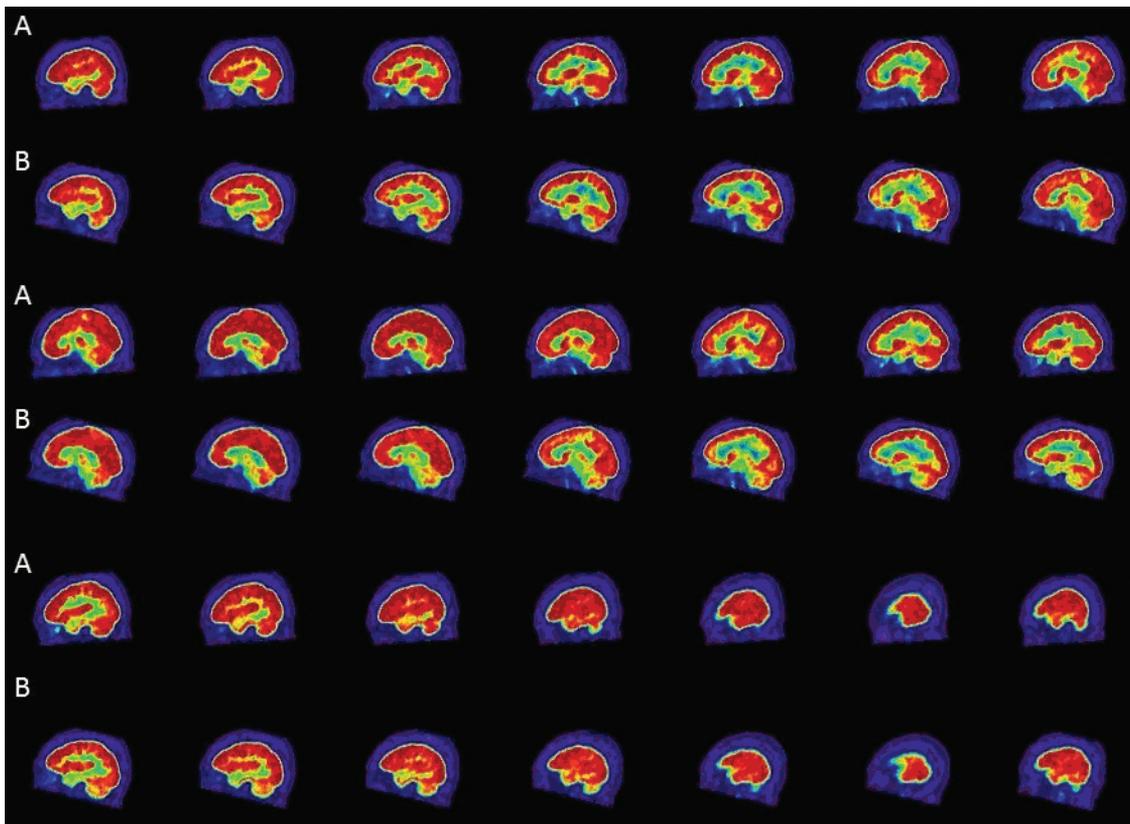

Figure 1—18-fluorine-fluorodeoxyglucose-positron emission tomography (18F-FDG-PET) of a patient with zolpidem induced sleepwalking, sleep related eating disorder, and sleep-driving. A: 18F-FDG-PET off zolpidem. B: 18F-FDG-PET on zolpidem. FDG was administered to patient 1 h after ingestion of 10 mg zolpidem. Statistical parametric mapping comparison of the 2 sequences shows no significant differences.

was found asleep behind the wheel by police. She had a vague recollection of this event, but thought that she was dreaming. After her evaluation, the patient's zolpidem was gradually withdrawn; all sleep related activities immediately ceased and have not recurred during 6 months of follow-up.

18F-FDG-PET Analysis

The first PET study in our patient was performed after discontinuation of zolpidem for 2 months. A second PET study FDG was administered 1 h after the administration of 10 mg zolpidem. The patient was asleep in the scanner during both PET studies. Statistical parametric mapping comparison between our patient's 2 studies demonstrated no significant differences (Figure 1).

DISCUSSION

Zolpidem is an imidazopyridine drug indicated for short-term insomnia at a dosage usually ranging from 5 to 10 mg per day.⁵ Though considered a non-benzodiazepine since its imidazopyridine structure differs from benzodiazepine fusion of benzene and diazepine, zolpidem is a benzodiazepine receptor agonist with high binding affinity for the GABA_A (gamma-amino butyric acid type A) receptor expressing the α_1 subunit. Benzodiazepines and benzodiazepine receptor agonists like zolpidem bind to the GABA_A receptor at sites that are distinct from the GABA binding site, thereby allosterically affecting the activity of the ligand-operated chloride channel.

GABA is the main inhibitory neurotransmitters in the mammalian central nervous system (CNS). GABA_A receptors exist as pentameric protein complexes, assembled from a combination of at least 19 subunits from 7 distinct gene families (α , β , γ , δ , ϵ , θ , and π). Synaptic GABA_A receptors are responsible for modulating benzodiazepine sensitivity and typically contain $\alpha_{1,2,3, \text{ or } 5}$, $\beta_{2 \text{ or } 3}$, and the γ_2 subunits.⁶ GABA_A receptor sensitivity to benzodiazepines is mediated through α subunits. Benzodiazepines bind to synaptic GABA_A receptors containing α_1 , α_2 , α_3 , or α_5 subunits with comparable affinity. The GABA_A receptor expressing the α_1 subunit corresponds to the benzodiazepine ω_1 receptor.⁷ GABA_A receptors containing the α_1 , α_2 , α_3 , or α_5 subunits correspond to ω_2 benzodiazepine receptors. The ω_3 benzodiazepine receptor is not related to the GABA_A receptor. Extrasynaptic GABA_A receptors are primarily composed of $\alpha_{4,6}$ subunits in combination with δ subunits, and are insensitive to benzodiazepines. The current benzodiazepine receptor nomenclature (ω_1 , ω_2 , and ω_3) replaced the previous anatomical localization classification (central benzodiazepine receptor type 1, central BZ-1; central benzodiazepine receptor type 2, central BZ-2; and peripheral benzodiazepine receptor type 3, BZ3) because of the existence of "central" benzodiazepine receptors with peripheral localization, and "peripheral" benzodiazepine receptors with central localization.

Zolpidem was developed as a drug with a structure different from benzodiazepines, allowing affinity for only a given subset of central benzodiazepine receptors resulting in hypnotic properties without additional anticonvulsant and myorelaxant properties of benzodiazepines. In contrast to benzodiazepines

like clonazepam, diazepam and flunitrazepam, which lack selectivity for the ω_1 , ω_2 , or ω_3 benzodiazepine receptor subtypes; zolpidem has a high affinity for ω_1 .⁸

A possible explanation for zolpidem-induced nocturnal events is that after an arousal from sleep into wakefulness, nocturnal activity (i.e., walking, eating, or driving) occurred and was subsequently not recalled after returning to sleep because of the sedation-mediated amnesic properties of zolpidem. Another possibility is that an arousal occurred out of slow wave sleep with the parasomnia occurring in electroencephalographically verifiable sleep. We felt our patient experienced the later, given her incoherent interactions with her husband during her nocturnal events. Patients who do not recall waking events on zolpidem are typically cognitively functional, and retain the ability to speak in coherent short phrases.⁹

Sleepwalking is a relatively common condition affecting 10% of adults.¹ Recently hotels across the United Kingdom reported an increase in the number of hotel guests found to be sleepwalking.¹⁰ Though the incidence of zolpidem induced sleepwalking has been reported to be low, it is possible that many cases of unexplained sleepwalking may be secondary to zolpidem given its widespread use.^{3,4}

Along with sleepwalking, SRED, and sleep-driving parasomnias, zolpidem has been anecdotally reported to produce a range of unexpected beneficial effects. These include improvement in the following conditions: post-stroke Broca's aphasia; blepharospasm; quadriplegia of central pontine myelinolysis; catatonia of schizoaffective disorder; dementia with apraxia; post-anoxic minimally conscious states; bradykinesia, akinesia, and dystonia in Parkinson disease; post-levodopa dyskinesias in Parkinson disease; vertical saccadic eye movements and parkinsonism in progressive supranuclear palsy; restless legs syndrome; post-anoxic spasticity; and spinocerebellar ataxia (Table S1 summarizes the available reports of improvement in varied neurological conditions with zolpidem use). Effects were usually noted within 30 min of ingestion of the non-extended release formulation and lasted for 2 to 4 h, corresponding with a time to peak plasma concentration of approximately 1.2 h and a half-life of approximately 2.5 h.

Zolpidem effects might be mediated through its anti-anxiety effects, its benzodiazepine receptor agonist properties, its GABAergic activity, or some combination of all three. For example, symptoms of Parkinson disease worsen with anxiety. The improvement noted in Parkinson disease with zolpidem use may be secondary to its anxiolytic effect through a GABAergic effect on the limbic system or elsewhere. The improvement seen in blepharospasm, catatonia, and restless legs syndrome may be caused by the benzodiazepine ω_1 receptor agonist activity of zolpidem. However, opposing this theory of purely benzodiazepine agonist mediated effects, is that parasomnias like sleepwalking are often treated with benzodiazepines like clonazepam; yet zolpidem seems to induce parasomnias in a susceptible subpopulation.

The action of zolpidem via synaptic GABA_A receptors with α_1 subunits may produce different clinical responses depending upon regional distribution of receptor subtypes. Benzodiazepines bind to all the synaptic GABA_A receptors, which are expressed throughout the nervous system. Even though zolpidem is a preferred α_1 agonist, α_1 subunits are expressed widely

throughout the CNS.¹¹ Benzodiazepine-insensitive extrasynaptic GABA_A receptors containing $\alpha_{4,6}$ subunits show much more regional specificity than benzodiazepine-sensitive synaptic GABA_A receptors containing $\alpha_{1,2,3}$, or 5.

Zolpidem has a less recognized but limited binding affinity to ω_2 benzodiazepine receptors. ω_1 and ω_2 receptors are also widely expressed throughout the human brain.¹² At higher doses these lower binding affinities may be expressed resulting in unexpected clinical outcomes. For example, anecdotally there appears to be differential efficacy of high dose zolpidem (70 mg/d) for blepharospasm, and low dose zolpidem (5-10 mg/d) for parkinsonian features. (Surprisingly at the high doses used by Garretto et. al for blepharospasm and Evidente for early onset Parkinson disease, 5 of 6 patients reported no somnolence, and only one patient had to discontinue the medication secondary to drug-induced diarrhea.^{13,14} Somnolence was overcome with slow dose titration.)

The potential clinical significance of preferred GABA_A α_1 subunit/ ω_1 receptor activation is unclear. For example, it was previously thought that zolpidem did not possess significant myorelaxant properties similar to benzodiazepines. However, anecdotal reports of efficacy for zolpidem in post-anoxic spasticity, parkinsonian dyskinesias/tremors, blepharospasm, and restless legs syndrome provides anecdotal evidence to the contrary. Zolpidem may affect many neurological diseases through binding at a variety of locations simultaneously (Figure 2). Zolpidem binding at one anatomical location is unlikely to explain all of its myriad effects. Also, electrophysiological studies suggest that different GABA subunit combinations may mediate different physiological and pharmacological properties of the ligand-operated ion channel.¹¹ Therefore, even though zolpidem has a high affinity for GABA_A receptors with the α_1 subunit, different pharmacological responses may result from different subunit combinations with the α_1 subunit. As a result, clinical efficacy in a given disease is difficult to correlate with binding and receptor activation at a single GABA_A/benzodiazepine receptor type, at a single anatomic site, or at a single dose.

An intriguing theory on the etiology of sleepwalking and SRED concerns the presence of theoretical *cerebral pattern generators* (CPGs).^{15,16} CPG are thought to be neuronal collections in the brain, brainstem or spinal cord that can potentially control innate motor behaviors essential for survival like feeding and locomotion. Diffuse zolpidem cortical binding may cause release of CPGs associated with evolutionarily conserved motor patterns such as walking and eating, leading to subsequent disorders of arousal like somnambulism and SRED. Since some CPGs may reside in the cortex, zolpidem use also release cortical patterns associated with overlearned behaviors, such as driving.

In an attempt to identify zolpidem-induced changes in cerebral glucose metabolic rates, an 18F-FDG-PET was performed in our patient on and off zolpidem. Gillin et al. compared the effects of 10 mg zolpidem and placebo on cerebral glucose metabolic rates in 12 young normal volunteers (mean age: 22.5 y) using 18F-FDG-PET.¹⁷ In that study FDG was administered about 1 h after oral administration of zolpidem while the patient was in electroencephalographically (EEG) verifiable stage 2 sleep and at a time of expected zolpidem peak concentrations (1.2 ± 0.2 h)

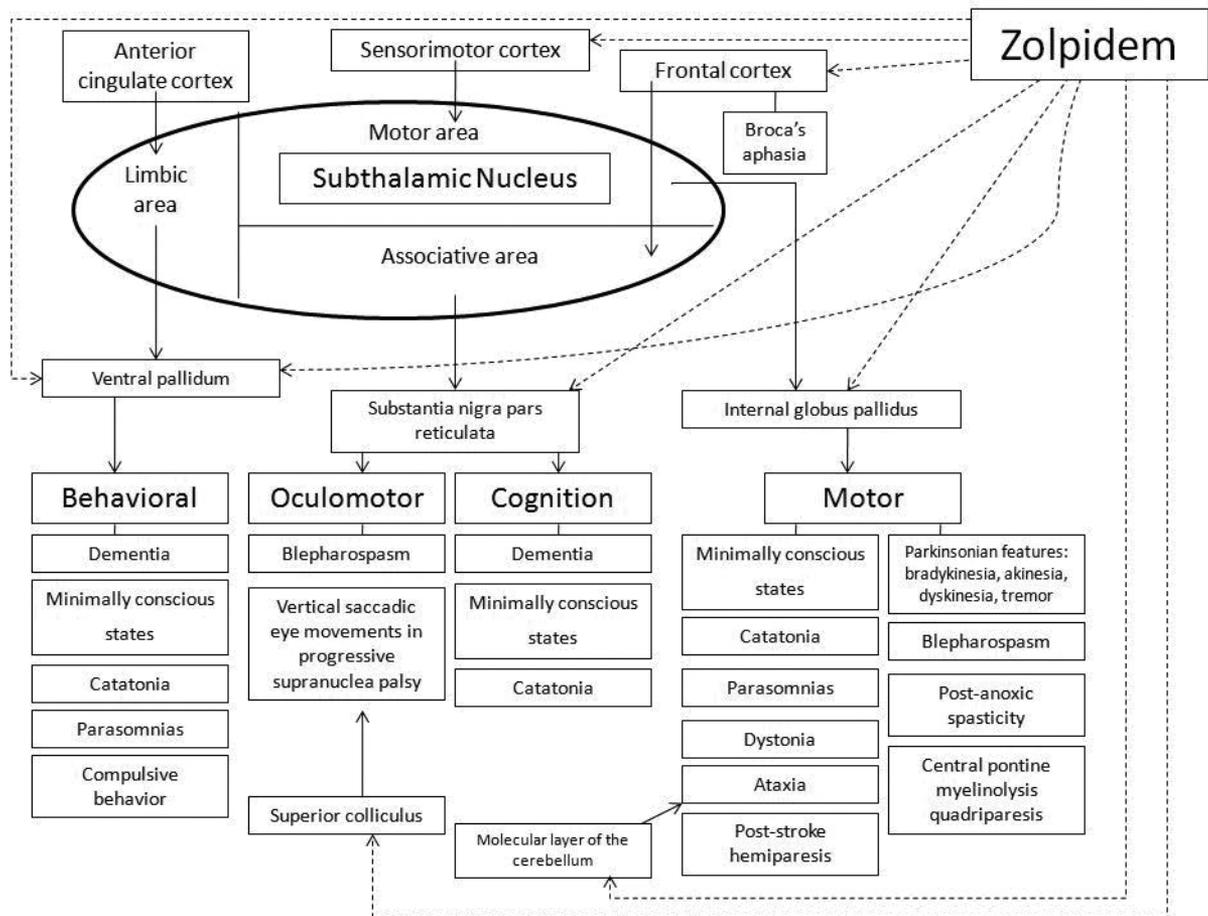

Figure 2—Regional distribution of zolpidem binding, and the potential clinical consequences. Zolpidem is a benzodiazepine receptor agonist with high binding affinity for the GABA_A (gamma-aminobutyric acid type A) receptor expressing the α_1 subunit. Benzodiazepines and benzodiazepine receptor agonists like zolpidem bind to the GABA_A receptor at sites that are distinct from the GABA binding site, thereby allosterically affecting the channel. GABA_A receptor sensitivity to benzodiazepines is mediated through α subunits. Zolpidem's action via synaptic GABA_A receptors with α_1 subunits may produce different clinical responses depending upon regional distribution of receptor subtypes. Benzodiazepines bind to all the synaptic GABA_A receptors, which are expressed throughout the nervous system. Even though zolpidem is a preferred α_1 agonist, α_1 subunits are expressed widely throughout the CNS. Given zolpidem's many binding sites, the improvement noted across a range of neurological disorders are difficult to localize to binding at a single anatomic location. GABA_A α_1 subunits/ ω_1 benzodiazepine receptors are widely distributed throughout the central nervous system, in many more areas than indicated in this simple schematic figure.

in plasma (and presumably brain). Gillin et al. found that across all cortical areas glucose metabolic rates were not significantly different on placebo versus zolpidem. Our patient's results were similar to those seen in Gillin's normal volunteers.

Compared to wake, whole brain cortical glucose metabolic rates decrease in NREM and REM stage sleep.¹⁸ One would expect a decline in cortical glucose metabolic rate with the use of sleep-inducing hypnotics like zolpidem. However, our results, along with those of Gillin show otherwise. The reasons for this are unknown.

One possible explanation may be that PET is too insensitive a tool to detect subtle localized or generalized glucose metabolic rate differences on and off zolpidem in the normal brain. If such differences could be identified, then patients who are susceptible to developing parasomnias could be identified prior to use. More importantly, this may also provide insight into other extraordinary anecdotal effects of zolpidem.

A limitation of our PET analysis was that the scan was not performed in EEG verified slow wave sleep (SWS), when para-

somnias are thought to emerge. Future 18F-FDG-PET studies in patients with zolpidem induced parasomnias could be attempted during EEG verified SWS on and off zolpidem to identify differences in glucose metabolic rates not seen in our analysis. However, this may prove to be difficult given the variable presence of SWS and the need to wait 1 h after FDG injection prior to the PET scan. By the time the patient receives the FDG injection and the scan is performed, the patient may no longer be in SWS. And though parasomnias tend to emerge in SWS, they can potentially arise from any NREM stage.

Temporal resolution is not a major limitation of PET studies in that in order to scan a brain the cortical area is divided into thirds and scanned in 3 successive 5-min sessions that are then compiled together to form an entire cortical scan. As a result, the PET findings in any particular cortical area are an estimation of glucose metabolic rate over a five minute time window. Despite this small time window, 18F-FDG-PET findings would be difficult to correlate with a particular arousal in a period of SWS. Similar studies may be performed on and off medica-

tion in NREM and REM to assess differences in brain cortical glucose metabolic rates, though the procedural limitations described above would still apply.

Single photon emission computed tomography (SPECT) studies have been used successfully to show increased cerebral blood flow in a range of cortical areas after zolpidem administration despite a more limited spatial resolution than PET. SPECT has been used to show increased regional blood flow in the frontal cortex in Broca aphasia, the cerebellum in spinocerebellar ataxia, and the contralateral hemisphere in hemiparetic patients.¹⁹⁻²¹ In normal baboon models, SPECT has been used to demonstrate that zolpidem does not cause changes in regional cerebral blood flow in normal baboons. However, in baboons with cortical injuries, zolpidem increased blood flow to the injured areas.²² Zolpidem mediated increase in regional cerebral blood flow to injured cortical areas on SPECT was attenuated by the use of flumazenil, a benzodiazepine receptor antagonist.²³ The baboon studies correlate to the case report of Brefel-Courbon et al. of a patient in a post-anoxic minimally conscious state showing arousal on clinical exam and increased cerebral glucose metabolism on 18F-FDG-PET in the bilateral post-rolandic territories and frontal lobes after zolpidem administration.²⁴ The normal baboon SPECT study findings also correlate with the 18F-FDG-PET findings in our neurologically intact patient and Gillin's normal volunteer cohort.¹⁷

To date no large scale randomized controlled trials exist assessing the efficacy of zolpidem for aphasia, blepharospasm, catatonia, central pontine myelinolysis, dementia with apraxia, Parkinson disease, progressive supranuclear palsy, restless legs syndrome, post-anoxic spasticity, or spinocerebellar ataxia. The clinical benefit of zolpidem for patients in minimally conscious states is currently being explored in clinical trials.²⁵ These results may also help to further understand sleep-wake mechanisms and the function of hypnotics.

The anecdotal benefits of zolpidem have provided hope that damage to brain tissue after strokes anoxic insults previously thought to be permanent may actually be reversible. Zolpidem may reactivate cortical areas that have undergone injury-induced dormancy, or there may be more redundancy built into our brains than previously believed, e.g. CPGs. GABAergic hypnotics like zolpidem through diffuse cortical binding may somehow unmask this redundancy.

Future studies may also shed light on whether different susceptibilities to zolpidem induced parasomnias and its other effects may depend upon the formulation used. For example, Chiang et al. reported 2 patients who experienced zolpidem induced sleepwalking and SRED on only the extended release formulation and not the non-extended release formulation.²⁶ Validation of these anecdotal findings and investigations into the new sublingual formulation of zolpidem may provide insight into how formulation dependent pharmacokinetics may influence an individual's susceptibility to zolpidem-induced parasomnias.²⁷

Investigations into the mechanisms of action of GABAergic induced parasomnias may overturn therapeutic nihilism for a variety of neurological disease. Capitalizing upon zolpidem's myriad anecdotal serendipitous effects, basic science research using animal models of non-sleep-wake related neurological disorders may provide us with a of understanding how the brain reorganizes itself after injury. Also genetic analysis of individu-

al patients may also provide insight into potentially identifiable pharmacogenetic vulnerabilities/susceptibilities. These exciting and unexplored avenues of research may be used in the treatment of disease previously thought untreatable.

ACKNOWLEDGMENTS

We thank David Lilien, M.D., for performing the 18F-FDG-PET studies; James Patterson, M.D., for performing a statistical parametric mapping comparison of the two 18F-FDG-PET studies; Eduardo Gonzalez-Toledo, M.D., Ph.D., for help in creating Figure 1; and Richard Zweig, M.D., for comments on the manuscript.

Table S1—Zolpidem: A Spectrum of Unintended Effects and Potential Uses. SRED: sleep-related eating disorder.

Reference	Age, sex, and clinical state	Dose	Description of response
Aphasia			
Cohen et al. 2004 ¹⁹	52, female, stroke of left insula, putamen, and superior temporal gyrus with resultant Broca aphasia	Zolpidem 10 mg once/d Time to response: 20 minutes Duration of response: unknown	Patient regained effective speech, naming, and repetition.
Blepharospasm, Meige syndrome (oromandibular dystonia and blepharospasm)			
Garretto et al. 2004 ¹³	Three patients Patient 1: 57, woman, Meige syndrome Patient 2: 63, male, blepharospasm Patient 3: 66, male, Meige syndrome	Patient 1: Zolpidem 10 mg every 2-3 h (70 mg/d) Time to response: 30 min Duration of response: 3 h Patient 2: Zolpidem 10 mg 3 times/d Time to response: 20-30 min Duration of response: 3 h Patient 3: Zolpidem 10 mg twice a day Time to response: 30 min Duration of response: 3 h	Blepharospasm improved in all 3. Effect on oromandibular dystonia in the 2 patients with Meige syndrome was not mentioned.
Catatonia			
Thomas et al. 1997 ²⁸	21, woman, schizoaffective disorder. One month after discontinuation of haloperidol, patient developed severe oppositional behavior, mutism, staring, posturing, and refusal of food.	Zolpidem 10 mg once/d Time to response: 15 min Duration of response: 4 h	All behavior and motor symptoms resolved on zolpidem.
Central pontine myelinolysis			
Wang et al. 2007 ²⁹	51, female, post-surgical complication resulting in central pontine myelinolysis with spastic quadriparesis and pseudobulbar palsy	Zolpidem 10 mg once/d Time to response: 20 min Duration of response: 4 h	Regained facial expression, effective speech, and smooth limb movements
Compulsive behavior while awake			
Tsia et al. 2007 ³⁰	Three previously healthy patients Patient 1: 34, female Patient 2: 40, female Patient 3: 50, female	Zolpidem 10 mg once/d All 3 patients exhibited compulsive behaviors (cleaning, shopping, and eating) with anterograde amnesia for the events.	Events were not considered to be sleepwalking because patients were able to communicate fluently and perform normally beyond the compulsive activity. Events stopped with cessation of zolpidem in all 3 patients.
Dementia with apraxia			
Jarry et al. 2002 ³¹	60, woman, alcoholic, reduced cognition, memory loss, apraxia, inability to join in conversation	Zolpidem 10 mg once/d Time to response: 45-60 min Duration of response: 3 h	Improvement in cognition and praxis. Regained the ability to perform simple chores around the home.
Minimally conscious states			
Claus et al. 2000 ³²	28, male, motor vehicle accident resulting in post-anoxic minimally conscious state	Zolpidem 10 mg once/d, Time to response: 15 min Duration of response not explicitly stated	Interacted spontaneously and responded to simple questions with short appropriate answers

Reference	Age, sex, and clinical state	Dose	Description of response
Claus et al. 2006 ³³	Three patients: Patient L: 31, male, Patient N: 31, male, Patient G: 29, male. All 3 had motor vehicle accidents resulting in post-anoxic minimally conscious state	Doses unknown. Time to response: L: 20-30 min, N: 1 h; G: 20-30 min. Duration of response was 4 h for all 3 patients.	L: meaningful interactions/ conversations with caregivers, purposeful response to stimuli, voluntary behavior. N: Cessation of random screaming episodes. Watched television and laughed at funny scenes. Stated his name and age. G: Meaningful interactions with caregivers. Lifted hands, counted to 5, and smiled on command.
Brefel-Courbon et al. 2007 ²⁴	48, male, suicide attempt by hanging resulting in post-anoxic encephalopathy with minimally conscious state	Zolpidem 10 mg once/d Time to response: 20 min Duration of response: 2-3 h	Increased arousal; communicated with family; swallowed food; moved spontaneously in bed
Cohen et al. 2008 ³⁴	35, male, cardiac arrest resulting in post-anoxic encephalopathy with minimally conscious state	Zolpidem 5 mg once a day → 10 mg in the morning and 5 mg in the evening → 10 mg twice/d, Time to response: 1 h Duration of response: 3-6 h depending on dosing	Zolpidem 5 mg once a day: Increased arousal and more interactive with caregivers. Could toss a football Zolpidem 10 mg/ 5 mg: Walked with assistance Zolpidem 10 mg/ 10 mg: Spoke more frequently and fluently. Walked unassisted.
Shames et al. 2008 ³⁵	50, woman, cardiac arrest resulting in post-anoxic encephalopathy with minimally conscious state	Zolpidem 10 mg once/d Time to response: 30 min Duration of response: 3 h	Increased arousal. Alert and oriented to self and place. Cessation of athetoid movements. Regained full voluntary movements of all 4 extremities.
Parkinson disease, Parkinsonian features			
Daniele et al. 1997 ³⁶	10 patients, mean age 69.9	Zolpidem 10 mg once/d In the responders (6/10 patients): Time to response: 45-60 min Duration of response: 2-4 h	6/10 patients showed motor improvement in facial expression, rigidity, akinesia, bradykinesia, posture and gait
Ruzicka et al. 2000 ³⁷	45, female, Parkinson disease with generalized choreic dyskinesia post-levodopa administration	Zolpidem 5 mg per day Time to response: 30 min Duration of response: 2 h	Limb and trunk dyskinesia ceased on zolpidem
Farver et al. 2001 ³⁸	31, male, schizoaffective disorder, illicit substance abuse (cocaine, amphetamines, marijuana) Patient developed parkinsonian rest tremor on antipsychotic medications. Tremor failed to respond to lowering the antipsychotic dose, adding anticholinergic or dopaminergic medications, or switching to novel antipsychotics.	Zolpidem 5 mg 4 times/d	The patient's tremors resolved within 1 month of zolpidem. With withdrawal of zolpidem the tremors returned. They ceased once again when zolpidem was restarted.

Reference	Age, sex, and clinical state	Dose	Description of response
Evidente 2002 ¹⁴	Three patients with X-linked early onset parkinsonism with dystonia (Lubag syndrome) Patient 1: 41, male Patient 2: 38, male Patient 3: 36, male	Patient 1: Zolpidem 10 mg every 2 h Time to response: 15 min Duration of response: 2 h Patient 2: Zolpidem 10 mg twice/d Time to response: 40 min Duration of response: 3 h Patient 3: Zolpidem 10 mg twice/d Time to response: 45 min Duration of response: 2 h	All three patients had improvement in dystonia and parkinsonism on zolpidem
Progressive supranuclear palsy (PSP)			
Daniele et al. 1999 ³⁹	10 patients with PSP, mean age: unknown	Crossover trial: All patients received zolpidem 5 mg once a day, zolpidem 10 mg once a day, levodopa-carbidopa 250 mg-25 mg, and placebo. Time to response to zolpidem: 40-60 min Duration of response to zolpidem: 2 h	Zolpidem, unlike levodopa-carbidopa or placebo, improved saccadic eye movements in 4/10 patients on Zolpidem 10 mg/d
Mayr et al. 2002 ⁴⁰	61, male	Zolpidem 5 mg/d Time to response and duration of response: unknown	Patient showed improvement in vertical gaze palsy and parkinsonism. Patient showed response for 4 weeks. Second trial of zolpidem 2 months later showed no benefit.
Psychostimulant effect			
Gericke et al. 1994 ⁴¹	33, male, depression	Zolpidem 80 mg/d. Patient self-increased the dose from 10 mg per day due to insomnia and accidentally discovered a stimulant effect at higher doses with improvement in depression. Time to stimulant response: 20 min Duration of response: 5-6 h	Generalized tonic-clonic seizure occurred at 80 mg per day.
Restless legs syndrome			
Bezerra et al. 2002 ⁴²	8 patients, 3 male, Mean age: 50.8	Zolpidem 10 mg once/d Time to response: mean of 4 days Continued response on medication with no relapses	Positive response was noted in all patients, regardless of age and severity of restless legs syndrome
Sleepwalking with or without sleep related eating disorder (SRED)			
Sauvanet et al. 1988 ⁴	Post-marketing study showed 1 of 96 patients developed sleepwalking on zolpidem	Dose unknown	Data not available
Mendelson 1994 ⁴³	20, male, participant in clinical study of nocturnal effects of sedative medications History of sleepwalking as a child.	Zolpidem 10 mg at bedtime before polysomnogram.	Investigator initiated auditory tone aroused patient out of stage 4 sleep. Patient stood up and walked on the bed. He was confused when sleep technician entered room and asked him to sit. He had vague memory of the events
Ganzoni et al. 1999 ³	Post-marketing study showed 7 of 1972 patients developed sleepwalking on zolpidem	Dose unknown	Data not available

Reference	Age, sex, and clinical state	Dose	Description of response
Harazin et al. 1999 ⁴⁴	46, male, shift work related insomnia Negative history for sleepwalking	Zolpidem 10 mg at bedtime	Within 4 days of initiation of zolpidem he would arise at night to prepare a meal and eat it. He had no memory of the events. Medication was discontinued. Unknown whether events recurred off zolpidem.
Morgenthaler, et. al. 2002 ⁴⁵	Five patients Mean age: 61.4, 3 male All 5 patients had restless legs syndrome, 3 had obstructive sleep apnea All 5 patients had a negative history for sleepwalking	Zolpidem 10-20 mg once/d	All exhibited sleepwalking and SRED 4/5 had vague memory of the events. Events ceased in all patients with zolpidem discontinuation
Sattar et al. 2003 ⁴⁶	47, male, bipolar disorder. Negative history for sleepwalking.	Citalopram 40 mg once/d, valproic acid 250 mg twice/d, Zolpidem 5 mg at bedtime	Sleepwalking started when valproic acid was added to citalopram and zolpidem. He had no memory of the events. Events ceased when valproic acid was withdrawn and returned when valproic acid was restarted.
Sharma et al. 2005 ⁴⁷	19, male, schizoaffective disorder Negative history for sleepwalking	Zolpidem 10 mg at bedtime	Within a few days of initiation of zolpidem he started to sleepwalk and talk incoherently. He had no memory of the events. Events ceased with zolpidem discontinuation.
Najjar 2007 ⁴⁸	46, female, depression, obstructive sleep apnea on continuous positive airway pressure therapy Negative history for sleepwalking or parasomnias	Zolpidem extended-release form 6.25 mg once/d	Sleepwalking and SRED began immediately after initiation of zolpidem use and ceased immediately after it was discontinued.
Chiang et al. 2008 ²⁶	Two patients: Patient 1: 75, female Patient 2: 70, female Both patients had restless legs syndrome, obstructive sleep apnea, and used continuous positive airway pressure therapy Both patients had a negative history for sleepwalking or SRED	Both patients had sleepwalking and SRED on zolpidem extended release 12.5 mg once/d. Neither patient experienced sleepwalking or SRED on the immediate release form of zolpidem.	Both patients experienced sleepwalking and SRED immediately after initiation of extended release zolpidem use and ceased immediately after it was discontinued
Sansone et al. 2008 ⁴⁹	51, female,	Zolpidem 10 mg at bedtime	Arose at night to prepare a meal and eat it. She had no memory of the events. Events stopped with cessation of zolpidem.
Post-anoxic spasticity			
Shadan et al. 2004 ⁵⁰	28, male, cardiac arrest resulting in post-anoxic spasticity	Zolpidem 10 mg once a day Time to response: 20 min Duration of response: 2-4 h	Decrease in muscle rigidity, spasticity and dystonic posturing
Spinocerebellar ataxia			
Claus et al. 2004 ²¹	5 members of a family, 3 male, Mean age: 33	Zolpidem 10 mg once/d Time to response: 1 h Duration of response: unknown	4/5 patients showed improvement of ataxia with zolpidem

Abstract

Marked by difficulty falling or staying asleep and/or poor sleep leading to daytime dysfunction, insomnia contributes to functional impairment, poor health, and increased healthcare utilization when left untreated. As many as two-thirds of Iraq and Afghanistan military veterans complain of insomnia. Older veterans of prior conflicts report insomnia occurring since initial service, suggesting a chronic nature to insomnia in this population. Despite insomnia's high prevalence and severe consequences, there is no theoretical model to explain either the onset or chronicity of insomnia in this growing patient population. Existing theories view insomnia as an acute, unidirectional phenomenon and do little to elucidate long-term consequences of such problems. Existing theories also fail to address mechanisms by which acute insomnia becomes chronic. This paper presents an original, integrated theoretical model that draws upon constructs from several prominent behavioral medicine theories to reconceptualize insomnia as a chronic, cyclical problem

The views expressed in this article are those of the authors and do not necessarily reflect the position or policy of the Department of Veterans Affairs or the United States government.

Contributors

Dr. Hughes developed the first draft of the conceptual model and wrote the first draft of the manuscript. Drs. Ulmer, Gierisch, Hastings, and Howard served as theoretical consultants during the development of the conceptual model and assisted with review and editing of the final manuscript. All authors have contributed to and have approved the final manuscript.

Conflict of Interest

The authors have no conflicts of interest to disclose.

that is both a consequence and predictor of stress. Additional research examining the relationships between stress, sleep, resilience, and outcomes of interest could inform clinical and research practices. Addressing sleep problems early could potentially enhance adaptive capacity, thereby reducing the risk for subsequent negative outcomes.

Keywords

insomnia; sleep; stress; coping; resilience; veterans

Sleep is a basic biological need responsible for a range of restorative functions including emotion regulation and memory consolidation, muscle and tissue repair, and stress hormone regulation (Dement & Vaughan, 1999). Despite its necessity, sleep is often ignored as a core health behavior, rarely addressed within biopsychosocial assessments or routine primary care visits, and generally not integrated into chronic disease management programs. Sleep problems are particularly common among United States military veterans, with one-half to two-thirds of the 2.5 million U.S. military troops who served in Afghanistan (Operation Enduring Freedom, OEF) and Iraq (Operation Iraqi Freedom, OIF) complain of insomnia problems on returning home (Amin, Parisi, Gold, & Gold, 2010; Seelig et al., 2011). Insomnia complaints are also prevalent among veterans of earlier wars, including Vietnam and Korea conflicts. Additionally, many of these older veterans report that sleep problems initially began during or immediately following their military service and have persisted in the decades since separating from the military (Hughes & Martin, 2015; Ryden et al., 2015).

These findings suggest insomnia problems are chronic within veteran populations; yet, a lack of longitudinal data prohibits researchers from identifying mechanisms that contribute to such chronicity and from understanding how such problems change over a veteran's life course. Given sleep problems are tied to a number of negative physical and psychological outcomes (Fernandez-Mendoza & Vgontzas, 2013), it is critical that researchers and clinicians develop a better understanding of this growing problem. The overarching goal of this paper is to offer a theoretical model of insomnia in the veteran population. Although this model can be applied to veterans of all ages and military cohorts, a major goal of the model is to place insomnia-like sleep problems of returning OEF/OIF veterans into a larger, lifespan context as a means of advocating for additional research on the role sleep problems may play in longterm health and aging. While military-specific stressors will be addressed, we believe that elements of this integrated model can be applied to other patient populations, including those who have experienced significant stress or trauma.

Insomnia in Military Veterans

Chronic Insomnia Disorder is a common behavioral sleep disorder clinically defined as dissatisfaction with sleep quantity or quality marked by complaints of difficulty falling or staying asleep, waking up earlier than desired, or sleep that is non-restorative and the cause of significant daytime impairment. Such problems are not related to other medical or sleep disorders, exist despite adequate opportunity and environment for sleep, and are endorsed three or more nights per week for three months or longer (American Psychiatric Association, 2013). Insomnia and/or insomnia-like symptoms are present in 27–54% of military

personnel and veterans (Hoge, W. et al., 2008; Mysliwec, McGraw, Smith, Trapp, & Roth, 2013), rates that are two to three times higher than in the general U.S. adult population (Ford, Cunningham, Giles, & Croft, 2015; Roth, 2007). The rate of incident insomnia cases in military personnel saw a 19-fold increase from 2000 to 2009 (Mysliwec et al., 2013). The prevalence of insomnia among Veterans Health Administration (VHA) users is expected to continue to rise as many troops who served after September 11, 2001 continue to retire from military service and begin accessing VHA healthcare in the coming years (Campbell, Shattuck, Germain, & Mysliwec, 2015).

Risk Factors

Both modifiable and non-modifiable risk factors contribute to insomnia. This paper addresses the role of stress regulation and coping in sleep problems with a behavioral etiology. Insomnia-like sleep problems may be a function of an individual's stress response whereby poor sleep is a function of inadequate coping and/or poor regulation of stress across physiological, cognitive, and/or emotional processes. In this context, stress refers to any event or stimulus that causes a disruption in balance, or homeostasis. Laboratory studies indicate that higher baseline levels of stress reactivity are associated with insomnia and predict future cases of the disorder (Drake, Friedman, Wright, & Roth, 2011; Drake, Richardson, Roerhs, Scofield, & Roth, 2004). In addition, individuals with insomnia have been shown to report experiencing more daily stressors and negatively evaluating such stressors (Morin & Ivers, 2003).

Initial military involvement, including enlistment and basic training, present a range of different stressors and often trigger sleep disturbance due to irregular schedules and ongoing physical, social, and emotional demands (Peterson, Goodie, Satterfield, & Brim, 2008). Deployment to a war region typically requires several days of laborious travel and crossing of multiple time zones that can disrupt one's natural circadian rhythm, or sleep schedule, and trigger sleep difficulties (Troxel et al., 2015). Deployment typically involves irregular work schedules, overnight watch demands, exposure to warzone and combat-related stressors, and risk of physical and psychological injury, including traumatic brain injury. While no research has formally documented the cause, or trajectory, of insomnia in military personnel, it is likely that one or more of the aforementioned factors served as an initial trigger of insomnia symptoms.

Recent research has focused on sleep problems among active duty military personnel, including increasing rates of incident insomnia and sleep apnea diagnoses (Mysliwec et al., 2013), heightened mental health risks associated with insomnia symptoms (Gehrman et al., 2013), and the link between sleep and impaired work performance (Seelig et al., 2016; Troxel et al., 2015). Less research has focused on sleep after military retirement. Stressors related to military separation, or retirement, and reintegration into civilian life can also trigger insomnia (Bramoweth & Germain, 2013). Additionally, many service members experience an inability to return to a "normal" sleep schedule after experiencing short sleep duration or irregular schedules while deployed (Castro, Kintzle, & Hassan, 2015; Haynes, Parthasarathy, Bootzin, & Krakow, 2013). Additional reintegration-related stressors include readjustment to family and social circles, securing civilian employment, maintaining

financial stability, and living with the physical and psychiatric comorbidities caused by deployment or combat-related stressors. These stressors can cause difficulty falling or staying asleep, or sleep that is restless and disturbed, thereby creating new sleep problems or exacerbating existing problems that began prior to or during deployment.

Consequences of Insomnia

Persistent insomnia can lead to poor health outcomes and chronic conditions (Fernandez-Mendoza & Vgontzas, 2013; Taylor et al., 2007), exacerbate symptoms of traumatic brain injury (Macera, Aralis, Rauch, & MacGregor, 2013), reduce overall quality-of-life (Katz & McHorney, 2002), and increase risk for morbidity and premature mortality (Dew et al., 2003; Kripke, Garfinkel, Wingard, Klauber, & Marler, 2002). Chronic sleep problems can also negatively impact day-to-day outcomes including task performance (Pilcher & Huffcutt, 1996), stress coping (Hamilton, Delwyn, & Karlson, 2007), and management of chronic health conditions (Ahn, Jiang, Smith, & Ory, 2014).

Function, Performance and Health Management—Chronic insomnia impairs function and performance across cognitive, emotional, social, and physical domains (Killgore, Balkin, & Westensten, 2006; Killgore et al., 2008; Pilcher & Huffcutt, 1996). Adequate functioning in these areas enables veterans to adapt to and cope with daily hassles and reintegration stressors noted earlier. However, impairments in one or more domains can reduce ability to cope with acute and ongoing stressors. As a result, functional performance and independence decline, thereby decreasing the likelihood of successful reintegration into civilian life (Institute of Medicine, 2013; Pilcher & Huffcutt, 1996).

Many of these aforementioned impairments can also reduce a veteran's capacity to cope with health-related stressors, a concept of particular interest to clinicians and health services researchers within the VHA. Medically complex patients, defined as individuals with two or more chronic conditions, who are challenged by managing such conditions (Shippee, Shah, May, Mair, & Montori, 2012), represent a growing subgroup of veterans utilizing VHA healthcare (Yoon, Schott, Phibbs, & Wagner, 2011; Yu et al., 2003). Medical complexity is often marked by a cycle of ongoing acute and chronic health-related stressors. Patients cycle through these stressors and strive to achieve and maintain a balance between workload demands (i.e. management of chronic diseases) and physical and psychological resources (Zullig et al., 2016). Successful balance and management of stressors is bolstered by high physical and psychological reserve and capacity (Zullig et al., 2016). These new models of complexity support the idea that capacity is malleable and can be impacted by resources, behaviors, and events on individual and community levels. Although sleep problems, including insomnia, are gaining more attention within the VHA, sleep patterns and behaviors are not explicitly addressed in these models.

Mental Health—Insomnia symptoms are common among veterans with mental health disorders. In one study, more than three-quarters reported difficulty falling or staying asleep and just over one-half reported being at least moderately distressed about sleep that was restless or disturbed (Ulmer et al., 2015). Although this research sample was designed to over-recruit veterans with mental health symptoms, this same study drew attention to the

notably high prevalence of sleep difficulties in veterans without a mental health diagnosis, including approximately seventy percent who met clinical criteria for poor sleep quality, defined as a score of five or greater on the Pittsburgh Sleep Quality Index (Buysse, Reynolds, Monk, Berman, & Kupfer, 1989).

The high rate of sleep problems among veterans without mental health diagnoses is alarming given that research with veteran and non-veteran populations has found that chronic sleep problems predict incident mental health diagnoses (Baglioni et al., 2011; Breslau, Roth, Rosenthal, & Andreski, 1996; D. Ford & Kamerow, 1989; Perlis et al., 2006) and suicidal ideation (Pigeon, Britton, Ilgen, Chapman, & Conner, 2013; Pigeon, Pinquart, & Connor, 2012) as well as persistence of existing mental health problems, including depression (Pigeon, Unutzer, & Perlis, 2008), and increased risk for readmission to a partial hospitalization psychiatry program (Koffel, Thuras, Chakravorty, Germain, & Khawakaja, 2015). In a large study of OEF/OIF service members, researchers found that military personnel with predeployment insomnia symptoms had greater odds of developing depression, anxiety, and PTSD at follow-up (Gehrman et al., 2013). Another longitudinal study found that insomnia measured at four months post-deployment was a significant predictor of depression and PTSD at 12-months post-deployment (Wright et al., 2011).

While it is too early to examine the long-term effects of military service on OEF/OIF service members' health, a great deal can be learned from studying the aging trajectories of veterans from earlier conflicts, including the Vietnam War. By better understanding how early or mid-life military service contributed to long-term outcomes in these cohorts, researchers and clinicians can develop new practices that can be translated into more effective and preventive-oriented care for veterans of more recent conflicts (Marmar, 2009). For example, nearly 40 years after the conclusion of the Vietnam War, Marmar and colleagues (2015) noted that lifetime and current diagnoses of PTSD and major depression were prevalent among veterans.

PTSD has been linked to increased healthcare utilization and costs in veterans of recent and earlier war conflicts (E. Hoge, Austin, & Pollack, 2007; Schnurr, Spiro III, & Paris, 2000). A growing line of research suggests that some veterans involved in earlier war conflicts experience premature functional decline and accelerated aging (Lohr et al., 2015; Wolf et al., 2016) as a result of service-related experiences and injuries, including PTSD. Much of this research points to the detrimental effects of PTSD, yet little research has isolated mechanisms that link early or mid-life military experiences to PTSD and subsequent decline. While sleep problems were not measured directly in the aforementioned studies, sleep problems are a core component of PTSD diagnostic criteria (American Psychiatric Association, 2013). Given this common symptom pattern, it is possible that untreated sleep problems of Vietnam Era veterans partially contributed to mid- or late-life PTSD. However, the lack of longitudinal data and absence of sleep questionnaires in this data prevent this hypothesis from being confirmed. The model presented here illustrates one potential pathway through which early life trauma and insomnia problems may impact mid- or late-life physical and mental health.

Insomnia and Resilience as Missing Links between Military Service and Poor Outcomes

Insomnia problems contribute to negative health outcomes and can become chronic, surfacing repeatedly over one's life course. However, mechanisms contributing to this chronicity have not been identified. The mechanisms linking sleep problems, including insomnia, to new mental health diagnoses remain unclear. However, one hypothesized explanation is that chronic poor sleep reduces one's coping abilities. As a result, when subsequent stressors do arise, individuals with sleep problems respond with reduced coping abilities (Gehrman et al., 2013). A reduced capacity to positively cope with stress may lead to a more negative stress outcome, such as PTSD (Benight & Bandura, 2004).

Researchers studying active duty military and veteran populations have a growing interest in resilience and its role in everything from operational readiness during deployment period to mental health and readjustment in the post-deployment period (Seelig et al., 2016; Stanley, Schaldach, Kiyonga, & Jha, 2011; Troxel et al., 2015; Young-McCaughan, Peterson, & Bingham, 2011). A recent RAND report suggested that healthy sleep is critical to resilience, operationalized as service members' performance and operational readiness, during deployment (Troxel et al., 2015). Despite this growing interest, no consensus definition of resilience has been established nor have any theories describing the relationship between sleep, resilience, and health outcomes been proposed or tested. Further, most research has focused on active duty service members with a paucity of research on the role resilience, particularly when defined as a psychological construct rather than mere outcome, might play in sleep problems among veterans.

Much of the early resilience research was rooted in developmental psychology where researchers largely focused on resilience as a positive outcome in children who had experienced early-life stress or adversity (Garmezy, 1971; Werner, 1995). However, much of this early research only examined major life events or stressors and failed to recognize how daily stressors or hassles, such as strains related to social, occupational, or financial hardships, impact resilience. Much of the stress and coping literature suggests that the cumulative impact of daily hassles is more stressful and more detrimental to an individual's overall psychological and physical health (Charles, Piazza, Mogle, Sliwinski, & Almeida, 2013; DeLongis, Coyne, Dakof, Folkman, & Lazarus, 1982) compared to major life events. Additionally, early resilience research ignored the concept of stress proliferation, or the idea that "stress begets stress," meaning that individuals who experience major life stressors are more susceptible to experiencing the effects of subsequent stressors (Pearlin, Schieman, Fazio, & Meersman, 2005; Pearlin & Skaff, 1996). As suggested earlier, veterans may face a series of stressors during the re-integration period. While not empirically tested to date, it is likely that daily hassles outnumber major life events and that many of these hassles contribute to stress-induced sleep problems, including insomnia. Furthermore, bouts of insomnia may also act as daily hassles in which the cumulative effects of these repeated bouts trigger additional stress and resulting sleep problems.

More contemporary approaches recognize resilience as a dynamic, multilevel, and multicomponent capacity for adapting to stress (Masten, 2001, 2007). This capacity draws on adaptive processes and abilities across behavioral, physiological and psychological systems. Modern conceptualizations of resilience also emphasize the role of health behaviors

including sleep, diet, and physical activity as important contributors to enhancing one's resilience (Southwick, Bonnano, Masten, Panter-Brick, & Yehuda, 2014). By focusing on health behaviors, contemporary research emphasizes the importance of going "upstream" of resilience and working to identify pertinent mechanisms, such as modifiable health behaviors, that can enhance or degrade resilience.

Integrated Theoretical Model

The discussions above suggest that the causes and consequences of insomnia in U.S. military veterans are complex and that sleep may play an important role in longterm mental and physical health. Below, we present an innovative integrated theoretical model that could be used to better understand the growing problem of insomnia among military veterans. This model builds on the 3P Model of Insomnia (Spielman & Glovinsky, 1991). Widely used in clinical assessment and interventions, the 3P Model provides a framework for understanding insomnia through three interrelated, sequential factors – predisposing, precipitating, and perpetuating (see Figure 1). These factors encompass genetic, constitutional, environmental, experiential, and behavioral contributors to sleep problems, respectively. The interaction between and progression across the three factors ("3Ps") transform acute insomnia symptoms into a chronic insomnia disorder.

Although widely regarded as the leading explanatory model of insomnia, the 3P Model could benefit from several additions which are addressed in the remainder of the paper. Our integrated model offers a more thorough understanding of insomnia by exploring the following additions. First, the model provides greater clarification of the mechanisms operating within each of the three factors. Second, unlike the 3P Model that conceptualizes insomnia and sleep problems as a consequence of a stressful event, this model recognizes sleep problems as both a stress response (consequence) and an independent stressor (predictor) that may trigger additional, negative reactions. Third, this model explores both short- and long-term consequences of insomnia, acknowledging its potential effects of insomnia on physiological, psychosocial, and cognitive domains. Finally, this model includes a dimension of time which may encourage additional studying of long-term consequences of sleep, including consideration of stress proliferation and cyclical patterns of increased stress, poor sleep, and negative outcomes that some veterans experience, including those of earlier wars.

The primary aim of the integrated theoretical model presented here (Figure 2) is to encourage a broader conceptualization of insomnia problems in U.S. military veterans. The proposed model integrates and expands upon the three major components of the 3P Model: predisposing (Boxes 1 and 2), precipitating (Box 3), and perpetuating (Box 10) factors. Drawing on constructs from several key behavioral medicine theories (see Figure 1), the model depicts potential mechanisms by which a stressful event (Box 3) contributes to insomnia problems (Box 11), impaired function (Box 12), reduced resilience (Box 13), and poor health outcomes (Box 14). Unlike existing theories that assume only a unidirectional relationship between stressful events and insomnia, our model proposes that insomnia is cyclical in nature. Here, insomnia is a consequence of stress *and* a predictor of additional stress. Insomnia impairs function, which reduces adaptive capacity, thereby increasing one's

risk for subsequent stressful events. Thus, the cycle begins anew, potentially triggering what will become a chronic problem (Pathways U and V). As shown, this model places a particular emphasis on the consequences of chronic, untreated insomnia.

Predisposing factors

Predisposing factors of insomnia refer to modifiable and non-modifiable factors such as a genetic, biological, or psychological vulnerability to stress and/or chronic health problems. The diathesis-stress model suggests individuals possess a diathesis, or predisposing characteristic(s), that increase vulnerability to a negative stress response or outcome (Monroe & Simons, 1991). Such characteristics include genetic risk factors, sociodemographic factors, early trauma, personality traits, and biobehavioral developmental factors including neurological and cognitive functioning. Of note, adverse childhood experiences, including exposure to domestic violence, parental separation or divorce, and emotional or physical abuse, are more common among military servicemembers compared to non-servicemembers (Blosnich, Dichter, Cerulli, Batten, & Bossarte, 2014). Not only are early life events associated with poor physical and mental health outcomes in adulthood (Cabrera, Hoge, Bliese, Castro, & Messer, 2007), they may increase susceptibility to additional stressors, as described in above explanations of stress proliferation. When confronted with subsequent military or non-military stressors (Box 3), both early life events and personal characteristics may increase an individual's risk for negative outcomes.

In addition, the theory of sleep-related stress reactivity posits that individuals with high levels of baseline stress reactivity (i.e., higher basal cortisol levels and more negative/ anxious psychological dispositions) have greater susceptibility to developing insomnia (Box 2) (Drake, Pillai, & Roth, 2014). High sleep-related stress reactivity is positively associated with stress susceptibility and heightened responses across physiological and psychological domains. Stress reactivity is marked by a hyperactive adrenal system (i.e., elevated levels of stress and adrenal hormones) and poor emotional and cognitive regulation, which are manifested in an inability to sleep in a high stress situation (Drake et al., 2004; Harvey, Tang, & Browning, 2005; Perlis, Giles, Mendelson, Bootzin, & Wyatt, 1997). This diathesis, or predisposition to a negative outcome (Box 2), then interacts with a personal or environmental stressor such as military deployment, retirement, or reintegration-related challenges (Box 3) to trigger a stress response, as suggested by the Diathesis-Stress Model (Monroe & Simons, 1991).

Precipitating factors

Precipitating factors represent major life or environmental stressors that trigger insomnia-like sleep problems. As addressed above, it is the interaction between predisposing factors, or diathesis, and an environmental stressor or event (precipitating factor) that triggers a stress response (Monroe & Simons, 1991). Multiple predisposing and precipitating factors can occur sequentially or simultaneously. For some veterans, deployment-related stressors (i.e. combat exposure, service-related injury) may trigger insomnia symptoms, whereas for others, stressors related to military retirement and civilian reintegration (i.e. family obligations, occupational or financial stress, injury and/or rehabilitation challenges) may initiate these symptoms. Additionally, some veterans may experience one major stressor, or

precipitating factor, while others may experience a series, of smaller, daily stressors. It is this accumulation of stressors that serves as the precipitating event for insomnia.

In addition to the interaction noted above, Lazarus and Folkman's Transactional Model of Stress and Coping (Glanz & Schwartz, 2008) builds on the diathesis-stress model to suggest that a stress response depends on a "transaction," or interaction, between the individual and environment. This model emphasizes that an individual's appraisal of a stressor (i.e., precipitating event) vis-à-vis susceptibility and severity (primary appraisal) (Box 4), and perceived ability to cope with a stressor (self-efficacy) (secondary appraisal) (Box 5), directly influence the coping efforts and behaviors he or she chooses to enact (Box 8). These processes are moderated by dispositional coping style (Box 7) and degree of social support (Box 6) and mediated by coping efforts, including the use of problem- or emotion-focused strategies (Box 7). For example, some veterans who perceive military culture as discouraging stress disclosure and/or that military status artificially protects against negative outcomes (Box 4) may be less likely to disclose having experienced a stressful event and therefore less likely to seek help (Box 8). Other veterans may perceive re-integration to be stressful and a trigger for other negative outcomes (i.e. additional family or occupational stress). However, if these individuals do not have strong self-efficacy, social support or coping skills, they may be less likely to seek help for stress-induced insomnia problems (Boxes 8 and 9), and, as a result, experience significant insomnia problems and related consequences. Additional factors may also impact an individual's decision to seek care, including the availability of and access to trained sleep specialists, prior experiences with sleep or other behavioral treatments, and personal treatment preferences.

Perpetuating factors

Acute insomnia problems become chronic through a combination of the perpetuation of unhealthy sleep behaviors and the conditioned arousal resulting from an inability to achieve and/or maintain sleep and the consequential shift in sleep patterns (Pathway O). Perpetuating factors represent unhealthy sleep behaviors used to cope with poor sleep, including following an irregular sleep schedule, spending excessive time in bed even when not sleeping, or increasing alcohol or caffeine intake to either induce sleep or wakefulness, respectively (Box 10) (Morin, 1993; Morin et al., 2006). In line with the constructs of the Transactional Model of Stress and Coping (Glanz & Schwartz, 2008), positive coping efforts reduce insomnia symptoms while negative coping efforts, including those listed above, exacerbate symptoms of poor sleep. Many of these behaviors, including spending time in bed while not sleeping or attaching negative cognitions to an inability to sleep, generate feelings of frustration, fatigue, and anxiety, each of which becomes paired, or conditioned, with the bed and bedroom. Over time, these negative thoughts and behaviors reinforce an inability to initiate and maintain quality, uninterrupted sleep. Such negative associations and reinforcement demonstrate core characteristics of classical and operant conditioning, respectively (Perlis et al., 1997).

Bandura's Social Cognitive Theory (McAlister, Perry, & Parcel, 2008) highlights several constructs central to health behavior and health promotion. When applied to sleep, these constructs aid in further explaining the mechanisms of Spielman's perpetuating factors

(Spielman & Glovinsky, 1991), particularly how cognitions co-occurring with unhealthy sleep behaviors become associated with sleep. First, reciprocal determinism suggests that unhealthy sleep behaviors and a poor sleep environment are bidirectional, constantly influencing and reinforcing one another. Second, prolonged unhealthy behaviors diminish an individual's capacity for self-regulation and self-efficacy for maintaining healthy, restorative sleep behaviors. Finally, chronic problems and frustration associated with not being able to sleep condition an individual's sleep-related outcome expectations to be negative rather than positive. Negative expectations can discourage an individual from reducing unhealthy, maladaptive behaviors in favor of healthier coping strategies.

Proliferation of Sleep Problems

While the 3P Model of Insomnia provides a larger framework for understanding risk, development, and continuation of insomnia, it was not originally designed to address consequences of unresolved or residual sleep problems. The 3P Model suggests insomnia is experienced in a unidirectional, linear fashion and assumes that insomnia is resolved by treating perpetuating factors. Future studies of insomnia, including new iterations of the 3P model, could benefit from a more longitudinal approach. Such an approach should be applied to both epidemiological studies examining trajectories of insomnia and to treatment studies.

Cognitive Behavioral Therapy for Insomnia (CBT-I) is the recommended first-line treatment for insomnia (National Institutes of Health, 2005; Qaseem et al., 2016). CBT-I targets perpetuating factors of insomnia (as shown in Box 10), including unhealthy behaviors and cognitions, and is effective in the short term (12–18 months) (Morin et al., 2006). CBT-I and other behavioral treatments have been shown to effectively reduce insomnia symptoms and severity in veterans (Germain, Shear, Hall, & Buysse, 2007; Karlin, Trockel, Spira, Taylor, & Manber, 2015; Trockel, Karlin, Taylor, & Manber, 2014). However, some veterans continue to have either subthreshold or clinically significant symptoms following treatment (Trockel et al., 2014). The lack of long-term follow-up (i.e. beyond 6 or 12 months after treatment completion) makes it difficult to gauge the longterm trajectories of these individuals and the number who experience future bouts of insomnia. It is unclear whether these residual problems resulted from lack of sufficient follow-up (i.e. participants need additional time to adjust to a new sleep schedule and experience full treatment effects) or whether existing interventions could benefit from one or more revisions (i.e. booster sessions, general coping strategies, or tips for managing high stress reactivity). Additionally, veterans may experience an additional stressor that triggers insomnia after completing a course of CBT-I treatment. Additional research is needed to examine the extent to which prior CBT-I treatment remains effective after experiencing subsequent stressors.

One possible explanation for the chronicity of sleep problems is impaired and/or reduced coping capacity. As addressed in the first portion of this paper, poor sleep contributes to impaired cognitive and functional performance (Box 12). In line with these findings and laboratory studies demonstrating impaired performance following sleep deprivation, it is hypothesized that reduced function resulting from chronic sleep problems also negatively impact an individual's reserve or adaptive capacity to respond to subsequent stressors (Box

12). This prediction is in line with health-related definitions of resilience, defined as a dynamic process of physiological and psychological adaptation to acute and chronic stress (Irwin, 2014; Lavretsky, 2014). Over time, chronic sleep problems, particularly sleep deprivation, lead to an ever-increasing allostatic load on physiological and psychological systems (McEwen, 2006; McEwen & Karatsoseso, 2015), thus contributing to excessive “wear and tear” on the body (Seeman, Singer, Rowe, Horwitz, & McEwen, 1997). Increasing allostatic load reduces the likelihood that an individual is able to successfully respond to or cope with subsequent stressors (Juster, McEwen, & Lupien, 2010; McEwen & Karatsoseso, 2015). This reduced stress capacity then contributes to poor physical and psychological health outcomes (Box 14).

There may be benefits to future research examining how impaired coping capacity may interact with high levels of stress reactivity, and what impact this combination of factors may have on future bouts, or relapses, of insomnia. If such an interaction is present, it may be that innovative hybrid interventions, such as those informed by principles of CBT-I and Mindfulness Based Stress Reduction (MBSR) may be effective in targeting both unhealthy sleep behaviors and underlying stress reactivity. MBSR has been shown to reduce physiological and psychological stress reactivity (Sharma & Rush, 2014) and an initial test of one such hybrid program, Mindfulness Based Therapy for Insomnia, which combines principles of CBT-I and MBSR, demonstrated promising results in reducing severity of insomnia symptoms (Ong et al., 2014). Although CBT-I curriculum teaches sleep-related coping strategies, it does not include more general stress and coping strategies. Integrating some of these strategies into behavioral sleep treatments may improve long-term coping and help reduce the likelihood of chronic insomnia.

Future directions

The proposed theoretical model highlights the etiological and clinical complexity of insomnia in U.S. military veterans, placing a particular emphasis on untreated insomnia problems. Severe sleep problems, such as insomnia, might occur at one point in time, typically triggered by a major life or environmental stressor, but their antecedents are found early in life and their consequences can extend for years or decades beyond the triggering stressful event(s). The model presented herein is meant to encourage researchers and clinicians to apply lifespan models to the problems of stress, insomnia, and health outcomes in veterans. While longitudinal data collection is time and resource intensive, such information would allow researchers to better understand the temporal nature and interrelationships between stressful events, sleep problems, and negative physical and psychological outcomes. Although not shown in this model, insomnia may co-occur with other sleep disorders, including sleep disordered breathing, restless leg syndrome, and chronic nightmares. Future iterations of the model should take a holistic approach to sleep and acknowledge these other common sleep disorders.

Sleep problems, particularly insomnia, are often assumed to be an acute consequence of deployment or reintegration. However, this model highlights the potential cyclical nature of insomnia, noting that chronic problems can deleteriously impact veterans’ long-term health and function. This model also highlights the importance of studying major life events and

daily stressors as both predictors and consequences of insomnia problems. Finally, as alluded to above, sleep and resilience are likely important yet under-studied mechanisms in veterans' long-term health. Additional research focusing on the multidimensional nature of resilience, including how physiological and psychological adaptive capacities contribute to an individual's stress response, is warranted. Future research examining these relationships and mechanisms could prove fruitful in both clinical and research settings, particularly as an increasing number of OEF/OIF veterans retire from military service and begin to utilize both VA and community healthcare services. As our theoretical model suggests, addressing sleep problems early could potentially enhance a veteran's adaptive capacity, thereby reducing the risk for negative physical and psychological outcomes across the lifespan. Finally, the constructs and mechanism outlined in this particular model may have application to non-veterans, including individuals who have experienced a significant life stressor or traumatic event. Future iterations of the model should highlight the mechanisms of insomnia and comorbid mental and physical health conditions.

Acknowledgments

The authors wish to thank Wizdom Powell, PhD, MPH who provided comments on an initial version of the conceptual model and manuscript.

Role of Funding Sources

This work was supported by facilities and resources at the Center of Innovation for Health Services Research in Primary Care at the Durham VAMC (CIN 13-410); Office of Academic Affiliations, VA Health Services Research & Development (TPH 21-000), and University of North Carolina Program on Integrative Medicine (Hughes: NIH/NCCIH T32AT003378). None of the funding sources had a role in developing this material, writing the manuscript, or the decision to submit the paper for publication.

Highlights

- Chronic insomnia problems are highly prevalent among US military Veterans
- Existing theoretical models view insomnia as a unidirectional phenomenon
- An integrated model is proposed that explains insomnia as a chronic, cyclical problem
- Insomnia should be viewed as a both a consequence and predictor of stress

Study Objective. To measure the association of symptoms attributed to residual effects of sleep medication (e.g., drowsiness, difficulty concentrating, and impaired memory) on self-reported functioning and satisfaction with these medications. *Methods.* Individuals using prescription medications for insomnia were invited to complete an Internet-based survey. Respondents were compared according to the presence of self-reported residual effects; relationships between severity of these effects and outcomes were modeled using regression. Measures included the Brief Insomnia Questionnaire, Work Productivity and Activity Impairment Questionnaire, and SATMED-Q. Subgroup analyses were conducted with patients aged ≥ 65 years. Approximately 80% reported experiencing ≥ 1 residual effect. The severity of residual effects was associated with increased residual effect-related work impairment, including absenteeism (RR = 1.46, $p < 0.001$), presenteeism (RR = 1.12, $p < 0.001$), overall work impairment (RR = 1.13, $p < 0.001$), and nonwork activity impairment (RR = 1.11, $p < 0.001$). More severe residual symptoms were also associated with increased difficulty in home management (Beta = .31, $p < 0.001$), ability to work (Beta = .31, $p < 0.001$), social relationships, (Beta = .32, $p < 0.001$), close personal relationships (Beta = .30, $p < 0.001$), and lower medication satisfaction (Beta = $-.37$, $p < 0.001$). *Conclusions.* Individuals using medications for insomnia commonly experience symptoms considered as residual effects, and these symptoms are associated with greater interference of sleep-related problems at work, at home, and with social relationships.

1. Introduction

Insomnia is a debilitating condition that accompanies several sleep, medical, and psychiatric disorders. It is diagnosed via subjective reports of persistent difficulty falling asleep, staying asleep, and/or experiencing sleep of poor quality. Insomnia confers significant daytime symptoms such as fatigue, low energy, impaired cognitive functioning, mood disturbance, and perceptions of decreased global functioning. In fact, daytime symptoms are those which most frequently lead patients to seek treatment [1]. Acute insomnia regularly occurs with life events or sleep schedule changes. For some, however, insomnia becomes unrelenting and chronic. Overall, insomnia has become a prevalent and costly public health

concern, associated with long-term effects on functioning and quality of life.

Approximately 25% of U.S. adults report dissatisfaction with their sleep, 10–15% report insomnia symptoms, and 6–10% have an insomnia disorder [2]. Population-based longitudinal data show nearly 70% of patients with baseline insomnia also report insomnia one year later, and 50% of those with baseline insomnia continue to report insomnia up to three years later [3, 4]. In fact, insomnia has become one of the most prevalent complaints in the primary care setting [5]. Moreover, high rates of comorbidity between insomnia and medical/psychiatric disorders have been described. Odds ratios reported by the 2002 U.S. National Health Interview Survey and the U.S. National Comorbidity Survey showed those with

insomnia to be twice as likely to present with congestive heart failure and up to five times more likely to present with a psychiatric disorder [6, 7]. Further, insomnia is strongly associated with hypertension and pain conditions, as well as greater risk of mortality, specifically in older adults [8–10].

Treatment can consist of behavioral/psychological interventions and/or pharmacotherapy. In general, it is considered that primary insomnia and secondary insomnia respond to both pharmacotherapy and behavioral/psychological intervention [11, 12]. Common agents to treat insomnia include over-the-counter agents (OTCs, antihistamines, melatonin, and herbal preparations), prescription hypnotic drugs (benzodiazepines, BzRAs, chronobiotic agents, and low-dose doxepin hydrochloride), and other prescription agents not specifically indicated for insomnia (antidepressants, antipsychotics, and anticonvulsants) [13]. However, sleep-promoting agents can produce adverse effects, particularly in the elderly [13]. Residual sleep medication effects have the potential to interfere with quality of life and include drowsiness, difficulty concentrating, headaches, nausea, dry mouth, oversleeping, and nightmares. Memory can also be affected, including impaired short-term memory and periods of amnesia reported in the literature [14–16].

Of the hypnotics, benzodiazepines and nonbenzodiazepine hypnotics with longer half-lives tend to produce residual impairment or “hang over,” particularly with middle-of-the-night dosing and regular use [17, 18]. Residual effects of hypnotics include sedation, cognitive impairment, motor incoordination, ataxia, dizziness, and gastrointestinal upset. In the elderly, the use of sedating drugs is dangerously associated with increased fall risk [19]. Meanwhile, the use of some antidepressants to treat insomnia has been associated with increased suicidal ideation, increased mania/hypomania in patients with bipolar disorder, and exacerbation of restless legs syndrome [20]. Further, the use of anticonvulsants (e.g., pregabalin) can produce daytime sedation, dizziness, and cognitive impairment [13]. Finally, the use of antipsychotics has been correlated with exacerbation of restless legs syndrome and increased mortality, particularly in elderly individuals [11]. From the standpoint of concern for public safety, insomnia treatments have been shown to impair next-day driving and increase the risk of motor vehicle accidents, particularly in women [21].

As above, older patients are particularly vulnerable to residual sleep medication effects. Meta-analysis of patients aged 60 years and older, who were free of other psychiatric disorders ($N = 2,417$), showed significantly higher odds of adverse cognitive events, adverse psychomotor effects, and daytime fatigue when patients used any hypnotic sedative, compared with placebo [22]. A large ($N = 15,528$) study of nursing home patients (mean age = 81), with hip fracture documented in Medicare Part A and Part D fee-for-service claims, showed elevated risk of hip fracture among users of a nonbenzodiazepine hypnotic sleep drug. Effects were particularly strong in new users [23].

Ultimately, residual sleep medication effects are associated with impaired functioning and lowered quality of life in insomnia patients and confer safety risks for both the patients and the public. Moreover, the literature reports older

patients to be at heightened risk for adverse side effects [13]. Little research, however, has characterized the impact of adverse side effects across multiple domains of functioning in the same group of patients—particularly in the elderly. The current study was conducted to collect information on the relationship between self-reported residual effects of prescription sleep medications and patient-reported outcomes. A secondary objective of the study was to describe the relationship between these symptoms and outcomes in users of these medications aged 65 years and older, since, as described above, these patients may be particularly vulnerable to residual effects [13].

2. Materials and Methods

The present study was a cross-sectional survey of current and former users of prescription medications for sleep reporting a diagnosis of insomnia ($N = 2,250$). For the purpose of estimating the burden of residual effects, only those currently using a sleep medication ($n = 1,605$) were included. Those reporting residual sleep medication effects were compared to those reporting no residual effects, and the relationship between severity of residual effects and outcomes was modeled using regression. Subgroup analyses were conducted with patients aged 65 years or older due to reported vulnerability to adverse sleep medication effects [13].

Respondents were recruited primarily from previous respondents to the U.S. National Health and Wellness Survey (NHWS). The NHWS is a cross-sectional survey administered via the Internet to a sample of adults (18 years and older) who were identified through a web-based consumer survey panel. Members of the panel are recruited through opt-in emails, coregistration with other panels, e-newsletter campaigns, and online banner placements. All panelists explicitly agreed to become panel members, registered through unique email addresses, and completed in-depth demographic registration profiles. Invitations to participate in the NHWS were sent using a random stratified sampling framework to ensure the final sample of NHWS participants is representative of the adult population in the U.S. according to the Current Population Survey (CPS) of the U.S. Census (United States Bureau of the Census, 2012) in terms of age, gender, and white/non-white racial identification. Because of the size of the target sample and inclusion criteria of this study, additional respondents were also identified through the Light Speed Research Ailment Panel, which is composed of general panel members who have self-identified as having certain medical conditions.

Only those who were aged 18 years or older, self-reported a diagnosis of insomnia, and did not self-report diagnosis for sleep-disordered breathing, narcolepsy, shift work disorder, parasomnia, or other sleep condition were included in the survey. For inclusion in the current analysis, respondents also had to report current use of a prescription medication for sleep.

2.1. Procedure. Respondents were interviewed through a self-administered, Internet-based questionnaire between December 5th and 18th, 2012. The protocol and questionnaire

were reviewed and approved by Essex Institutional Review Board (Lebanon, New Jersey, USA) prior to recruitment of participants.

The presence and severity of residual effects were assessed through a series of items assessing to what extent the respondent experienced each of the nine side effects when they take their insomnia medication. These were feelings of drowsiness, difficulty concentrating, difficulty remembering, headaches, nausea, dry mouth, oversleeping, amnesia, and nightmares, using a Likert scale from 1 (None) to 5 (“Very Severe”). Drowsiness, difficulty concentrating, difficulty remembering, headaches, nausea, dry mouth, and oversleeping were also combined by summing the ratings of severity to provide an overall index of residual symptoms.

Respondents who indicated at least one residual symptom completed the Work Productivity and Activity Impairment, Specific Health Problem (WPAI-SHP) questionnaire [24]. The specific health problem was residual symptoms, and the term used in the instrument for residual symptoms was “next-day effects.” Respondents were informed that this term was meant to indicate any side effects they feel the day after taking the medication. Four subscales (absenteeism, presenteeism, overall work impairment, and activity impairment) were generated in the form of percentages, with higher values indicating greater impairment. Absenteeism represents the percentage of work time missed due to next-day effects of sleep medication in the past seven days, and presenteeism represents the percentage of impairment in the past seven days while at work. Overall work impairment represents the overall amount of impact to work productivity due to either absenteeism or presenteeism (since they are mutually exclusive) in the past seven days. Activity impairment represents the percentage of impairment experienced during daily activities in the past seven days. Only employed respondents provided data on absenteeism, presenteeism, and overall work impairment but all respondents who reported at least one residual symptom rated their activity impairment.

Information on sleep difficulties was assessed using the Brief Insomnia Questionnaire (BIQ [25]). Information collected in the BIQ included in this analysis was the number of nights out of the past 7 with sleep problems due to trouble falling asleep, trouble staying asleep, trouble waking too early, waking feeling tired or unrested, and nights with at least one of these problems. The degree to which the individual’s sleep problems interfered with home management, ability to work, social relationships, and close personal relationships was also assessed in the BIQ using a modified version of the Sheehan Disability Scales. These are scored from 0 to 10, with higher numbers indicating greater interference. A “don’t know” response is also provided, and those who selected this option were excluded from analysis of the relevant item.

Insomnia Treatment History. A variety of items were used to characterize the respondents’ treatment history for insomnia. These include the year diagnosed with insomnia, type of diagnosing doctor, type of prescribing doctor, type of doctor currently managing insomnia, whether the respondent is

currently seeing a healthcare provider for insomnia, and previous prescription medications taken for insomnia.

Satisfaction with current medication was measured by the SATMED-Q [26]. This scale includes a total of 17 items that measure treatment satisfaction across multiple domains, including the presence and interference caused by side effects, the efficacy of the medication, convenience and ease of use, impact of medicine on everyday life, the follow-up from the doctor, and the patient’s overall opinion of the medicine.

Health characteristics and risk behaviors incorporated in the analysis included body mass index (BMI; underweight, normal weight, overweight, and obese), alcohol consumption (consume alcohol versus abstain from alcohol), cigarette smoking (current smoker versus nonsmoker), and whether the person reports exercising vigorously in the past 30 days. The severity of respondents’ comorbid medication conditions was assessed using the Charlson comorbidity index (CCI [27]). The CCI is calculated by weighting the presence of the following conditions and summing the result: HIV/AIDS, metastatic tumor, lymphoma, leukemia, any tumor, moderate/severe renal disease, hemiplegia, diabetes, mild liver disease, ulcer disease, connective tissue disease, chronic pulmonary disease, dementia, cerebrovascular disease, peripheral vascular disease, myocardial infarction, and congestive heart failure. The greater the total index score, the greater the comorbidity burden on the patient. Because insomnia commonly presents with psychiatric disorders, self-reported psychiatric diagnoses were also included in the questionnaire, including alcoholism, anxiety, bipolar disorder, depression, fibromyalgia, and schizophrenia.

2.2. Analysis. Analyses were conducted both on the full sample (aged 18 and older) and among the portion of the sample aged 65 years and older. Initial analyses compared those experiencing no residual symptoms to those who experienced at least one residual symptom using chi-square test for categorical variables and independent-samples *t*-tests for continuous variables. The relationship between the severity of residual effects and outcomes was also analyzed using multivariable regression. The multivariable models adjusted for covariates to reduce the likelihood that observed effects of residual symptoms were due to confounding factors. Covariates included gender (male versus female), race/ethnicity, age (continuous), BMI (overweight, obese, and missing versus normal/underweight), household income, comorbidity burden according to CCI, and a variety of psychiatric illnesses, which were found to be associated with residual symptoms during review of bivariate analyses. Models of treatment satisfaction were conducted using the total score from the SATMED-Q and were conducted using maximum likelihood linear regression. Likewise, ratings of disability were approximately normally distributed and also analyzed using linear models. Models of impairments measured by the WPAI were conducted using generalized linear models (GLMs) specifying a negative binomial distribution and a log-link function. All analyses were conducted first in the full sample and repeated in the subsample aged 65 and older.

3. Results

Sample characteristics are presented in Table 1. Respondents were 52 years old on average, 78% were female and 87% were white. Most had their insomnia diagnosed and managed by a general practitioner. Psychiatric comorbidities were common among the sample, with approximately 50% reporting depression and approximately one-third of the sample reporting an anxiety disorder.

Approximately 80% of current users (1,274/1,605) indicated some level of residual symptoms. Those reporting residual symptoms were slightly younger on average, but otherwise there were few demographic characteristics that differed across the presence of residual symptoms (Table 2). However, health characteristics differed according to presence of residual symptoms, with anxiety, depression, schizophrenia, and fibromyalgia all more likely among those with residual symptoms relative to those without residual symptoms, while alcoholism and bipolar disorder were marginally more likely. Psychiatrists were more often the diagnosing and prescribing doctor for those with residual symptoms than those without. The burden of comorbid conditions as represented by the CCI did not differ according to residual symptoms.

Problems with sleep in the prior 7 nights were common in current users of sleep medications. The presence of residual symptoms was associated with one additional day waking up tired/unrested, but not with the number of nights out of the past 7 with trouble falling asleep, staying asleep, or waking before the alarm (Table 3). In contrast, the impact of poor sleep on functioning was greater among those with residual effects, however, as ratings of interference in home management, ability to work, social relationships, and close relationships were all significantly higher among those reporting residual effects. Likewise, those who experienced residual symptoms were less satisfied with their current sleep medication than those who did not experience any residual symptoms (69.2 versus 76.0, $p < 0.001$).

Correlational analyses confirmed that when present, severity of residual symptoms was associated with worse outcomes and lower satisfaction. All residual symptoms were significantly associated with greater ratings of work and activity impairment in bivariate correlations. Difficulty concentrating and drowsiness were particularly burdensome, which were correlated with work and activity impairment $r_s = .46-.49$. Likewise, the severity of difficulty concentrating ($r_s = -.347$, $p < 0.001$) and grogginess ($r_s = -.366$, $p < 0.001$) was most associated with (reduced) satisfaction with sleep medication (data not presented).

Regression analyses confirmed the association between residual symptoms and outcomes. The severity of residual symptoms was associated with lower satisfaction as measured by the SATMED-Q, (Beta = $-.37$, $p < 0.001$). The severity of residual symptoms was also associated with increased residual symptom-related work impairment, including absenteeism (RR = 1.46, 95% CI: 1.34–1.60, $p < 0.001$), presenteeism (RR = 1.12, 95% CI: 1.09–1.14, $p < 0.001$), overall work impairment (RR = 1.13, 95% CI: 1.10–1.15, $p < 0.001$), and impairment in nonwork activities (RR = 1.11, 95% CI: 1.10–1.13, $p < 0.001$). The severity of residual symptoms was also

associated with increases in sleep-related interference on the four domains measured in the BIQ in the regression analyses; home management (Beta = .31, $p < 0.001$), ability to work (Beta = .31, $p < 0.001$), social relationships, (Beta = .32, $p < 0.001$), and close personal relationships (Beta = .30, $p < 0.001$) were all similarly affected.

Analysis of those aged 65 and older also revealed a high proportion (71%; 195 of 273) of current users reporting at least one residual symptom. As in the full sample, the rates

of anxiety, depression, schizophrenia, and fibromyalgia were higher among those with residual symptoms (Table 4). Unlike the full sample, patients aged 65 or older with residual symptoms had higher CCI scores relative to those without residual symptoms.

Results of comparisons of sleep outcomes also mirrored those of the full sample (Table 5). The number of nights with different types of sleep problems were comparable across those with and without residual symptoms except for

TABLE 5: Sleep-related trouble according to the presence of residual symptoms in respondents 65 years and older.

	Residual symptoms				<i>p</i> value
	None (<i>N</i> = 78)		One or more (<i>N</i> = 195)		
	Mean	SD	Mean	SD	
Nights out of 7 with trouble falling asleep	4.6	2.5	5.2	2.1	0.059*
Nights out of 7 with trouble staying asleep	5.4	2.2	5.4	2.2	0.822
Number of days out of 7 wake up before alarm	4.6	2.7	4.3	2.7	0.461

Note: * indicates Welch's test was used in lieu of parametric *t*-test due to nonhomogeneity of variance.

days waking up tired or unrested. Also consistent with the full sample, levels of disability due to sleep problems were elevated in those with residual symptoms relative to those without for all four domains measured. Those who experienced at least one residual symptom also had marginally lower satisfaction than those without any residual symptoms (74.7 versus 78.5, $p = 0.057$).

As in the full sample, the expected relationship between residual symptoms and satisfaction with sleep medication was seen in the correlations between satisfaction and ratings of individual residual symptoms (data not presented). Difficulty concentrating was most closely related to satisfaction ($r_s = -.34$, $p < 0.001$). Total residual symptoms and difficulty concentrating were most closely related to sleep medication-related impairment to nonwork activities (both $r_s = .46$, $p < 0.001$).

Regression results demonstrated that total residual symptoms were associated with lower satisfaction with current medication among those aged 65 years and older (Beta = $-.37$, $p < 0.001$). The severity of residual symptoms was also associated with increases in sleep-related interference on home management (Beta = $.30$, $p < 0.001$), social relationships (Beta = $.26$, $p < 0.001$), and close personal relationships (Beta = $.27$, $p < 0.001$). Total residual symptoms were also associated with impairment to nonwork activities on the WPAI (RR = 1.18, 95% CI: 1.11–1.25, $p < 0.001$).

4. Discussion

This study described the relationship between perceived residual sleep medication effects and a wide range of important outcomes for insomnia patients. This was the first study, to our knowledge, to describe the magnitude of the relationship between residual sleep medication effects and this large array of patient-reported outcomes, particularly in a single, large sample. Findings are particularly novel for the older patients, as the literature focuses primarily on what the residual effects are, rather than their correlates, for this demographic group.

Residual medication effects—such as feelings of being drowsy, groggy, or sluggish the next day, difficulty concentrating/remembering, or sleeping too much—were reported by approximately four out of every five individuals currently using prescription sleep medication. Overall, findings showed significant burden experienced by patients reporting residual sleep medication effects relative to those not reporting such effects.

Though patients with and without perceived residual effects suffered a similar number of nights with sleep problems (falling asleep, staying asleep, waking before the alarm, or any problem), the experience of residual effects was associated with an average of one more day per week of “unrestful sleep.” One potential explanation is that the residual effects of the sleep medication itself are responsible for the difference, though this is only speculation; the present analysis was not designed to identify the cause. Patients reporting residual effects were also less satisfied with their medications. Moreover, there were clear relationships between increasingly severe residual symptoms and decreased satisfaction, as well as increasingly severe residual symptoms and greater work and activity impairment, and greater sleep-related interference in home management, ability to work, and social relationships. Though respondents reporting residual effects indicated they experienced more psychiatric symptomatology and other comorbidities than those not experiencing such effects, the relationships between functioning and residual symptom severity remained significant after these and other relevant covariates were accounted for.

Analysis of older patients showed a similar pattern of relationships. Differences between those with and without residual symptoms were only marginal, but the correlation between increasingly severe residual symptoms and decreased satisfaction was of considerable magnitude. Increasing symptom severity corresponded with greater impairment across residual symptom-related nonwork activities, home management, ability to work, and social relationships. These relationships held when relevant covariates were included as well.

In support of prior research, insomnia patients experiencing residual symptoms comprise a group who are under particular strain, even relative to other already-burdened insomnia patients. This study uniquely describes the depth of this strain, which appears to occur across a wide range of domains and is likely affecting patients' global functioning and quality of life. Increasing residual symptom severity appears to affect level of impairment. Regarding financial burden, the strain could be indirectly affecting the work force and healthcare system. As hypothesized, older patients experiencing residual sleep medication effects showed the additional burden of more medical comorbidities. The comorbid conditions could potentially be aggravated or exacerbated by sleep medication side effects.

There are a number of limitations of the current study that should be considered alongside the results. Most importantly, this was an observational study, and the correlational nature of the data collection precludes any causal attribution. Likewise, the cross-sectional design does not allow us to ascertain whether the residual symptoms precede difficulties in home management, ability to work, and so forth, or whether residual symptoms occur in response to a worsening of such problems. Indeed, some residual symptoms, such as grogginess and difficulty concentrating, are also symptoms of insomnia, so some of the residual symptoms reported here may instead be symptoms of inadequately treated insomnia rather than next-day effects of sleep medication or a combination of both inadequate efficacy and medication side effects. Residual effects were self-reported rather than using objective measures of attention, memory, or reaction time. Another study limitation includes the margin of error inherent in any study using self-report measures, though insomnia itself can only be diagnosed via self-report, making self-report vital to this study [11]. Finally, the residual sleep medication effects we reported likely relate to other medical, psychosocial, quality of life, and economic outcomes that we did not measure. We may thus be underestimating the true extent of humanistic and economic burden.

5. Conclusions

Ultimately, patients who experience residual sleep medication effects represent a group with significant impairment of workplace, home, and social life activities; as the perceived severity of the residual symptoms increases, so does the burden. Thus, thorough medical and psychosocial/behavioral assessment of individuals experiencing residual effects is recommended (especially for the elderly). Also, improved management of insomnia would be beneficial. Behavioral and cognitive interventions have essentially no side effects and have been shown to lead to long-lasting, sustained improvements in sleep symptoms and parameters over 6 months to 24 months [28]. However, the degree of sleep medication use in this sample demonstrates that many may prefer, or need, pharmacotherapy for insomnia, highlighting a need for medications with fewer residual symptoms. The development of sleep medications with reduced residual effect profiles will be important for treatment of this patient population.

Cannabis sativa L. has been utilized for treatment of pain and sleep disorders since ancient times. This review examines modern studies on effects of Δ^9 -tetrahydrocannabinol (THC) and cannabidiol (CBD) on sleep. It goes on to report new information on the effects on sleep in the context of medical treatment of neuropathic pain and symptoms of multiple sclerosis, employing standardized oromucosal cannabis-based medicines containing primarily THC, CBD, or a 1:1 combination of the two (*Sativex*[®]). Sleep-laboratory results indicate a mild activating effect of CBD, and slight residual sedation with THC-predominant extracts. Experience to date with *Sativex* in numerous Phase I–III studies in 2000 subjects with 1000 patient years of exposure demonstrate marked improvement in subjective sleep parameters in patients with a wide variety of pain conditions including multiple sclerosis, peripheral neuropathic pain, intractable cancer pain, and rheumatoid arthritis, with an acceptable adverse event profile. No tolerance to the benefit of *Sativex* on pain or sleep, nor need for dosage increases have been noted in safety extension studies of up to four years, wherein 40–50% of subjects attained good or very good sleep quality, a key source of disability in chronic pain syndromes that may contribute to patients' quality of life.

Introduction. – Sleep disorders are important syndromes in modern medicine that include parasomnias, or sleep-disruptive events, as well common associated afflictions such as snoring and sleep apnea. The most common disorder is insomnia, or lack of sleep, said by the *National Institute of Neurological Disorders and Stroke* to afflict 60 million Americans [1]. Insomnia is a major risk factor for associated morbidity even in the absence of illness, and is associated with markedly increased prevalence of depression, anxiety, absenteeism [2], accidents [3], and utilization of health care resources [4]. Sleep disruption itself, as in shift work in nurses, may contribute notably to anxiety and functional bowel disorders [5]. When such sleep disturbances occur secondary to pain, they can be termed '*symptomatic insomnia*'. Pain at night at least three times a week was identified as a significant factor in excessive daytime sleepiness in older adults [6]. When sleep disturbance accompanies chronic pain or disease, attendant treatment becomes increasingly problematic. Despite the prevalence and pervasiveness of symptomatic insomnia, very few studies have addressed it, particularly with respect to possible effects of analgesics on sleep. For example, use of non-steroidal anti-inflammatory drugs may be associated with gastroesophageal reflux [7] that itself aggravates insomnia [8].

Fewer studies yet have employed modern methods of electroencephalography (EEG) or polysomnography to assess sleep disorders associated with chronic pain. Results of recent investigations are sobering, as formal sleep monitoring of patients with advanced cancers demonstrated that opioid treatment and pain disrupted nocturnal sleep, prolonged sleep latency, and limited attainment of sleep stages 3 and 4 as well as rapid eye movement sleep [9]. Further investigation indicated that such sleep disturbances were attributable to opioid treatment itself, which contributed to depression and even enhanced pain [10]. In light of such data, it is clear that new approaches to chronic pain and resultant sleep disorder are necessary.

Cannabis sativa L. and its derivatives have been known since ancient times for their analgesic, soporific, and hypnotic effects. While mentioned frequently as beneficial to sleep in a variety of pathological conditions in 19th-century sources on Indian hemp [11], modern studies on cannabinoids and their therapeutic effects on sleep have received little attention in modern medical literature until the last few years. As will be noted, these are indications for which standardized cannabis-based medicine promises palliation and symptomatic relief that may contribute greatly to patients' global impressions and subjective sense of relief of their condition.

The primary psychoactive ingredient of cannabis is Δ^9 -tetrahydrocannabinol (THC), many of whose actions are mediated *via* the CB₁ G-protein coupled receptors that cluster in nociceptive areas of the brain [12], spinal cord [13][14], and peripheral nervous system [15] (see [16] for an excellent review). THC Activity mimics that of the natural endocannabinoids, anandamide (AEA, arachidonylethanolamide) and 2-arachidonylglycerol (2-AG), that are likewise partial agonists on the CB₁ receptor, that modulate pain responses in integrative centers such as the periaqueductal grey matter [17] and pain in relation to stress [18]. Another important phytocannabinoid, the non-psychoactive cannabidiol (CBD), is not only an analgesic, anti-inflammatory, and antioxidant in its own right [19–21], but it is also reported to allay various THC adverse effects including sedation, tachycardia, and anxiety [22]. Recent work has demonstrated that CBD antagonizes tissue necrosis factor alpha (TNF- α) in a rodent model of rheumatoid arthritis [23], and enhances adenosine receptor A2A signaling *via* inhibition of an adenosine transporter [24], suggesting an important therapeutic role in various inflammatory and chronic pain states.

Additional cannabis components including terpenoids and flavonoids also have analgesic properties that may be significant [25]. Historical and scientific aspects of cannabinoids and pain have been described for migraine [26], obstetrics and gynecology [27], and gastroenterological conditions [28]. A clinical endocannabinoid deficiency has been hypothesized in relation to migraine, fibromyalgia, and idiopathic bowel syndrome [29].

In the current review, we will examine modern studies on effects of THC and CBD on sleep, and then report new information on the effects of cannabis-based medicines on sleep as a secondary outcome measure in the context of randomized clinical trials of medical treatment of chronic pain states, including neuropathic pain (NP), symptoms of multiple sclerosis (MS), and rheumatoid arthritis.

Clinical Studies of Cannabinoids and Sleep. – The soporific qualities of cannabis were noted in the ancient Indian *ayurveda* tradition [30]. Subsequently, the great

taxonomist *Linnaeus* recognized cannabis as *narcotica* and *anodyna* in his *Materia Medica* in the 18th century [31] (p. 214). *William B. O'Shaughnessy* reintroduced cannabis to Western medicine from India in the 19th century [32], wherein it produced sleep and pain reduction for victims of rheumatism and many other conditions. Benefits on sleep were noted in various pain states [11] throughout the 19th and early 20th century, when cannabis medicines subsequently fell from common medical usage due to lack of standardization and daunting problems with dosing and quality control.

Scientific study of cannabinoids entered the modern era in the early 1960s with the isolation of THC [33]. Early studies revealed that THC reduced sleep latency in normal and insomniac subjects, and caused some suppression of slow wave sleep (Stages 3 and 4) [34], often with a residual 'hangover' effect the next day [35]. No formal studies of cannabinoids to date have included electroencephalography or polysomnography in symptomatic conditions or chronic pain states.

In a recent case report [36], treatment with *Marinol*[®] (dronabinol, synthetic THC) effectively reversed serious insomnia in three patients afflicted with intractable pruritus associated with cholestatic liver disease. Similarly, in a limited trial of *Marinol*, 2.5 mg at night in five dementia patients, a reduction was observed in nocturnal motor activity ($p = 0.028$) [37].

A series of experiments with cannabidiol performed in Brazil were summarized in 1981 [38], with observations based on subjective sleep assessments. Of two subjects taking CBD 300 mg twice a day (BID) for 2 d, one reported having slept more heavily, but no performance abnormalities were evident. Ten more subjects took 200 mg CBD vs. placebo on four separate occasions with no significant differences in subjective functioning, or level of alertness. Two of four subjects taking CBD, 10 mg BID for 20 d, complained of isolated episodes of daytime somnolence on rare occasions. Another experiment compared placebo to CBD, 3 mg/kg/d divided BID in eight subjects. One reported somnolence for a week, another for the entire 30 d, and a third reported improvement in baseline insomnia.

Subsequently, this group assessed 15 subjects with 40, 80, and 160 mg oral doses of CBD as a hypnotic vs. nitrazepam, 5 mg, and placebo in a double-blind randomized trial. This low dose of benzodiazepine and lower dose of CBD produced little effect on sleep. The highest CBD dose, however, seemed to extend sleep and reduce episodic waking in 10/15 subjects subjectively, while also reducing dream recall. No hangover symptoms were noted.

Cannabinoid Effects on Brain Chemistry in Sleep. – The key role of the endogenous cannabinoid system in regulation of sleep–wake cycles was suggested by the finding that the CB₁ antagonist/inverse agonist SR 141716A produces arousal in rats at the expense of slow-wave sleep [39]. This was further highlighted by the finding that the endocannabinoid anandamide (AEA) seems to mediate sleep induction and interacts with oleamide in this regard [40]. Subsequently, a Japanese group demonstrated the inhibition of serotonin and ketanserin (5-HT_{2A} antagonist) binding to the 5-T receptors by AEA [41]. A mild but similar response has recently been demonstrated for CBD [42], and cannabis terpenoids [43], suggesting a possible synergy with the CB₁ agonist, THC. Certain terpenoid components of cannabis are sedating in their own right (reviewed in [44], particularly terpineol [45]).

Recently, CBD was shown to inhibit uptake of AEA, and weakly inhibit its hydrolysis [46], making it, in effect, an inducer of AEA function, and suggesting a modulatory role for this agent in sleep. Additionally, a functional role for endocannabinoids in regulation of respiratory stability in sleep to prevent sleep apnea has been suggested [47]. Finally, it has recently been demonstrated that CBD administered intracerebroventricularly in rats increased wakefulness in the lights-on period, and increased enhancement of c-FOS expression in hypothalamus and dorsal raphe nucleus [48], supporting a clinical alerting effect for this agent [22], as discussed below.

New Data on Sleep Modulation with Cannabis-Based Medicine Extracts (CBMs). – *GW Pharmaceuticals* received a license from the *British Home Office* in 1998 to cultivate cannabis and extract it as a standardized botanical drug substance for formulation into finished pharmaceutical products. Early indications have focused on multiple sclerosis (MS) and chronic pain, especially neuropathic, or associated with cancer and rheumatoid arthritis. Chemovars of cannabis were selected *via Mendelian* genetics to express one predominant phytocannabinoid [49][50]. Cloned plants undergo liquid CO₂ extraction to produce botanical drug substances that contain predominantly THC (*Tetranabinex*®), CBD (*Nabidiolex*®), or a 1:1 combination of the two (*Sativex*®; *Fig. 1*) [51][52]. *Sativex* is administered oromucosally *via* a pump-action spray with each 100- μ l pump-action actuation providing 2.7 mg of THC, 2.5 mg of CBD plus other phytocannabinoids, terpenoids, and phytosterols [25], in a base of 50% EtOH and 50% propylene glycol with 0.05% peppermint flavoring. Pharmacokinetic data on this material is available from recent publications [53]. The preparation has onset of activity in 15–40 min, which allows patients to titrate dosing requirements according to pain levels or other symptoms with an acceptable profile of adverse events.

Fig. 1. *Sativex oromucosal cannabis based medicine* (photo: *Ethan Russo*, 2003)

A total of 1000 patient years of *Sativex* exposure in over 2000 experimental subjects has been amassed in Phase-II and -III clinical trials. A slight majority of subjects had no previous recreational or medicinal cannabis exposure, but comparative efficacy results have been identical in cannabis-experienced and cannabis-naïve cohorts with no evidence of inadequacy of subject blinding [54][55]. Patients are generally able to find a stable dose at which they obtain therapeutic relief without unwanted psychoactive effects. All randomized controlled trials (RCTs) were performed with *Sativex* added as an adjunct to existing drug regimens in patients with intractable symptoms, *i.e.*, patients considered treatment-resistant and remained on best available analgesic therapy and hypnotic medication, if prescribed. A concerted effort has been made in this review to include data from all available *Sativex* clinical trials; no negative data were excluded.

Sativex was approved in June 2005 for marketing as a prescription medicine in Canada under a *Notice of Compliance with Conditions* (NOC/c) for central neuro-pathic pain in multiple sclerosis (MS). An *Investigational New Drug* (IND) application to study *Sativex* in intractable cancer pain patients in the USA was approved by the FDA in January 2006. Two independent reviews of *Sativex* have recently been published [56][57].

The effects of oromucosal high-THC extract (*Tetranabinex*®), 15 mg, and THC-CBD extract doses of 5 and 15 mg of THC-equivalent were assessed by *Nicholson et al.* in eight subjects with respect to nocturnal sleep, early morning performance, memory, and residual sleepiness in a double-blind placebo-controlled four-way cross-over study with EEG monitoring [58]. While the THC extract, 15 mg, alone produced little effect on sleep architecture, sleep latency was reduced, memory was impaired, and residual sleepiness and mood changes were observed ($p < 0.05$). Both dose levels of combined THC-CBD extract decreased Stage 3 sleep ($p < 0.05$) over placebo, and the 15-mg doses increased wakefulness ($p < 0.05$) compared to 5-mg doses. The 5-mg doses of THC-CBD extract actually produced faster reaction times on the digit recall test ($p < 0.05$) over placebo. The authors noted that whereas impaired memory was observed the next day when 15-mg THC extract was given alone overnight, there were no such effects when THC was concomitantly accompanied by 15 mg of CBD, as in *Sativex*. Conclusions were that THC was sedative, while, in contrast, the presence of CBD was alerting, tended to counteract THC adverse effects on cognition, and impaired wakefulness.

In subsequent Phase-II and -III clinical trials, sleep quality was assessed with questionnaires completed by clinical trial subjects. Visual Analogue Scales (VASs) and Numerical Rating Scales (NRSs) are familiar instruments to many clinicians and have traditionally been used to quantify patient-rated subjective experiences. The two types of scale have similar sensitivity and reliability, but NRS is generally preferred by patients for ease of use. NRS and VAS are well-established and validated for the measurement of pain [59]. As is the case with pain, there is no objective gold standard by which to quantify the quality and quantity of sleep in patients participating in clinical trials. For this reason, most of the studies included in this review utilized NRSs or VASs to measure sleep and sleep disturbance. For example, *Wade et al.* [60] used VASs attached to the following questions: ‘How was your quality of sleep last night?’/‘How much sleep did you get last night?’/‘How did you feel when you awoke this morning?’ The anchors at each extremity of the 10-cm line were ‘best imaginable’ and ‘worst

imaginable for the first two questions, and *totally refreshed* or *totally unrefreshed* for the third. As an example of NRS, Rog *et al.* [61] used an 11-box (0–10) scale attached to the following instruction: ‘On a scale of 0–10 please indicate how your nerve pain disrupted your sleep last night. Please tick one box only’. The anchors were ‘did not disrupt sleep’ and ‘completely disrupts (unable to sleep due to pain)’. Such measures appear to have good face validity.

These and other studies of cannabis-based medicines on pain and sleep are summarized in the *Table*.

In a Phase-II study in 24 patients with intractable neurogenic symptoms including MS and chronic pain, *Tetranabinex*, *Nabidiolex*, and *Sativex* were tested in a double-blind-*N*-of-1 RCT vs. placebo by Wade *et al.* [66]. Significant improvement was seen with both *Tetranabinex* and *Sativex* on pain (especially neuropathic) ($p < 0.05$), but *post-hoc* analysis showed symptom control was best with *Sativex* ($p < 0.0001$), with slightly less intoxication than with THC-predominant extract. *Sativex* significantly improved sleep quality ($p = 0.041$; Study GWN19902; *Fig. 2*) [66]. The authors noted that, compared to placebo, the CBD-predominant extract significantly improved pain, the THC-predominant extract yielded significant improvements in pain, muscle spasm, spasticity, and appetite, and combined THC:CBD extracts (*Sativex*) significantly improved muscle spasm and sleep. They also observed that the visual analogue scale for *Sativex* was significantly improved over baseline for 20 subjects in the sleep category ($p < 0.05$). Of particular note in this trial was the confirmation of the CBD component as alerting, while high THC extract (*Tetranabinex*) improved sleep parameters (although not statistically significantly over placebo in this trial), while the combination of the two (*Sativex*) improved sleep synergistically.

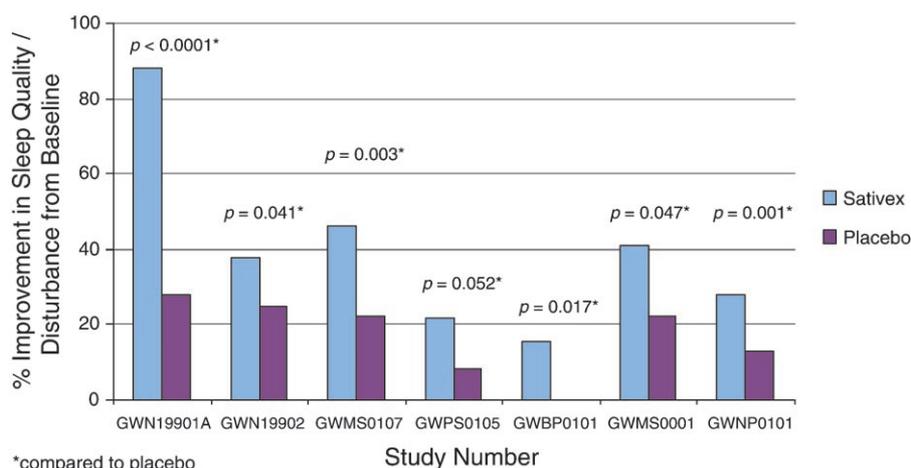

Fig. 2. Compendium of results of *Sativex* on sleep in earlier Phase II–III RCTs in multiple sclerosis (MS) and intractable chronic pain

In a Phase-II double-blind crossover *N*-of-1 study of intractable chronic pain in 34 subjects by Notcutt *et al.* [67], visual analogue scales for pain were significantly improved for *Tetranabinex* and *Sativex* extracts over placebo ($p < 0.001$). *Sativex*

produced best results for pain in MS subjects ($p < 0.0042$). Marked improvement was observed on sleep duration ($p = 0.0001$) and quality ($p = 0.0001$; Study GWN19901A; Fig. 2). The authors commented that *Sativex*, while having little effect on the recorded sleep hours, rather produced marked changes in reported sleep quality from the ‘poor’ or ‘fair’ to ‘good’ categories. The sleep quality measure represented a global assessment by the subject of sleep duration, depth, and relative degree of sleep disruption. Finally, they posited that improvement of sleep by the drug might prove to be one of its major benefits in chronic pain and MS.

In a Phase-III randomized placebo-controlled clinical trial in central neuropathic pain due to MS over 5 weeks in 66 patients by *Rog et al.*, subjects showed mean NRS analgesia favoring *Sativex* over placebo ($p = 0.009$), and significant benefit of *Sativex* over placebo was observed in sleep disturbance ($p = 0.003$) [61] (Study GWMS0107; Fig. 2).

In another Phase-III RCT in intractable pain in 79 subjects with MS, diabetic neuropathy, or other conditions by *Notcutt et al.* [72], the *Sativex* cohort utilized escape analgesia a mean of 20.57% of days vs. 50.12% for placebo ($p = 0.002$). Sleep disturbance was also reduced by *Sativex* vs. placebo (Study GWPS0105; Fig. 2), with a treatment difference favoring the former ($p = 0.045$).

In a Phase-III double-blind placebo-controlled trial of peripheral neuropathic pain with allodynia in 125 subjects by *Nurmikko et al.* [73], *Sativex* produced highly statistically significant improvements in pain levels ($p = 0.004$) and dynamic allodynia ($p = 0.042$). Marked reductions in sleep disturbance were observed ($p = 0.001$; Study GWNP0101; Fig. 2) [73].

In the largest clinical study of brachial plexus avulsion and central neuropathic pain to date by *Berman et al.* [68] in 48 subjects in a double-blind cross-over design assessing oromucosal *Tetranabinex*, *Sativex*, and placebo, comparable benefits were noted in Box Scale-11 pain scores with *Tetranabinex* ($p = 0.002$) and *Sativex* extracts ($p = 0.005$). Sleep disturbance scores favored *Sativex* over placebo ($p = 0.017$) [68] (Study GWBP0101; Fig. 2), with sleep quality scores also favoring *Sativex* ($p = 0.019$).

In another Phase-III RCT focusing on mixed neurogenic symptoms in MS by *Wade et al.* [60], the greatest improvement following *Sativex* was noted in spasticity ($p = 0.001$). Subjects also demonstrated benefit on sleep disturbance ($p = 0.047$; Study GWMS0001; Fig. 2). From this cohort, 137 patients elected to continue on *Sativex* in safety-extension (SAFEX) studies [74]. Rapid reductions were noted in the first twelve weeks in pain VAS in 47 affected patients with sustained improvements for more than one year. During that time, there was no escalation of dose indicating an absence of tolerance to analgesic or other therapeutic benefits of the preparation. Similarly, no withdrawal syndrome (as defined by *Budney et al.* [75]) was noted in a subset of 25 patients who voluntarily stopped the medicine abruptly. Upon resumption, benefits resumed at the prior established dosages. Improvements in sleep were also maintained [74].

Additional data from patients with central and peripheral neuropathic pain who completed these RCTs have been collected in a second SAFEX study of some 507 subjects taking *Sativex* for at least one, and up to four years. These data confirm the continued efficacy of *Sativex* in maintaining improvements in subjective sleep parameters. As in the prior SAFEX in MS subjects with mixed symptoms [74], no

Table. *Clinical Studies of Cannabis Based Medicines on Pain and Sleep*

Drug	Clinical indication	Subject number (N)	Trial duration	Results/reference
Cannabis (smoked)	HIV neuropathy	50	5 days	> 30% pain reduction vs. placebo ($p=0.04$), sleep NA [62]
<i>Cannador</i>	Spasticity in MS	419	15 weeks	Improvement over placebo in subjective pain associated with spasm ($p=0.003$), sleep ($p=0.025$) [63]
<i>Cannador</i>	Post-herpetic neuralgia	65	4 weeks	No benefit observed on pain, sleep NA [64]
<i>Cannador</i>	Post-operative pain	30	Single doses, 1 day each	Decreasing pain intensity with increasing dosage ($p=0.01$). Sleep NA formally. One complaint of sleep disturbance [65]
<i>Sativex</i>	Neurogenic pain	20	Series of 2-week N-of-1 crossover blocks	Improvement with <i>Tetranabinex</i> and <i>Sativex</i> on VAS pain vs. placebo ($p<0.05$), symptom control best with <i>Sativex</i> ($p<0.0001$). <i>Sativex</i> improved sleep quality ($p=0.041$) [66]
<i>Sativex</i>	Chronic intractable pain	24	12 weeks, series of N-of-1 crossover blocks	VAS pain improved over placebo ($p<0.001$) especially in MS ($p<0.0042$). Sleep duration and quality both improved ($p=0.0001$) [67]
<i>Sativex</i>	Brachial plexus avulsion	48	6 weeks in 3 two-week crossover blocks	Benefits noted in Box Scale-11 pain scores with <i>Tetranabinex</i> ($p=0.002$) and <i>Sativex</i> ($p=0.005$) over placebo. <i>Sativex</i> improved sleep disturbance ($p=0.017$) and sleep quality scores ($p=0.019$) [68]
<i>Sativex</i>	Central neuropathic pain in MS	66	5 weeks	Numerical Rating Scale (NRS) analgesia improved ($p=0.009$), sleep disturbance ($p=0.003$) vs. placebo [61]
<i>Sativex</i>	Peripheral neuropathic pain	125	5 weeks	Improvements in NRS pain levels ($p=0.004$), dynamic allodynia ($p=0.042$), sleep disturbance ($p=0.001$) vs. placebo [69]
<i>Sativex</i>	Rheumatoid arthritis	56	5 week	Improvements over placebo morning pain on movement ($p=0.044$), morning pain at rest ($p=0.018$), DAS-28 ($p=0.002$), and SF-MPQ pain at present ($p=0.016$), sleep quality ($p=0.027$) [70]

Table (cont.)

Drug	Clinical indication	Subject number (N)	Trial duration	Results/reference
Sativex	Pain after spinal injury	117	10 days	NSD in sleep disturbance and NRS pain scores, but improved Brief Pain Inventory ($p=0.032$) and Patients Global Impression of Change ($p=0.001$, odds ratio 3.4).
Sativex	Intractable cancer pain	177	2 weeks	Improvements in NRS analgesia vs. placebo ($p=0.0142$), <i>Tetranabinex</i> NSD. Sleep quality NSD [71]
Sativex	Intractable lower urinary tract symptoms in MS	135	8 weeks	Improvement in bladder severity symptoms ($p=0.001$) and nocturia episodes ($p=0.01$) over placebo.

dose escalation over time was necessary to maintain efficacy, supporting a lack of tolerance to this clinical benefit. Specifically, in an initial combined cohort of 287 subjects with central or peripheral neuropathic pain (Fig. 3), ca. 40% of subjects attained good-to-very-good sleep quality with maintenance of up to two years. Fewer than 20% of subjects had less than satisfactory results in their assessments of sleep quality.

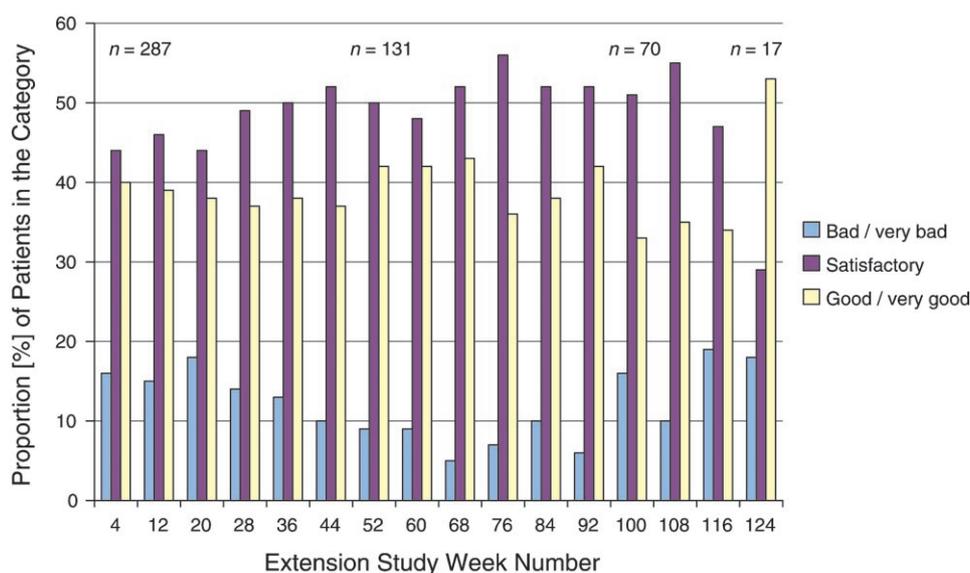

Fig. 3. Cumulative data on sleep disturbances (sleep quality scores) in a long-term safety-extension (SAFEX) study of central and peripheral neuropathic pain patients treated with Sativex (Study GWEXT0102)

An examination of adverse event profiles from the two SAFEX studies (137 and 537 subjects, resp.) reveals that complaints attributed to poor sleep or residual fatigue are infrequent after regular use of *Sativex* (Fig. 4).

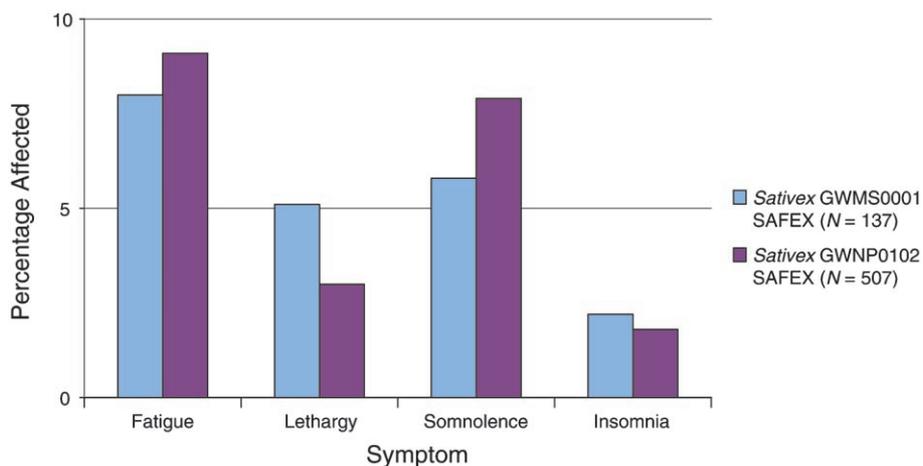

Fig. 4. Graph of fatigue and other adverse events attributable to sedation or sleep disturbance in safety-extension studies of mixed symptoms of multiple sclerosis (MS) (SAFEX GWMS0001, N = 137), and peripheral and central neuropathic pain (SAFEX GWNP0102, N = 507) taking *Sativex* for greater than one and up to four years. Rates of associated complaints are all less than 10%.

In a Phase-II double-blind, randomized placebo-controlled five-week study of 56 rheumatoid arthritis patients with *Sativex* by Blake *et al.* [70], employing nocturnal treatment only, subjects received a maximum of 6 sprays each evening (16.2 mg THC + 15 mg CBD). In the final treatment week, many study measures favored *Sativex* over placebo: morning pain on movement ($p=0.044$), morning pain at rest ($p=0.018$), 28-joint disease activity score (DAS-28; $p=0.002$), and Short Form *McGill* Pain Questionnaire (SF-MPQ) pain at present ($p=0.016$). Sleep quality favored *Sativex* over placebo ($p=0.027$) (Fig. 5, a).

Results of a Phase-III study ($N=177$) comparing *Sativex*, *Tetranabinex*, and placebo in intractable pain due to cancer unresponsive to opiates by Johnson and Potts [71] demonstrated that *Sativex* produced highly statistically significant improvements in analgesia ($p=0.0142$), while *Tetranabinex* was not significantly different from placebo, suggesting that the presence of CBD in the *Sativex* preparation contributed to pain control. Sleep quality in this study was not significantly improved over placebo, perhaps due to its short duration of only three weeks.

Similarly, in a Phase-II study of neuropathic pain after spinal injury, whereas no significant difference was noted in the primary outcome measure of average daily pain due to a large placebo response, the Brief Pain Inventory (BPI) did improve ($p=0.032$), as did the Patients Global Impression (PGI) of change ($p=0.001$, odds ratio 3.4). No changes in sleep over placebo were noted in this brief ten-day trial (unpublished findings).

In a Phase-III RCT of MS patients with intractable lower urinary tract symptoms and frequent accompanying pain in 135 subjects, *Sativex* produced a significant

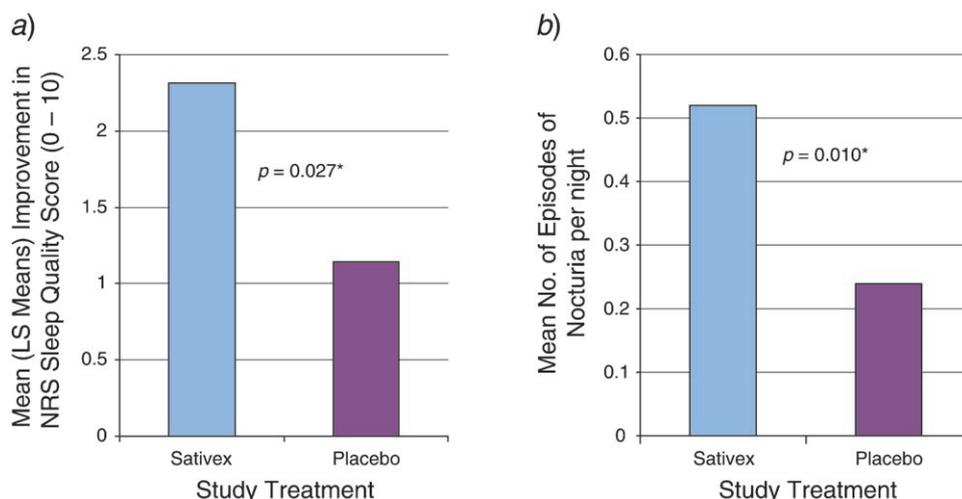

Fig. 5. a) Effect of Sativex vs. placebo on rheumatoid arthritis sleep quality GWCR1016 ($N=58$; 0–10 NRS, 0=‘very good’ and 10=‘very bad’). b) Effect of Sativex vs. placebo on nocturia in intractable lower urinary tract symptom patients with multiple sclerosis ($N=135$).

improvement over placebo in bladder symptom severity ($p=0.001$) and in nocturia episodes ($p=0.010$) affecting sleep (Fig. 5,b) (Fowler et al., GW Pharmaceuticals data on file, manuscript in preparation).

Common Adverse Events (AE) of *Sativex* acutely in RCTs have included complaints of bad taste, oral stinging, dry mouth, dizziness, headache, nausea, or fatigue, but do not generally necessitate discontinuation, and proved less common over time. Cumulative subject withdrawals from the RCTs secondary to AEs attributable to *Sativex* have occurred in 10.7% of all subjects, and in 10.8% of MS subjects (data on file, GW Pharmaceuticals, May 24, 2006). Figures ranged from 12.5% in the first Phase-II trial [60], while 0% of *Sativex* subjects withdrew due to attributable AEs in studies of lower urinary tract symptoms in MS [76] and brachial plexus avulsion [68].

Placebo-controlled trials have also been conducted with an oral plant-derived cannabis-based medicine, *Cannador*, which contains variable THC:CBD ratios [22]. This was examined in a large trial alongside *Marinol* (synthetic THC) and placebo in MS patients (Table). In neither the acute trial (CAMS) reported by Zajicek et al. [63], nor its 12-month long-term follow-up [77], were significant improvements noted in sleep with *Cannador* or *Marinol*. These data would support the proposition that benefits of cannabis-based medicines on sleep in the context of symptomatic treatment may be specific to a preparation’s formulation and/or delivery system, and the improvement with one preparation cannot necessarily be extrapolated to another. Another study of *Cannador* in post-operative pain (Table) showed decreased pain with increasing dosage, but sleep was not assessed formally (NA) [65]. One subject noted sleep disturbance. Finally, *Cannador* was utilized in a four-week study of post-herpetic neuralgia (Table), but no benefit was observed on pain, and sleep was NA formally [64].

Results are recently available from the first RCT of smoked cannabis on pain, in sensory neuropathy due to HIV/AIDS or its treatment (*Table*) [62]. A greater than 30% reduction in pain *vs.* placebo was noted in this five-day trial, but sleep effects were not reported. An additional study is planned in California to assess effects of cannabis on sleep disturbance in similarly affected patients (http://www.cmc.ucsd.edu/geninfo/drummond_abs.htm). The FDA has recently published guidelines for botanical medicines that mandate parameters required for *New Drug Approval* [78]. The difficulties inherent in standardizing herbal cannabis, and pulmonary issues associated with its inhalation [79], make it unlikely that regulatory approval would be attainable in most nations of the world [54].

No head-to-head trials of *Sativex vs.* smoked cannabis have been performed, but a comparison of AE profiles from self-selected SAFEX study subjects on *Sativex* with those of smoked-cannabis patients utilizing standardized cannabis in government programs in Canada [80] and the Netherlands [81][82] supports the concept that *Sativex* was much better tolerated, especially with respect to mental status and cognitive issues [54].

Discussion. – Chronic pain, neurological illness, and sleep disorders are clearly comorbid conditions. Upwards of 80% of MS patients suffer from debilitating fatigue symptoms and complain of significant sleep disturbance. Additionally, chronic pain accompanies MS in up to 60% in some surveys, with a citation of 48% in a recent study [83], further compromising the ability of patients to attain rest. *Tachibana et al.* [84] noted that such problems in MS arise from legion sources: pain, spasticity, muscle spasm, restless legs syndrome, myoclonus, and lower urinary tract symptoms, resulting in sleep disturbance in 80% of 28 subjects. It was felt by these authors that these problems were rarely addressed therapeutically. MS may also be associated with sleep apnea, a condition that has recently been demonstrated to respond favorably to treatment with THC in an animal model [47].

A recent study of sleep and fatigue in 60 MS subjects is quite germane [85], with over half noting difficulty with sleep disturbance at least two nights per week. Fatigue and excessive daytime sleepiness affected 64 and 32% of subjects, respectively. Those problems correlated best to difficulties with middle-of-the-night insomnia that subjects attributed most often to pain/discomfort (21.7%) or nocturia symptoms (72.5%). These symptoms were improved by *Sativex* treatment in the above discussed RCTs. Comparison of rates of fatigue, lethargy, somnolence, and insomnia in *Sativex* SAFEX subjects (*Fig. 4*) supports very remarkable amelioration compared to MS patients in the *Stanton* study [85], many of whom were already taking pharmacotherapy for such symptoms. The authors of the latter study specifically recommended symptomatic treatment of pain and nocturia as strategies to minimize sleep disturbance and its diurnal sequelae.

Similar sleep complaints affect patients with other etiologies of neuropathic pain. A current review article strongly suggested treatment of chronic pain with agents that concomitantly improve sleep [86]. A survey of 173 adults with neuropathic pain reported significantly higher rates of sleep disturbance and daytime somnolence *vs.* controls [87], with improvement after institution of specific treatment. Unfortunately, sleep disturbance continued in 43% of 140 subjects suffering from diabetic neuropathy despite treatment [88].

In a recent review [89], the authors state, ‘*The alterations of THC on sleep EEG and its rebound effect, its side effects before sleep induction, and its residual effects after awakening have contraindicated its clinical use as a sedative hypnotic*’. Data from the clinical research on *Sativex* reviewed in this article are not consistent with this conclusion. Rather, the available evidence to date would suggest that *Sativex* improvement in subjective sleep parameters, and satisfaction in patients with MS and neuropathic pain, with symptomatic relief of pain, spasms, nocturia, and related complaints. From limited sleep-laboratory information, it seems unlikely that its use will result in significant change in sleep architecture. *Sativex* does not benefit all patients, but in those who do respond, the beneficial effects are maintained consistently over time without evidence of tolerance, and are not accompanied by unusual cognitive sequelae [54]. Of course, additional in-depth studies are needed to confirm these contentions and might include formal neuropsychological testing and polysomnography.

Sativex patients and their caregivers have remarked to their physicians how the medicine had transformed their lives through its ability to allow them more restful sleep, increase their daytime level of function, and markedly improve their quality of life. Its addition to the pharmacopoeia may be welcomed by patients, families, and physicians.

Abstract

Background: The New South Wales State Government recently proposed a trial of the medical use of cannabis. Australians who currently use cannabis medicinally do so illegally and without assurances of quality control. Given the dearth of local information on this issue, this study explored the experiences of medical cannabis users.

Methods: Australian adults who had used cannabis for medical purposes were recruited using media stories. A total of 147 respondents were screened by phone and anonymous questionnaires were mailed, to be returned by postage paid envelope.

Results: Data were available for 128 participants. Long term and regular medical cannabis use was frequently reported for multiple medical conditions including chronic pain (57%), depression (56%), arthritis (35%), persistent nausea (27%) and weight loss (26%). Cannabis was perceived to provide "great relief" overall (86%), and substantial relief of specific symptoms such as pain, nausea and insomnia. It was also typically perceived as superior to other medications in terms of undesirable effects, and the extent of relief provided. However, nearly one half (41%) experienced conditions or symptoms that were not helped by its use. The most prevalent concerns related to its illegality. Participants reported strong support for their use from clinicians and family. There was almost universal interest (89%) in participating in a clinical trial of medical cannabis, and strong support (79%) for investigating alternative delivery methods.

Conclusion: Australian medical cannabis users are risking legal ramifications, but consistent with users elsewhere, claim moderate to substantial benefits from its use in the management of their medical condition. In addition to strong public support, medical cannabis users show strong interest in clinical cannabis research, including the investigation of alternative delivery methods.

Background

While cannabis has long been part of folk pharmacopeia, there is a burgeoning body of research on its therapeutic potential. This has largely drawn on scientific advances in our understanding of the pharmacology of cannabis, and its complex interactions with the central nervous system, particularly endogenous brain reward pathways [1]. In addition to basic experimental research, case reports, sur-

veys of people using cannabis for medical conditions and prospective clinical trials of cannabis-based medicines are consolidating the evidence that cannabis may play a role in the management of some medical conditions. Authoritative reviews of this evidence indicate that cannabis has therapeutic potential for conditions such as HIV- and cancer-related wasting, nausea and vomiting resulting from

chemotherapy, neurological disorders such as multiple sclerosis and chronic pain [1-4].

While current research reveals exciting therapeutic opportunities, there is an ongoing debate about the virtues of obtaining such benefits from the complex chemical cocktail contained in the whole plant or from one or more components isolated and developed into a synthetic pharmaceutical product. This debate cross-cuts important issues such as the difficulties of reliable dosing when using the natural product, whether the potential harms of smoking cannabis due to its ease of titration overshadow its therapeutic benefits, and whether different medical conditions will respond more favourably to the whole plant or to different constituents in isolation or combination. However, underlying these issues is the reality that most people who use cannabis medicinally do so by using black market supplies of an illicit drug.

As with the opiates, evaluations of the therapeutic potential of cannabis occur in the context of a vigorous political debate on the use of an illicit drug with dependence potential for medicinal purposes. This situation is clearly evident in the United States, where there is an ongoing legal challenge by the Federal Government over the States' rights to allow cannabis to be used by registered medical users. Despite Canada's recent decision to provide a controlled supply of natural cannabis to registered users, and approvals for the marketing of Sativex, a pharmaceutical cannabis extract, in some countries, currently most users would rely on home-grown cannabis, or supplies obtained from friends, families, dealers and medical compassion clubs.

To date, there has been little interest in Australia in formally investigating the therapeutic potential of cannabis or investigating the practices of current medical users. In 1999 the NSW State Government commissioned a Working Party to investigate the issue and recommend research and legislative options. Among their recommendations were: controlled clinical trials of cannabis, investigations into delivery methods other than smoking, surveys of current medical cannabis users and legislative amendments to allow compassionate use [4]. Subsequently, in 2003 the NSW Government announced it would conduct clinical trials, but despite generating significant publicity, there has been no further commitment by the NSW Government on this issue. The 2004 National Drug Strategy Household Survey found widespread public support for medical cannabis use, with 68% supporting a change in legislation to permit use for medical purposes and 74% supporting a clinical trial of medicinal cannabis use [5]. It is not known how many people use cannabis for medicinal purposes in Australia. Those who do use it engage in an illegal behaviour and risk arrest. Those that rely on

black market supplies use a product of unknown source and quality.

Several surveys in the US, UK, Germany and Canada [6-12] have reported perceived improvements in a variety of medical conditions following cannabis use. However, we know very little about the experiences of Australian users, and how they compare to findings in other studies. These authors are aware of only two unpublished Australian studies conducted in northern NSW; in 1998 a survey of 202 users recruited at the Nimbin HEMP Embassy [13], and in 2003 a survey of 48 members of a medical cannabis information service [14].

This paper presents the results of a study of 128 users, which aimed to learn more about their patterns of use, experiences and concerns, and interest in participating in a medical cannabis trial.

Methods

Sample

The sample comprised 128 people who used cannabis for medical purposes. To be eligible for the study, participants had to be living in Australia and to be currently using/have previously used cannabis for medical purposes. While the study targeted residents of Australia's most populous state, NSW (pop: approximately 6.7 million), we did not exclude participants from other parts of Australia (total pop: approximately 20 million).

As it is not known how many Australians use cannabis for medical purposes it was not possible to obtain a representative sample of such users. As this was an exploratory study to see who responded to a general call for participation in the survey, we did not target groups representing people with specific medical conditions (e.g., HIV/AIDS, multiple sclerosis) or hospital departments known to treat patients who may benefit (e.g., oncology, chronic pain clinics). Participants were primarily recruited from opportunistic media stories between November 2003 and August 2004, in newspapers, on radio and television. In addition, the Medical Cannabis Information Service (MCIS) in Nimbin, NSW, offered to tell its members about the survey and the International Association for Cannabis as Medicine (IACM), in Germany, placed the questionnaire on its website.

A total of 147 enquiries were received between December 2003 and August 2004 by telephone and email and approximately 170 questionnaires distributed (some people requested multiple copies to distribute). For example, the media stories generated enquiries from several GPs who said they would inform certain patients of the study. Of the 131 questionnaires returned, 128 were used for analysis (75% of questionnaires sent out). Of the three

Table 1: Conditions/symptoms experienced, duration, and conditions/symptoms requiring cannabis relief (n = 128).

Condition	(%) with condition	Median duration (yrs)	% used cannabis for relief of..*
Depression	60	10	56
Chronic pain	53	10	57
Arthritis	38	9	35
Migraine	22	18	17
Weight loss	21	4	26
Persistent nausea	20	6	27
Spinal cord injury	14	11	13
Spasms (spasticity)	13	8	16
Fibromyalgia	13	13	13
Wasting	13	5	11
ME (chronic fatigue)	13	16	13
Neuralgia/neuropathy	12	8	12
HIV/AIDS	9	15	8
Multiple sclerosis	7	9	7
Cancer	6	10	4
Other neurological disorder	6	5	6
PTSD	5	13	1 person
Irritable bowel syndrome	4	10	1 person
Glaucoma	3	29	2

*These figures do not necessarily equate with the % reporting a particular condition because some people reported using cannabis to relieve the particular symptoms (e.g., chronic pain, nausea) associated with a condition, rather than citing they used cannabis to relieve the condition itself (e.g., arthritis, cancer).

discarded questionnaires, one respondent was a recreational cannabis user and two had never used cannabis.

Questionnaire

The survey comprised an anonymous mail-out questionnaire, adapted from one developed by the MCIS in a recent study of its members [14]. Several issues were covered, including medical conditions/symptoms experienced, patterns of medical cannabis use, symptom relief and effects of use, comparison of cannabis to other medications, source and legal concerns (e.g., arrest), other concerns over use, opinion of family, friends and medical personnel, and interest in participating in a cannabis trial. The final version incorporated comments from researchers and clinicians interested in this issue.

Procedure

The study received ethics approval from the University of New South Wales Social/Health Human Research Ethics Advisory (HREA) Panel. Interested persons were screened for eligibility over the phone and informed of the purpose of the survey; assurances of anonymity and confidentiality were provided. Questionnaires were mailed to participants, completed anonymously and returned in a stamped, self-addressed envelope. Addresses were destroyed when the questionnaire was posted.

Analyses

Data were entered into SPSS (Version 12.0.1). As this was an exploratory study with a small sample size, this paper reports descriptive statistics only. Percentages are presented for categorical data; means (for normally distributed) and medians (for skewed data) are presented for continuous data. While data are usually presented on the overall sample, gender and age differences are presented for some variables, where they are of interest.

Results

Demographics

The sample was 63% male. Participants had a median age of 45 yrs (range 24–88), with almost one third (31%) aged 50 years or over, and one in ten (9%) aged 60 years plus. While the study targeted NSW residents (who represented 58% of participants), responses came from across Australia, especially Queensland (15%) and Victoria (12%). Residents of other States and Territories each comprised less than 3% of participants.

Participants reported a wide range of medical conditions and symptoms associated in the literature with the use of medicinal cannabis (Table 1), most commonly chronic pain (53%) and arthritis (38%). Approximately one in five reported migraine (22%), weight loss (21%) and persistent nausea (20%). However, depression was the most commonly reported condition/symptom (60%). Up to 35 other conditions/symptoms were listed, most commonly

Table 2: Patterns of medical cannabis use (n = 128 unless specified)

	Total (%)	Male (%)	Female (%)
Current use	85	86	83
Length of use			
<1 year	12	9	17
1–5 yrs	27	23	35
6–10 yrs	20	26	10
11–15 yrs	9	10	8
16–20 yrs	10	10	10
>20 yrs	21	23	19
Frequency of use (n = 126)			
several times a day	39	45	29
6–7 days/wk	24	19	31
1–5 days/wk	14	14	13
less than weekly	2	3	2
very seldom	2	1	2
as required	20	18	23

smoked as dry pipe (chillum)	10	13	4
smoked as water pipe (bong)	33	36	29
vaporiser	2	3	2
other	6	5	6

post traumatic stress disorder (PTSD) (5%) and irritable bowel syndrome (4%). It is important to note that we did not ask participants to distinguish between primary symptoms/conditions for which they sought treatment (e.g., cancer) and conditions which may have been secondary to this (e.g., depression) or consequent to treatment (e.g., chronic nausea). Multiple conditions (mean = 3.7, SD = 2.1, range = 1–10), of lengthy duration, were the norm, with three quarters (84%) reporting more than one condition and two thirds (67%) at least three conditions. Congruent with this picture, cannabis was used to relieve multiple symptoms (median = 3, range = 1–12), especially chronic pain (57%), depression (56%), arthritis (35%), persistent nausea (27%) and weight loss (26%).

Patterns of medical cannabis use

Participants had first tried cannabis for medical purposes at a median age of 31 years (range = 14–77). More than one quarter (29%) had discovered its therapeutic benefits as a spin-off from recreational use; others had tried it following concerns about the side-effects of their medications (14%), or a belief their medications or treatment were ineffective (13%), or had acted on the recommendation of a medical practitioner (10%) or friend (10%).

Table 2 presents data on patterns of medical use. Most (85%) were currently using cannabis therapeutically, even if sporadically. For those who had stopped, the main reasons were: their inability to obtain a regular supply (9/19 people), its illegality (7/19), cost (7/19) and disliking the side effects or route of use (each 3/19). Of those using intermittently, many reported their use would be more regular if it were more readily availability and cheaper.

Medical use was typically long-term and regular. Use of less than one year was uncommon (12%), with more than half (61%) having used it for at least six years; one in five reported very long-term use (more than 20 years). Most used at least weekly (75%), and more than half (59%) used almost daily or daily. Approximately one in five (22%) specified they used it "as required" for their condition (e.g., when pain was severe). Women tended to report shorter term use than men (52% vs. 31% citing use of 5 years or less).

It was most common for participants' medical use to be stable (22%) or largely unchanged since they started (17%), although it was most common for the amount used to vary according to their condition (35%). About one in ten indicated some increase in dose had been required (12%), while few reported a decrease (5%). Women tended to report more variable (44% vs. 29% of men) or short term use (15% vs. 6% of men); men tended to report an increase in the amount needed (17% vs. 4% of women).

In addition to medical use, three quarters (80%) of participants had used cannabis recreationally. Recreational use was less common among older participants (75% and 97% of recreational users were aged less than 50 years and 65 years, respectively). For almost half (46%), use in the past year had been solely medicinal, but the remainder reported recent recreational use – 29% in the past week, 19% in the past month and a further 6% in the past year.

Route of use

While most people had tried multiple routes for relief, overall smoking was the route most commonly reported (91%). Approximately half the sample (49%) also

smoked tobacco, and two thirds (64.1%) mixed their cannabis with tobacco.

Eating cannabis in cooked recipes was also very prevalent (49%). While vaporisers are not readily available in Australia, 8% had used them. In addition, four people had used tinctures and one used it topically in the bath or as a cream for a skin condition. Overall, smoking was also considered to be the most *helpful* route of use for symptom relief (74%), although concerns about this route of use were widespread. Consistent with Australian research on preferred route of use and age [15], older users (aged 50 years +) typically found joints the most helpful method of use (41% vs. 26% of younger users), while younger users preferred the use of waterpipes (43% vs. 13% of older users).

When asked to comment on the good and bad points of different methods of ingestion the most consistent response was that smoking of any form, particularly with tobacco, was detrimental to respiratory function (and health). This was of particular concern to non-smokers, some of whom did not know how to cook cannabis recipes. Despite attracting the bulk of negative comments, its popularity seemed to lie with its instant effect, its ease of titration and cost-effectiveness compared to the oral route. It seemed to "do the job". Eating was seen to be a much healthier option – it was "safer", tasty when cooked in a recipe, less obvious than smoking and could be done virtually anywhere. Some people liked its slow onset and long-lasting effects, but others claimed difficulties with titration and slow onset made it expensive and ineffective for rapid symptom relief.

Effects of cannabis use

When asked to rate the overall effects of cannabis on a Likert scale ranging from "I feel a lot worse" to "gives me great relief", cannabis was perceived to provide "great relief" (86%) or a little relief (14%). No one believed it had been detrimental to their condition or symptoms.

Positive ratings were ("great" or "good" relief) were also typical for its ability to relieve specific symptoms (Table 3). In addition, several other symptoms were noted, primarily insomnia (13% used for insomnia; of these 82% derived "great" relief).

Approximately three quarters of participants (71%) claimed to have experienced a return of their symptoms or condition on stopping cannabis, especially: pain (53% of those who claimed a return of symptoms), depression or anxiety (30%), insomnia (11%), spasm (10%) and nausea/vomiting or lack of appetite (9%).

Table 3: Symptom relief (n = 128)

Symptom relief required...*	Total (%)	Male (%)	Female (%)
Nausea relief	48	56	44
Of these, received:			
great relief	53	51	62
good relief	44	46	35
no effect	3	3	4
Pain relief	83	83	83
Of these, received:			
great relief	55	49	65
good relief	45	52	35
no effect	0	0	0
Ability to cope emotionally	66	70	60
Of these, received:			
great relief	45	40	54
good relief	54	58	46
no effect	1	2	0
Appetite stimulant	51	55	44
Of these, received:			
great relief	52	55	48
good relief	46	46	48
no effect	2	0	5
Decrease in spasms/tremor	39	36	44
Of these, received:			
great relief	43	43	43
good relief	55	54	57
no effect	2	4	0
Relief through relaxation	83	88	75
Of these, received:			
great relief	72	69	78
good relief	28	31	22
no effect	0	0	0

* No-one reported their condition was made worse

Only one in ten (11%) participants reported symptoms they believed were unrelated to their medical condition upon stopping cannabis, citing symptoms congruent with cannabis withdrawal such as anxiety or mood disturbance (including paranoia), insomnia, loss of appetite, restlessness and vivid dreams.

Comparison with other medicines

Almost two thirds (62%) of respondents claimed that they decreased or discontinued their use of other medicines when they started using cannabis medicinally. This was more common in males (65% vs. 58% of females) and older participants (aged 50 years +) (70% vs. 59% among younger participants). For some people this was a

Table 4: Comparison of cannabis with other medications (n = 128 unless specified).

	Total	Male	Female
Decreased or discontinued use of other medicines (n = 117*)	62%	65	58
Comparison of undesirable effects (n = 125)			
Cannabis produced much worse effects than other medicines	1	0	2
Cannabis produced somewhat worse effects	2	4	0
Undesired effects about the same	8	8	9
Other meds produced somewhat worse effects than cannabis	16	14	19
Other medicines produced much worse effects than cannabis	41	40	43
I have no undesirable effects from cannabis	31	33	28
Other medicines work differently	1	1	0
Comparison of relief provided (n = 118*)			
Other medicines work much better than cannabis	3	0	7
Other medicines work a bit better than cannabis	3	4	0
Other medicines work about the same as cannabis	9	8	9
Cannabis works a bit better than other medicines	13	11	15
Cannabis works much better than others medication	54	58	48
Only cannabis gives me relief from my condition	15	15	15
Other medicines work differently	2	0	4
Can't distinguish – use them together	1	1	2
Use cannabis to relieve side effects of other medicines	1	1	0

*Some people did not use other medications concurrently

substantial change, representing a shift away from chronic, high-dose medication use.

Perhaps not surprisingly, cannabis was typically perceived as superior to other medications in terms of undesirable effects, and the extent of relief provided (Table 4). Thus, cannabis was rated to produce equivalent (8%) or worse side effects (3%) by a minority of therapeutic users. It was considered to work "a bit" or "much better" than other medicines, or to be the only source of relief, by more than three quarters (82%). Two participants made the interesting comment that cannabis worked *differently* to other medicines, so could not be directly compared.

Despite the very positive response to the use of cannabis, nearly one half (41%; 36% of men and 50% of women) found it did not help certain conditions/symptoms. Almost one third (29%) said cannabis was less effective for certain types of pain, or extreme pain, with a further 12% specifying migraine or headache pain. Nearly one in ten (8%) reported no effect on depression or anxiety. More than one in ten (14%) specified that while cannabis could ease their symptoms and enabled them to cope, they realised that it could not cure their underlying condition. Younger participants were more likely than older participants to claim a condition not helped by cannabis (45% vs. 32% of those aged 50 years +).

Supply issues

Participants obtained medical cannabis from multiple sources (median = 1, range = 1–6; 44% had two or more sources), especially friends or family (58%) and dealers (42%). A substantial proportion grew their own (38%) while few (6%) obtained it from a compassion club or cooperative. Among those who purchased cannabis, the median weekly outlay was \$50 (range = \$1–\$500, n = 95).

When asked to comment on the variability of the cannabis they used, those who could obtain a consistent supply of high quality cannabis that suited their needs were in the minority. Typically, participants noticed variability along a number of lines, such as potency, effectiveness, intoxication and side-effects, which made titration difficult. While some noted the importance of factors such as the part of the plant used (e.g., leaf versus head/buds), strain (e.g., *sativa* versus *indica*), soil and climate, the overwhelming responses focussed on hydroponic versus soil-grown cannabis ("bush bud" or home grown cannabis), and home grown cannabis versus purchased cannabis.

Hydroponic cannabis was almost universally unpopular and was avoided where possible – despite its greater potency, it was also considered shorter acting, produced greater tolerance and worse side-effects than other cannabis. By comparison, soil-grown cannabis was perceived to

be less unpleasantly potent, natural ("organic"), less chemically treated, and with fewer side-effects. However, it was also perceived as harder to get. Home grown cannabis was seen as the best method of obtaining a consistent, safe supply of medicinal quality. A common response was that purchased cannabis was not to be trusted, and that unscrupulous growers who were more concerned with yield and greed compromised the quality of their crop with chemicals such as growth hormone and pesticides.

Concerns

A minority (13%) had no concerns over their medical cannabis use. Concerns over potential health effects (32%) or the risk of dependence (21%) were overshadowed by those relating to its illegal status (76%), the fear of being arrested (60%) and cost (51%). Indeed, one quarter (27%) claimed to have been arrested, cautioned or convicted in relation to their medical cannabis use, with this outcome more commonly reported by men (31% vs. 19% of women) and younger users (30% vs. 16% of users aged 50 years +). Other concerns mentioned (15%) were: the stigma of using, issues around parenting, pregnancy and relationships, availability, quality and difficulties in dose adjustment.

Support from others and interest in clinical trial

Most participants had a regular doctor (90%) and about a half had a regular specialist (55%). Virtually all (90%) had informed a clinician of their therapeutic use, typically reporting a supportive response from GPs (75% of those told), specialists (74%) and nurses (81%). Family and friends were largely considered supportive of the participant's use (71%).

Not surprisingly, there was widespread support for Government provision of cannabis to patients in a variety of circumstances. At least three quarters supported the supply of cannabis to any patient who was permitted to use it by being registered under a Government scheme (82%); more specifically, those patients who: could not afford to buy it on a regular basis (82%), could only purchase it on the black market (81%), couldn't ensure a consistent supply (75%), or were worried about quality control issues (77%). More than half endorsed the supply of patients who did not know anyone capable of growing it (72%), were concerned about hydroponically grown cannabis (72%), or who needed a supply quickly (66%).

Although not all participants were NSW residents, there was almost universal interest (89%) in participating in a clinical trial, in which a controlled supply of cannabis was grown and provided to registered medical cannabis users. There was also strong, although lesser, interest in trying alternative delivery methods such as a spray or tablet (79%).

While for some people, the availability of any cannabis-derived product that worked was their prime concern, alternative delivery methods were considered attractive as they obviated the necessity to smoke, removed concern about engaging in illegal behaviour and having to access the black market, and were more portable and acceptable than smoking. The main caveats on an alternative were that it was easy to titrate, quick, efficient, reliable and natural or safe – sprays and vaporisers were mentioned specifically by some as preferable to pills in this regard. A clear theme was the desire to keep the holistic, natural properties of cannabis rather than produce a chemical/synthetic drug with numerous binding and carrying agents. Nevertheless, there was recognition that different medical conditions may require different approaches, such as different active agents (e.g., THC versus other cannabinoids), strains or methods (e.g., slow release pill versus fast-acting spray).

The main reason for not supporting alternatives appeared to be that using the whole plant in its natural state was perceived to be the best method. In addition, for some the ritual of cannabis use was perceived as part of its medicinal benefit. There was also concern at political interference and its potential for exploitation and corruption in a trial.

Discussion

This exploratory study examined the patterns of medicinal cannabis use among a sample of 128 Australian adults who responded to media stories about this issue. Firstly, we need to acknowledge its limitations. As we do not know how many Australians use cannabis medicinally or their characteristics, we relied on the recruitment of volunteers through purposive sampling. Instead of targeting a particular group we used media stories disseminated widely on the radio, television and in newspapers to attract a cross-section of people. Thus, these results may not be representative of the experiences of all medicinal users, and may be affected by selection bias by excluding those who did not have access to these media, who did not wish to or could not contact us or did not return the questionnaire. We also attracted participants whose experiences with medical cannabis were typically positive, so they have little to tell us about people who have not found cannabis helpful or pleasant therapeutically. However, they still provide important information on these people's experiences, and raise important issues regarding the use of black market supplies of the cannabis plant and the development of cannabis-based pharmaceuticals. As the questionnaire was self-completed, there was potential for misunderstanding of the questions. However, the wording was straightforward, contact details were provided in the event of misunderstanding, and the results were remarkably consistent across participants, which encour-

ages us that the questions were understood. Despite being anonymous, several participants provided us with contact details in case further information was needed, and wrote additional comments about their experiences and attitudes. In addition, many of the findings are remarkably consistent with the findings of other local and international studies, as indicated below.

People in this study reported regular, ongoing medical use over quite long periods – with 61% using for more than five years and 20% reporting very long-term use of more than 20 years. However, as Ware and colleagues noted in their study of almost 1000 medical users [10], this was a group of chronically ill people with multiple long-standing conditions. The perceived need for alternative or additional symptom relief may reflect the fact that we recruited a sample of particularly entrenched medicinal cannabis users who were dissatisfied with conventional treatments, that medicinal cannabis use is more likely to be considered an option by people who find conventional treatments and medications unsatisfactory, or that many had been exposed to its perceived medical benefits quite early due to their recreational use. Larger studies addressing a broad cross-section of users may better answer this question.

Consistent with the literature on the conditions for which cannabis has been indicated, chronic pain, arthritis, persistent nausea and weight loss were among the most common conditions for which cannabis relief was sought. However, depression was the most common condition: more than half (56%) used cannabis to relieve depression, and two thirds (66%) used it to cope emotionally, universally obtaining great or good relief. Other studies have also reported cannabis use for the relief of depression, although not at this level [8-10,14]. The relationship between depression and cannabis use is controversial, with recent literature indicating that cannabis use may be implicated in depression and suicidal thoughts and behaviours. This would suggest that regular medicinal use may be contraindicated by placing people at risk of depression or self-harm. However, we do not know the type or aetiology of the depression cited by our participants. Many may have experienced depression and stress associated with their physical condition, which may have been alleviated along with any physical relief. The risk may also be greatest among heavy, younger users and those who may already be vulnerable to mental ill health due to their life circumstances [16-18]. Medical cannabis use patterns may not typically be regular enough to pose a great risk. Regardless, it is important that people considering the use of medical cannabis are aware of the risks of use [19]. A recent paper [20] has suggested that THC and cannabidiol, two major components of cannabis, may help alleviate bipolar disorder, recommending a pharmaceutical

product would be a safer option than crude cannabis, in which the balance of components is variable.

Consistent with local and international research on people with a variety of medical conditions [8-12,14], most participants claimed moderate to substantial benefits from cannabis, both in terms of their overall condition and management of individual symptoms. It was typically considered more effective and less aversive than other medications in managing their condition(s), the symptoms of which commonly re-emerged upon stopping (71%). While their use was often complementary to other medications and treatment, 62% had decreased or discontinued use of other medications when they commenced medicinal cannabis use. Nevertheless, cannabis was not a panacea – it did not help all conditions, particularly certain types of pain, and there was recognition that while it substantially improved quality of life it was not a cure. This is not necessarily surprising, as overall well-being and specific symptoms have multiple causes and can be affected by several factors, and is borne out by recent controlled clinical trials, for example, on chronic pain [21].

As others have reported (e.g., [8-10]) we also found that in addition to medical use, recreational use was common: most (80%) had used cannabis recreationally, with about one half (54%) of these reporting some recent use. Indeed, 29% had discovered its therapeutic potential through their recreational use. One participant raised the issue that part of the therapeutic effect for them was the ritual of use and the "high" experienced [6]. This demonstrates the difficulty of precisely identifying the therapeutic component when people are using the natural plant matter, and will continue to present a challenge for the development of cannabis pharmaceuticals. While some people may find the illegality, route of use and psychoactive effects of natural cannabis undesirable and prefer a manufactured pharmaceutical product, several in this survey claimed to prefer the holistic delivery of all the compounds present when using the natural plant. We need to know more about the effect of the different active chemicals on medical conditions and how their therapeutic potential is mediated by the context of use.

Nonetheless, this was not simply a sample of recreational users, especially as we attracted many older users who used exclusively for medical reasons (75% of those aged 50 years+). They did not fit the recreational user stereotype, were willing to take the risk of using an illicit drug, exposure to the illicit drug market and the possibility of arrest to gain symptom relief. Indeed, the most common concern over medicinal use was its illegality, fear of arrest and cost (all >50%). One quarter (27%) of participants had experienced legal ramifications due to their use. Several people commented that they had no alternative than

using an illegal drug, claiming that other medicines with negative and toxic effects (e.g., opiates) were legally prescribed, and that if nothing else worked for them they had the right to access cannabis without fear or stigma. Several made pleas for medical cannabis use to be treated as a medical, rather than a legal, issue, as their health and quality of life were at stake.

Smoking was the most common method of use; in addition, many were tobacco smokers or mixed cannabis with tobacco. Given the similarities between cannabis and tobacco smoke this is of particular concern for people who are ill, especially those with compromised immune systems. Despite acknowledgement of the risks of smoking and concerns expressed over its effects, it was considered the most helpful route of use. While eating was perceived as much healthier, until satisfactory solutions are achieved on titration and dosing issues, smoking will no doubt continue to be a popular method of obtaining relief.

Cannabis dependence was a concern for one in five participants (21%). This study provided indirect evidence that participants were unlikely to experience withdrawal symptoms on ceasing medical use, but this was only a crude measure. While the risk of dependence is probably low when used medicinally, this risk needs to be weighed up with the other concerns of the patient – for example, it may be low on the list of concerns for those with terminal illness [19].

Finally, participants reported that family and friends were likely to know about and support their medical cannabis use. These data also indicate that the medical profession is encountering, and frequently supporting, patients who use cannabis for symptom relief. Given their central role in the management of illness, it is important that clinicians are educated about the effects of cannabis, in order to assist patients in making informed decisions about their treatment. There was also clearly great interest among participants in a clinical trial and scope to investigate methods of delivery that avoid the health concerns associated with smoking cannabis, keeping in mind that some participants were reluctant to use a pharmaceutical product. In addition to distrust of unscrupulous participants in the black market, some were also distrustful of Government's motives and role in therapeutic research. It is therefore vital that any clinical trials are conducted in a rigorous, independent manner.

Conclusion

Overall, these findings are consistent with those of other surveys, in revealing the perceived effectiveness of cannabis for the relief of symptoms associated with several medical conditions. While a small study, it has several

implications. Firstly, people are risking the use of an illicit drug for its perceived therapeutic effects, and in some cases being arrested. Secondly, they are informing their clinicians about their medical use and frequently receiving support, highlighting the importance of ensuring clinicians are informed about cannabis. Finally, in addition to strong public support, medical cannabis users show strong interest in clinical cannabis research, including the investigation of alternative delivery methods.

Therapeutic Benefits of Cannabis: A Patient Survey

Charles W. Webb MD and Sandra M. Webb RN, BSN

Abstract

Clinical research regarding the therapeutic benefits of cannabis ("marijuana") has been almost non-existent in the United States since cannabis was given Schedule I status in the Controlled Substances Act of 1970. In order to discover the benefits and adverse effects perceived by medical cannabis patients, especially with regards to chronic pain, we hand-delivered surveys to one hundred consecutive patients who were returning for yearly re-certification for medical cannabis use in Hawai'i.

The response rate was 94%. Mean and median ages were 49.3 and 51 years respectively. Ninety-seven per cent of respondents used cannabis primarily for chronic pain. Average pain improvement on a 0-10 pain scale was 5.0 (from 7.8 to 2.8), which translates to a 64% relative decrease in average pain. Half of all respondents also noted relief from stress/anxiety, and nearly half (45%) reported relief from insomnia. Most patients (71%) reported no adverse effects, while 6% reported a cough or throat irritation and 5% feared arrest even though medical cannabis is legal in Hawai'i. No serious adverse effects were reported.

These results suggest that Cannabis is an extremely safe and effective medication for many chronic pain patients. Cannabis appears to alleviate pain, insomnia, and may be helpful in relieving anxiety. Cannabis has shown extreme promise in the treatment of numerous medical problems and deserves to be released from the current Schedule I federal prohibition against research and prescription.

Introduction

Research into the therapeutic benefits of cannabis has been severely limited by the federal Schedule I classification, which essentially prohibits any ability to acquire or to provide cannabis for studies investigating possible therapeutic effects. Limited studies have been done in Canada and in Europe, as well as several in California.

Hawai'i is one of twenty states (plus the District of Columbia) which allow certifications for use of medical cannabis. The authors have been certifying patients for use of medical cannabis in Hawai'i for more than four years. In an attempt to discover the perceived benefits and adverse effects of medical cannabis, we conducted a survey of medical cannabis patients.

Methods

Sample Selection

Between July of 2010 and February of 2011, we hand-delivered questionnaires to one hundred consecutive patients who had been certified for the medical use of cannabis for a minimum of one year and were currently re-applying for certification.

Survey Design and Administration

The subjects were verbally instructed to complete the questionnaire in the office at the time of re-certification or were provided a stamped and addressed envelope so they could complete the questionnaire at home. All patients were instructed to remain anonymous and to answer the questions as honestly as possible.

A universal pain scale was used to assess pain before and after treatment (0 = no pain, 10 = worst pain ever). Open-ended questions were asked to ascertain the following:

- (1) "Any adverse effects you have had from using medical cannabis?"
- (2) "Does medical cannabis help you with any other problems? If so, what?"

The purpose of the last question was to explore benefits outside the parameters of the state of Hawai'i's medical cannabis qualifying conditions.

Results

The overall response rate was 94%. The mean age was 49.3 years and the median age was 51. No data was collected on sex or race/ethnicity. Almost all respondents (97%) used medical cannabis primarily for relief of chronic pain.

Average reported pain relief from medical cannabis was substantial. Average pre-treatment pain on a zero to ten scale was 7.8, whereas average post-treatment pain was 2.8, giving a reported average improvement of 5 points. This translates to a 64% average relative decrease in pain.

Other reported therapeutic benefits included relief from stress/anxiety (50% of respondents), relief of insomnia (45%), improved appetite (12%), decreased nausea (10%), increased focus/concentration (9%), and relief from depression (7%). Several patients wrote notes (see below) relating that cannabis helped them to decrease or discontinue medications for pain, anxiety, and insomnia. Other reported benefits did not extend to 5% or more of respondents.

Six patients (6%) wrote brief notes relating how cannabis helped them to decrease or to discontinue other medications. Comments included the following: "Medical cannabis replaced my need for oxycodone. Now I don't need them at all." "I do not need Xanax anymore." "In the last two years I have been able to drop meds for anxiety, sleep, and depression." "I've cut back 18 pills on my morphine dosage."

A majority (71%) reported no adverse effects, while 6% reported a cough and/or throat irritation and 5% reported a fear of arrest. All other adverse effects were less than 5%. No serious adverse effects were reported.

Discussion

According to the Institute of Medicine, chronic pain afflicts 116 million Americans and costs the nation over \$600 billion every year in medical treatment and lost productivity.¹ Chronic pain is a devastating disease that frequently leads to major depression and even suicide.² Unfortunately, the therapeutic options for chronic pain are limited and extremely risky.

Spurred by efforts to encourage physicians to become more pro-active in treating chronic pain, US prescription opioids (synthetic derivatives of opium) have increased ten-fold since 1990.³ By 2009 prescription opioids were responsible for almost half a million emergency department visits per year.⁴ In 2010 prescription opioid overdoses were responsible for well over 16,000 deaths.⁵ A 2010 article in the *New England Journal of Medicine* addressing this problem is aptly titled “A Flood of Opioids, a Rising Tide of Deaths.”³ Drugs such as OxyContin[®] are so dangerous that the manufacturer’s boxed warning states that “respiratory depression, including fatal cases, may occur with use of OxyContin, even when the drug has been used as recommended and not misused or abused.”⁶ Clearly safer analgesics are needed.

The Hippocratic Oath reminds to “first, do no harm.” It cannot be over-emphasized that there has never been a death from overdose attributed to cannabis.⁷ In fact, no deaths whatsoever have been attributed to the direct effects of cannabis.⁷ Cannabis has a safety record that is vastly superior to all other pain medications.

Many physicians worry that cannabis smoke might be as dangerous as cigarette smoke; however, epidemiologic studies have found no increase in oropharyngeal or pulmonary malignancies attributable to marijuana.⁸⁻¹⁰ Still, since smoke is something best avoided, medical cannabis patients are encouraged to use smokeless vaporizers which can be purchased on-line or at local “smoke-shops.” In states that (unlike Hawai‘i) allow cannabis dispensaries, patients can purchase “vapor pens,” analogous to e-cigarettes and fully labeled regarding doses of THC and other relevant cannabinoids.

Tests have proven that smoke-free vaporizers deliver THC as well or even more efficiently than smoking, and that most patients prefer vaporizers over smoking.¹¹ Like smoking, vaporizers allow patients to slowly titrate their medicine just to effect, analogous to IV patient-controlled analgesia (PCA) that has been so successful in hospital-based pain control. This avoids the unwanted psychoactive side-effects often associated with oral medication such as prescription Marinol[®] (100% THC in oil) capsules which tend to be slowly and erratically absorbed and are often either ineffectually weak or overpoweringly strong.^{12,13} Because inhaled cannabis is rapid, reliable, and titratable, most patients strongly prefer inhaled cannabis over Marinol[®] capsules.¹⁴

While the relative safety of cannabis as medication is easily established, the degree of efficacy is still being established. The reported pain relief by patients in this survey is enormous. One reason for this is that patients were already self-selected for success: they had already tried cannabis and found that it worked for them. For this sample, the benefits of cannabis outweighed any negative effects. The study design may therefore lend itself to over-estimating the benefits and under-estimating the negative side-effects if extrapolated to the general population.

Another reason that the reported pain relief is so significant is that cannabis has been proven effective for many forms of

recalcitrant chronic pain. A University of Toronto systematic review of randomized controlled trials (RCT’s) examining cannabinoids in the treatment of chronic pain found that fifteen of eighteen trials demonstrated significant analgesic effect of cannabinoids and that there were no serious adverse effects.¹⁵

While opioids are generally considered to have little benefit in chronic neuropathic pain, several RCT’s have shown that cannabinoids can relieve general neuropathic pain,¹⁶ as well as neuropathic pain associated with HIV and with multiple sclerosis (MS).^{17,18} One study found that cannabis had continuing efficacy at the same dose for at least two years.¹⁹

Even low dose inhaled cannabis has been proven to reduce neuropathic pain. In a randomized, double-blind, placebo-controlled crossover trial involving patients with refractory neuropathic pain, Ware, et al, found that therapeutic blood levels of THC (mean 45 ng/ml achieved by a single inhalation three times a day) were much lower than those necessary to produce a cannabis euphoria or “high”(> 100 ng/ml).¹⁹

Cannabis is relatively non-addicting, and patients who stop using it (eg, while traveling) report no withdrawal symptoms. One author (Webb C.) worked for 26 years in a high volume emergency department where he never witnessed a single visit for cannabis withdrawal symptoms, whereas dramatic symptoms from alcohol, benzodiazepine, and/or opioid withdrawal were a daily occurrence.

So why is cannabis still held hostage by the DEA as a Schedule I substance? On June 18, 2010, the Hawai‘i Medical Association passed a resolution stating in part that:

“Whereas, 1) Cannabis has little or no known withdrawal syndrome and is therefore considered to be minimally or non-addicting; and

Whereas, 2) Cannabis has many well-known medical benefits (including efficacy for anorexia, nausea, vomiting, pain, muscle spasms, and glaucoma) and is currently recommended by thousands of physicians; and

Whereas 3) Cannabis has been used by millions of people for many centuries with no history of recorded fatalities and with no lethal dosage ever discovered; and

Whereas, Cannabis therefore fulfills none of the required three criteria (all of which are required) to maintain its current restriction as a Schedule I substance...

The Hawai‘i Medical Association recommends that Medical Cannabis be re-scheduled to a status that is either equal to or less restrictive than the Schedule III status of synthetic THC (Marinol[®]), so as to reduce barriers to needed research and to humanely increase availability of cannabinoid medications to patients who may benefit.”²⁰

Medical cannabis remains controversial mainly because the federal government refuses to recognize cannabis as an accepted medication. To this we would echo the words of Melanie Thernstrom in her excellent book *The Pain Chronicles*,² “How could treating pain be controversial?” one might ask, “ Why wouldn’t it be treated? Who are the opponents of relief?”

Conclusions

Cannabis is an extremely safe and effective medication for many patients with chronic pain. In stark contrast to opioids and other available pain medications, cannabis is relatively non-addicting and has the best safety record of any known pain medication (no deaths attributed to overdose or direct effects of medication). Adverse reactions are mild and can be avoided by titration of dosage using smokeless vaporizers.

More research needs to be pursued to discover degrees of efficacy in other areas of promise such as in treating anxiety, depression, bipolar disorder, autism, nausea, vomiting, muscle spasms, seizures, and many neurologic disorders. Patients deserve to have cannabis released from its current federal prohibition so that scientific research can proceed and so that physicians can prescribe cannabis with the same freedom accorded any other safe and effective medications.

Conflict of Interest

None of the authors identify a conflict of interest.

KEYWORDS

Cocaine;
Ecstasy;
Cannabis;
Marijuana;
Tetrahydrocannabinol;
Recreational drugs;
Sleep;
Withdrawal

Summary The illicit recreational drugs cocaine, ecstasy and marijuana have pronounced effects upon sleep. Administration of cocaine increases wakefulness and suppresses REM sleep. Acute cocaine withdrawal is often associated with sleep disturbances and unpleasant dreams. Studies have revealed that polysomnographically assessed sleep parameters deteriorate even further during sustained abstinence, although patients report that sleep quality remains unchanged or improves. This deterioration of objective sleep measures is associated with a worsening in sleep-related cognitive performance. Like cocaine, 3,4-methylenedioxymethamphetamine (MDMA; "ecstasy") is a substance with arousing properties. Heavy MDMA consumption is often associated with persistent sleep disturbances. Polysomnography (PSG) studies have demonstrated altered sleep architecture in abstinent heavy MDMA users. Smoked marijuana and oral Δ -9-tetrahydrocannabinol (THC) reduce REM sleep. Moreover, acute administration of cannabis appears to facilitate falling asleep and to increase Stage 4 sleep. Difficulty sleeping and strange dreams are among the most consistently reported symptoms of acute and subacute cannabis withdrawal. Longer sleep onset latency, reduced slow wave sleep and a REM rebound can be observed. Prospective studies are needed in order to verify whether sleep disturbances during cocaine and cannabis withdrawal predict treatment outcome.

Introduction

“Recreational drug use” is a term for a substance use pattern that has become highly prevalent. Recreational drug users are generally well-integrated and may belong to any social class. They usually resort to illegal drugs at weekend parties, in order to reduce stress and to escape from the daily routine. Also, the substances are welcome for their socializing properties, and some of them for their enhancement of dancing capabilities.

This review considers the illicit recreational drugs cocaine, ecstasy and marijuana. Further examples of substances used in the described manner are amphetamine, methamphetamine, LSD, psilocybin mushrooms, ketamine and gamma-hydroxybutyrate. Many of these drugs, in particular cocaine, are clearly not restricted to a recreational pattern of use.

It is estimated that 42% of US American adolescents have experience with marijuana before the end of secondary school, 9% with cocaine and 7% with ecstasy.¹ An estimated 4.2 million Americans are classified with current dependence on or abuse of marijuana, and almost 1.7 million with dependence on or abuse of cocaine.² These numbers are higher than the corresponding figures for prescription-type pain relievers used nonmedically (1.6 million), prescription-type tranquilizers (400,000) and heroin (300,000).²

We carried out a search in the electronic databases Medline (since 1966), Embase, PsycINFO, Psynex and the Cumulative Index to Nursing and Allied Health Literature (CINAHL). The key words included “cocaine”, “3,4-methylenedioxymethamphetamine”, “MDMA” and “ecstasy” as well as “cannabis”, “marijuana”, “tetrahydrocannabinol” and “THC”. These terms were entered into the databases in conjunction with the term “sleep”. Articles published until August 2007 were eligible, and reference lists of relevant articles were screened for further related studies.

Cocaine

Acute cocaine administration

The competitive inhibition of presynaptic dopamine transporters in the nucleus accumbens and prefrontal cortex, leading to an increase in dopamine availability, has been proposed to constitute the primary neurophysiologic equivalent of central cocaine effects.³ Acute subjective effects of cocaine intake are euphoria, orgiastic feelings, restlessness, motor activation and increased alertness.

Trouble sleeping is a frequently cited adverse effect of cocaine intake.^{4,5} Polysomnography (PSG) studies have confirmed the stimulant properties of cocaine, demonstrating longer sleep latency, reduced total sleep time and suppression of REM sleep after acute cocaine administration.^{6–8} Acute effects of cocaine upon sleep resemble those of other psychostimulants such as amphetamine.⁹

Cocaine withdrawal

During acute withdrawal, cocaine-dependent individuals often experience depressed mood, psychomotor agitation or retardation, increased appetite, fatigue, sleep disturbances and unpleasant dreams.^{10,11}

To date, eight PSG studies^{7,8,12–17} of cocaine withdrawal have been published, mostly non-randomized controlled trials (see Table 1). Three studies administered cocaine in simulated binges during the inpatient phase.^{8,16,17} Results were similar to the studies with previous binges in the patients’ natural environment.^{12–15} It has been shown that during acute cocaine withdrawal, total sleep time is significantly reduced,^{8,12–17} approximating that of untreated chronic insomniacs.²¹ Sleep onset latency is prolonged and sleep efficiency is decreased.^{8,12–18} An increase in REM sleep percentage and reduced REM latency are observed.^{7,8,12–16} These changes in REM sleep are consistent with the subjective withdrawal symptom of increased dreaming.^{10,11} It has been found that smaller doses of cocaine administered in the morning may improve sleep in cocaine-dependent subjects, probably by attenuating withdrawal effects.¹⁹

During the subacute phase of cocaine withdrawal, commonly defined as starting on day 10, PSG parameters of sleep continuity deteriorate even further. Total sleep time decreases,^{12–14,16,17} and sleep latency and sleep efficiency also change in the direction of even poorer sleep.^{12–14,16,17} REM latency remains significantly reduced.^{12,14,16}

It has been shown that cognitive performance deteriorates during subacute cocaine withdrawal.^{17,20} Reaction time on a vigilance task increases,^{17,20} which is considered to be a sensitive measure of growing sleep pressure in the context of sleep deprivation.²¹ Also, the sleep-dependent performance on a motor sequence task is compromised and correlates with an individual’s total sleep during withdrawal.¹⁷

These findings are most notable in view of the fact that subjective sleep quality remains unchanged or improves during subacute withdrawal.^{12,16,17,22,23} This phenomenon is the exact opposite of the

Table 1 PSG studies investigating sleep during cocaine withdrawal

Authors	Subjects (no.)	Intervention	Method	Major findings
Watson et al. ⁷	3 light cocaine users	1 drug night, 3 d recovery	PSG	Drug night: ↓ REM sleep. Recovery: REM rebound
Kowatch et al. ¹²	3 cocaine-dependent	17 d abstinence	PSG, subjective reports	↑ Wakefulness, ↓ SE, ↓ SWS, REM rebound, subjective: about same as usual

Thompson et al. ¹⁴	7 stimulant abusers	14 d abstinence	PSG	Acute withdrawal: REM rebound, subacute withdrawal: ↓ TST
Lukas et al. ¹⁵	20 cocaine- and heroin-dependent	9 d abstinence before buprenorphine treatment	PSG	↑ SOL, ↓ TST, ↓ SE, ↓ SWS, REM rebound
Johanson et al. ⁸	3 cocaine-dependent	8–10 d abstinence, 5 d of 600 mg cocaine, 15–16 d abstinence	PSG, MSLT	Cocaine use: ↑ SOL, ↓ SE, ↓ REM sleep. Withdrawal: ↑ SOL, ↓ SE, ↓ REM latency, MSLT: ↑ SOL during subacute withdrawal
Pace-Schott et al. ¹⁶	5 cocaine-dependent	3 d abstinence, 3 d of 600 mg crack, 15 d abstinence	PSG, subjective reports, cognitive tasks	↑ SOL, ↓ SE, ↓ REM latency across binge-abstinence, subjective: slight improvement, deterioration of cognitive performance
Morgan et al. ¹⁷	12 cocaine-dependent	3 d abstinence, 3 d of 223 mg cocaine, 17 d abstinence	PSG, spectral power, subjective reports, cognitive tasks	↑ SOL, ↓ TST, ↓ SE across binge-abstinence, ↑ δ spectral power during subacute withdrawal, subjective: improvement, deterioration of cognitive performance

Abbreviations: d, days; MSLT, multiple sleep latency test; PSG, polysomnography; SE, sleep efficiency; SOL, sleep onset latency; SWS, slow wave sleep; TST, total sleep time.

distorted sleep perception in primary insomniacs, who typically underestimate their sleep quality. It has not been studied why cocaine-dependent subjects do not recognize this deterioration of sleep during subacute withdrawal. A possible explanation is that, although slow wave sleep (SWS) percentage is low both during acute and subacute withdrawal,^{12–14,17} δ spectral power may increase during subacute withdrawal.¹⁷ An increased δ spectral power is associated with better self-reports of sleep quality.²⁴

Ecstasy

Acute and subacute ecstasy effects

3,4-Methylenedioxymethamphetamine (MDMA; “ecstasy”) is a drug that is frequently used by visitors of raves or techno parties in large dance

clubs. MDMA induces rapid release of serotonin via interaction with presynaptic serotonin uptake carriers.²⁵ MDMA also induces rapid dopamine release and binds to a variety of neurotransmitter receptors, especially serotonin 5-HT₂ receptors.²⁵ MDMA effects such as feelings of closeness to others, increased empathy and self-perception are summarized as the “entactogenic” properties of this agent (“entactogen” from Greek and Latin, “producing a touching within”). Furthermore, ingestion of ecstasy is associated with cognitive and perceptual changes that resemble effects of psychedelics and with amphetamine-like hyperactivity and increased energy.

MDMA users commonly report restless, disturbed sleep during the 48 h following MDMA intake.^{26,27} 3,4-Methylenedioxy-*N*-ethylamphetamine (MDE; “eve”) has similar effects as MDMA. The only PSG investigation on acute effects of entactogens was conducted with MDE. It showed an increase in

wakefulness and an almost complete suppression of REM sleep.²⁸

Persistent effects of heavy ecstasy use

A number of studies have indicated that heavy MDMA use is associated with persistent neuropsychiatric symptoms such as, most notably, impaired episodic memory and learning performance,²⁹ but also anxiety, depersonalization, depression, and sleep disturbances.^{26,30–32} Interpretation of these studies is complicated owing to methodological difficulties such as polydrug usage and the possibility of pre-existing differences.

There is conflicting evidence with respect to the PSG patterns in abstaining heavy MDMA users. A recent study³³ replicated earlier findings³⁴ that Stage 2 sleep is reduced in these individuals. Furthermore, Stage 1 sleep is increased and total sleep time is reduced, although findings were only near-significant in one study and significant in the other. There was a trend for reduced REM latency.³³ No significant correlations were detected between previous marijuana use and Stage 2 or Stage 1 sleep.³³ In a third PSG study of abstinent MDMA users, Stage 2 sleep was decreased without achieving statistical significance.³⁵ Furthermore, this study indicated that sleep efficiency and SWS are increased in ecstasy users.³⁵ However, these latter findings need to be viewed cautiously since control subjects had remarkably low sleep efficiency and decreased SWS.³⁵

Cannabis

Acute and chronic cannabis administration

The cannabis plant contains over 60 cannabinoids. Δ -9-Tetrahydrocannabinol (THC) is the constituent that is mainly responsible for the psychotropic effects of marijuana.³⁶ These psychotropic effects are mediated mostly by cannabinoid CB₁-receptors, which can be found in high concentrations in the frontal cortex, cerebellum and basal ganglia.³⁷ CB₁-receptors activate a variety of signal transduction pathways and interact with numerous neurotransmitters and neuromodulators. Acute subjective marijuana effects are highly variable, and contradictory effects may be observed depending on individual and condition. Often, marijuana induces mild euphoria, talkativeness, intensification of sensory experiences, difficulty concentrating, altered time perception, relaxation and drowsiness.

Interpretation of the available PSG studies of cannabis effects is difficult due to a number of

methodological limitations. Sample sizes were often small, and most studies were carried out in the 1970s. There is considerable heterogeneity with respect to administered dosage, time and route of administration, specificity for THC, and, notably, the extent of previous drug consumption, possibly leading to withdrawal effects during baseline or to tolerance. Several studies have shown that acute administration of THC decreases sleep latency,³⁸ and is associated with reports of greater ease in getting to sleep.^{39,40} Yet, arousing effects may predominate initially, and in a few studies with high THC doses or marijuana-naïve subjects, findings were more suggestive of increments in sleep onset latency.^{41–43} There is some evidence indicating that cannabis reduces Stage 3, but increases Stage 4 and total slow wave sleep,^{45–47} but contradictory effects have also been observed.⁴¹ Furthermore, it has been found consistently that THC decreases total REM sleep and REM density.^{41,46,48–51} Owing to the slow elimination of THC and its active metabolites, sedative effects are sometimes still present the following morning.^{38,47} The combination of THC with cannabidiol, an important non-psychoactive ingredient of marijuana, leads to an increase in wakefulness compared to THC alone.⁴⁷

PSG studies of chronic marijuana administration have suggested that some tolerance occurs to the sleep-inducing^{52,53} and SWS-enhancing^{45,51,52} effects of cannabis. Tolerance to REM sleep effects may be less pronounced,⁴⁶ but evidence is conflicting.^{48,53} A study of subjective changes of marijuana effects over the years indicated that desirable effects of marijuana upon sleep are reported less frequently after years of use compared to initial ratings.⁵⁴

Table 2 gives an overview over studies investigating the effects of cannabis upon objective sleep measures.

Cannabis withdrawal

Anger and irritability, anxiety and nervousness, restlessness, weight loss, sleep difficulty and strange dreams are frequently reported marijuana withdrawal effects.^{55–57} Less common symptoms are depressed mood, chills, shakiness, stomach pain and sweating.⁵⁵ Cannabis withdrawal resembles nicotine withdrawal with respect to symptom profile, magnitude and time course.^{58,59}

There is quite a substantial number of recent studies on subjective sleep measures during cannabis withdrawal.⁵⁵ Difficulty in sleeping and strange dreams have been reported with high cross-study reliability.⁵⁵ They generally occur within 24–72 h of discontinuation of cannabis use

Table 2 Studies investigating the effect of smoked marijuana and oral THC upon sleep

Study	Subjects (no.)	Intervention	Major findings
Gillin et al. ⁴²	3 psychiatric pts	40 mg THC	↓ REM sleep
Kales et al. ⁴⁷	4 naive, 4 chronic users	Smoked marijuana	↓ REM sleep. Recovery: REM rebound
Freemon ⁴⁸	2	20 mg THC	↓ REM %. Recovery: ↑ wakefulness, ↓ REM latency
Pivik et al. ⁶⁵	6	<20 mg THC	↓ WASO. Recovery: ↓ Stage 1, ↓ REM latency
Cousens and DiMascio ³⁸	9 insomniacs	10–30 mg THC	↓ Sleep onset latency
Bobon et al. ⁴³	1 psychiatric pt	20 mg Δ -8-THC	↑ Wakefulness, ↑ REM latency
Hosko et al. ⁴⁴	7 (2 naive, 1 heavy user)	20 mg THC	No consistent alterations
Pranikoff et al. ⁵²	30 chronic users	Smoked marijuana until "high"	↑ Stage 2, ↓ Stage 4 compared to abstinent users
Barratt et al. ⁴⁵	12	2 marijuana cigarettes (1.6% THC)	Acute: ↑ SWS, chronic administration: ↓ SWS. Withdrawal: ↓ SWS
Feinberg et al. ⁴⁶	7 chronic users	70–210 mg THC	↑ Stage 4, ↓ REM density, ↓ REM sleep. Withdrawal: ↑ SOL, ↓ SWS, REM rebound
Tassinari et al. ⁴¹	8 (7 naive)	70 mg THC	↑ Stage 2, ↓ REM sleep
Feinberg et al. ⁵⁰	4 chronic users	Marijuana extract (70–210 mg THC)	Low dosage: ↑ Stage 4, ↓ REM density. Withdrawal: ↑ SOL
Karacan et al. ⁵³	32 chronic users	Usual pattern of marijuana use	↑ REM %, ↑ SOL
Freemon ⁵¹	2	30 mg THC	Chronic administration: ↓ SWS. Withdrawal: ↑ wakefulness, ↓ SWS
Nicholson et al. ⁴⁷	8	15 mg THC, 5 mg THC+CBD, 15 mg THC+CBD	15 mg THC: ↑ sleepiness next morning. 15 mg THC+CBD: ↑ wakefulness, ↓ Stage 3, ↑ sleepiness next morning
Walther et al. ⁸⁹	6 pts with dementia and nighttime agitation	2.5 mg THC	↓ Nocturnal motor activity

Abbreviations: CBD, cannabidiol; MSLT, multiple sleep latency test; PSG, polysomnography; pts, patients; SOL, sleep onset latency; SWS, slow wave sleep; THC: Δ -9-tetrahydrocannabinol; TST, total sleep time; WASO, wakefulness after sleep onset.

and persist for 6–7 weeks.^{57,60} Resumption of cannabis use attenuates sleep disturbances.^{61–63} Treatment of cannabis withdrawal symptoms by means of oral substitution of THC improves sleep or even reinstates subjectively normal sleep.^{40,64}

The available PSG studies of cannabis withdrawal were designed as non-randomized, controlled trials. They have demonstrated increments in sleep onset latency and wakefulness after sleep onset.^{46,49–51} Total SWS is reduced^{45,46,51} and REM sleep is increased^{46,48,49,65}. This increase in REM sleep is consistent with the subjective abstinence symptom of "strange dreams".^{55,56}

Outlook

Every year, a combined 2.2 million Americans receive treatment for cocaine or cannabis abuse in specialized facilities, compared to 2.5 million alcoholics receiving specialized treatment.²

Treatment of cocaine and cannabis dependence is difficult and expensive.^{66,67} More research on potential pharmacotherapies is warranted.

It can be hypothesized that the poor sleep quality during cocaine withdrawal has detrimental effects upon treatment outcome. The demonstrated impairments of vigilance and learning performance may put cocaine users at increased risk of relapse. On the other hand, it has been shown that the severity of withdrawal symptoms including sleep disturbances predicts poor treatment outcome in cocaine dependence.⁶⁸ Similarly, it has been suggested that in cannabis dependence, sleep problems and other withdrawal symptoms make cessation more difficult and that resumption of cannabis use serves as a negative reinforcer.^{57,69,70} There is need for prospective studies to verify whether sleep disturbances during cocaine and cannabis withdrawal are predictive of relapse. Such a relationship would not only provide a prognostic tool, but it might also open new

perspectives on therapeutic strategies. In alcohol addiction, the predictive value of sleep disturbances for relapse has been established,^{71–73} and successful treatment options have been derived from this observation.⁷⁴

Substances recently tested as pharmacotherapy for cocaine abuse interact directly with sleep–wake mechanisms. The effectiveness of substances with gamma amino butyric acid (GABA)-mediated sedative properties such as baclofen has been demonstrated.^{75–77} Modafinil acts in the opposite direction, and constitutes another promising candidate for treatment of cocaine dependence.^{78,79} It is a stimulant substance that may be able to restore cognitive functioning in cocaine withdrawal, as it does in sleep-deprived individuals when given in the morning.⁸⁰ The question of whether modafinil possesses abuse potential is discussed controversially at present.^{81,82} There is need for randomized controlled trials that examine the effect of GABA-medications and stimulants such as modafinil upon objective sleep measures, cognitive performance as well as treatment outcome. This would shed more light upon the clinical relevance of the impairments of sleep-dependent cognitive performance.

Agonist replacement therapy has become a well-established approach to treat opiate and nicotine dependence. Preliminary findings of substitution therapy for cannabis dependence are promising,^{40,64} demonstrating an attenuation of withdrawal symptoms including sleep disturbances. Randomized controlled trials on the effect of THC substitution upon treatment outcome are under way.

The question of whether MDMA induces serotonin neurotoxicity in humans has become a field of extensive research.²⁹ Since PSG is a highly sensitive instrument to detect subtle neurophysiologic alterations, it might prove to be particularly useful in this matter.

Individuals who are exposed to experimental depletion of the serotonin precursor tryptophan develop acute serotonin deficiency. PSG studies of tryptophan depletion have been carried out in healthy individuals^{83–86} and in psychiatric patients.^{85–88} The bottom line of these studies is that tryptophan depletion is associated with an increase in wakefulness and Stage 1 sleep and with a reduction in Stage 2 sleep. Phasic activity of REM sleep is enhanced.

These PSG patterns are in agreement with the sleep architecture observed in abstinent heavy MDMA users.^{33,34} Prospective PSG studies are needed in order to investigate preexisting differences in sleep architecture between consequent

MDMA users and non-user controls. Such prospective studies would also be capable of determining to what extent restitution occurs with prolonged abstinence. To this end, ecstasy users and controls would need to be followed up over a period of several years. Furthermore, it should be determined whether PSG abnormalities correlate with other presumed evidence of MDMA neurotoxicity such as PET examinations using serotonin transporter ligands.²⁹

There is evidence that the sedative properties of marijuana may be of use in clinical practice. An open pilot study demonstrated the effectiveness and tolerability of THC for the treatment of agitated behavior at night in patients with severe dementia.⁸⁹ Nocturnal motor activity was reduced by 59% from baseline, as evidenced by wrist actigraphy. Other parameters such as appetite disturbances and irritability improved as well. No adverse effects were observed after single and repeated administrations of THC. A systematic review found that atypical antipsychotics often fail to reduce behavioral symptoms of dementia.⁹⁰ Adverse effects occur frequently.⁹⁰ For safety concerns, co-administration of benzodiazepines is not recommended.⁹¹ The limitations of the available treatment options warrant the search for effective and well-tolerated alternatives. Randomized controlled trials with large sample sizes and longer treatment periods are needed in order to corroborate the preliminary findings for THC.

Cannabis-based medicines have also been shown to improve subjective sleep quality in patients with chronic pain syndromes, such as multiple sclerosis, peripheral neuropathy, rheumatoid arthritis and cancer pain.⁹² To a great extent, this improvement may be due to analgesic, anti-inflammatory and spasmolytic effects³⁶ resulting in nocturnal symptom relief, in addition to the hypnotic properties of cannabis.

Practice points

1. Consider and routinely investigate the possibility that complaints of sleep disturbances may be related to use of illicit drugs, especially in younger patients.
2. In cocaine- or cannabis-dependent individuals, sleep disturbances including unpleasant dreams constitute important withdrawal symptoms and their treatment needs to be incorporated into the overall treatment plan.

3. Even if subjective assessments suggest normal or only slightly disturbed sleep during subacute cocaine withdrawal, PSG parameters may reveal considerable sleep disturbance. This sleep disturbance contributes to a deterioration of cognitive performance.

Research agenda

1. Prospective studies on the predictive value of sleep disturbances during cocaine and cannabis withdrawal for long-term outcome.
2. Randomized controlled trials of cocaine withdrawal investigating the effect of GABA-medications and stimulant substances (e.g. modafinil) upon objective sleep measures, cognitive performance and treatment outcome.
3. Prospective PSG studies of ecstasy use, in order to investigate preexisting differences in sleep patterns and to detect to what extent restitution occurs with continued abstinence.
4. Randomized controlled trials of THC for treatment of selected types of sleep disturbances such as circadian rhythm disturbances in patients with dementia.

Abstract

Background—The use of cannabis for medical purposes is proliferating in the U.S., and PTSD is an explicitly approved condition for accessing medical cannabis in 5 states. Prior research suggests that people with PTSD often use cannabis to help cope with their condition, and that doing so results in more frequent and problematic cannabis use patterns. Specific coping motivations, such as sleep improvement, among medical cannabis users, have not been examined.

Methods—The present study evaluated specific coping use motivations, frequency of cannabis and alcohol use, and mental health among a convenience sample of patients (N=170) at a medical cannabis dispensary in California.

Results—Those with high PTSD scores were more likely to use cannabis to improve sleep, and for coping reasons more generally, compared with those with low PTSD scores. Cannabis use frequency was greater among those with high PTSD scores who used for sleep promoting purposes compared with those with low PTSD scores or those who did not use for sleep promoting purposes.

Conclusions—Consistent with prior research, this study found increased rates of coping-oriented use of cannabis and greater frequency of cannabis use among medical users with high PTSD scores compared with low PTSD scores. In addition, sleep improvement appears to be a

Contributors Dr. Bonn-Miller designed the study and wrote the protocol. Drs. Bonn-Miller and Vandrey managed the literature searches and summaries of previous related work. Dr. Babson undertook the statistical analysis, method, and results. Dr. Bonn-Miller wrote the first draft of the manuscript. Dr. Vandrey provided editing and revisions to drafts. All authors contributed to and have approved the final manuscript.

Conflict of Interest All authors declare that they have no conflicts of interest.

primary motivator for coping-oriented use. Additional research is needed to examine the health consequences of this pattern of cannabis use and whether alternative sleep promoting interventions (e.g. CBT-I) could reduce the reliance on cannabis for adequate sleep among those with PTSD.

Keywords

cannabis; coping; medical marijuana; PTSD; sleep

1. INTRODUCTION

Cannabis is the most widely used illicit substance in the United States (SAMHSA, 2012) and the legalization of cannabis for medicinal purposes has become a growing trend. The approved conditions for which cannabis may be doctor-recommended varies at the state level, but most states allow medical use of cannabis for certain medical disorders/problems (e.g., cancer, severe and chronic pain, HIV/AIDS). The use of medical cannabis for psychological disorders, however, is not as common. Currently, only 5 of 20 states with medical cannabis laws explicitly allow the medical use of cannabis as a treatment for those with posttraumatic stress disorder (PTSD).

Though there has been a general dearth of empirical research speaking to the use and effects of cannabis among those with PTSD, existing evidence suggests that individuals with PTSD, particularly those with heightened hyperarousal symptoms, use cannabis primarily for coping reasons (e.g., Boden et al., 2013; Bonn-Miller et al., 2007a; Passie et al., 2012), and that such coping-oriented use may be associated with heavier and more problematic cannabis use patterns (e.g., dependence), as documented in the general population (Bonn-Miller and Zvolensky, 2009). Following, there has been increasing interest in understanding, among those with PTSD, the specific motives for which cannabis is used. In a study among 20 adult females with PTSD, Bonn-Miller and colleagues (2010) found poor sleep quality to interact with PTSD symptom severity in the prediction of coping-oriented cannabis use. Here, individuals with elevated PTSD symptoms and sleep problems were particularly likely to use cannabis to cope.

Though Bonn-Miller and colleagues (2010) documented the importance of sleep problems in terms of understanding the association between PTSD and coping-oriented cannabis use, little research has been conducted to examine whether specific symptoms of PTSD are being “treated” with cannabis use, and, in particular, whether individuals with PTSD use cannabis specifically to improve sleep, or instead to cope with negative affect more broadly. Here, recent work has demonstrated that specific psychoactive components of cannabis may initially facilitate sleep onset (Russo et al., 2007; Schierenbeck et al., 2008), though long-term and problematic use has been associated with sleep disturbances, including altered sleep architecture (Bolla et al., 2008; Vandrey et al., 2011). Additionally, there has yet to be an investigation of how specific coping motivations are associated with use frequency within this context.

The present study sought to examine (1) the specific cannabis motives that distinguish a medicinal cannabis-using individual with PTSD from an individual without PTSD, and (2) whether the interaction of PTSD and PTSD-specific use motives are associated with more severe use frequency. We hypothesized that medical cannabis users with PTSD would be more likely to report cannabis use specifically to improve sleep, compared to those without PTSD. Further, due to the development of tolerance to the sleep-inducing effects of cannabis (Schierenbeck et al., 2008), as well as prior documented associations between coping-oriented use and heavy cannabis use patterns (Bonn-Miller and Zvolensky, 2009), we hypothesized that those with PTSD who also used for sleep motives would evidence greater

cannabis use frequency. As research has demonstrated that depression and alcohol use are both associated with PTSD (McFarlane, 1998; Shalev et al., 1998) and cannabis use (Bovasso, 2001; Griffin et al., 2002), depressive symptoms and alcohol use were included as covariates.

2. METHOD

2.1 Participants

Study participants (N=217) were adult (18 and over) patients using cannabis obtained from a licensed medical cannabis dispensary in San Francisco, California. Of the participants enrolled in the study, 170 completed the requisite questionnaires and were included in data analyses. The mean age of the sample was 41 years ($SD=15$) and 22% were female. Participants were excluded based on inability to provide written informed consent to participate, and being under 18 years of age. The majority of participants self-identified as Caucasian (67.1%), followed by Black/Non-Hispanic (7.8%), Hispanic (7.8%), Black/Hispanic (3.0%), Asian (3.0%), and “Other” (11.4%). The most common self-reported conditions for which participants sought medical cannabis included anxiety (62.7%), chronic pain (55.6%), stress (47.9%), insomnia (47.9%), and depression (41.4%; see Bonn-Miller et al., 2013 for more complete description).

2.2 Procedure

Patients presenting to the medical cannabis dispensary were provided with the opportunity to participate in the study by research staff. After obtaining written informed consent to participate, interested individuals completed a battery of questionnaires. Research staff debriefed participants upon completion, and participants were entered into 1 of 4 drawings to receive a \$100 prize. Data describing self-reported cannabis use characteristics of this sample have been reported previously (Bonn-Miller et al., 2013). Study procedures were approved by the Stanford University IRB and conducted in accordance with the ethical principles of the Declaration of Helsinki.

2.3 Measures

2.3.1 Posttraumatic Stress—The PTSD Checklist-Civilian Version (PCL-C; Weathers et al., 1993) is a 17-item questionnaire in which respondents indicate presence and severity of symptoms of PTSD, derived from the DSM-IV symptoms for PTSD (APA, 2000). A total score was calculated. Consistent with recommendations among community samples (NCPTSD, 2013), a total score of 30 was used as a cut-off to generate two groups: those without PTSD (PCL score < 30) and those with probable PTSD (PCL score > 30). The PCL-C has excellent psychometric properties (Weathers et al., 1993). Cronbach’s $\alpha = .95$ in the current sample.

2.3.2 Cannabis Use Motives—The Comprehensive Marijuana Motives Questionnaire (CMMQ; Lee et al., 2009) was used to index motives for cannabis use. Participants rate how often they use cannabis for each of 36 reasons on a 5-point Likert-type scale (1 = “Almost Never/Never” to 5 = “Almost Always/Always”). These 36 items comprise 12 different domains (3 reasons/domain) of motives for use including: Enjoyment, Conformity, Coping (e.g., “To forget your problems”), Experimentation, Boredom, Alcohol, Celebration, Altered Perception, Social Anxiety, Low Risk, Sleep (e.g., “To help you sleep”), and Availability. Cronbach’s $\alpha = .74$ for CMMQ subscales in the current sample.

2.3.3 Cannabis Use Frequency—A single item from the Marijuana Smoking History Questionnaire (MSHQ; Bonn-Miller and Zvolensky, 2009) was used to determine past 30-day cannabis use, regardless of use motive (e.g., medicinal). Participants were asked to rate

the frequency of their cannabis use in the past 30 days on a scale of 0 “no use” to 8 “more than once a day.” The MSHQ has performed well in previous research, with convergent validity for the employed frequency item (Bonn-Miller and Zvolensky, 2009; Bonn-Miller et al., 2007b). In the present sample, scores ranged from 2-8 ($M = 7.09$, $SD = 1.37$).

2.3.4 Alcohol Use—The Alcohol Use Disorders Identification Test (AUDIT; Saunders et al., 1993) is a 10-item self-report measure of hazardous and harmful alcohol consumption. A total score is calculated to produce a global measure of problematic alcohol use. Cronbach’s $\alpha = .84$ in the current sample.

2.3.5 Depressive Symptoms—The Inventory of Depression and Anxiety Scale (IDAS; Watson et al., 2007) is a 64-item questionnaire measuring depression and anxiety. The General Depression subscale was employed as a measure of depressive symptoms and used as a covariate. Cronbach’s $\alpha = .84$ in the current sample.

2.4 Data Analysis

First, a series of t-tests were conducted to examine group (no PTSD versus probable PTSD) differences in terms of cannabis use motives. T-tests were adjusted ($p = .01$) for multiple comparisons. Next, we examined the interaction of motive for use (sleep and coping) and group on past 30-day cannabis use. Two separate hierarchical multiple regressions (HMRs) were conducted (one for sleep, one for coping motives) in which past 30-day cannabis use served as the outcome variable. Sleep and coping motives were selected, as these were the only two motives that were found to vary as a function of PTSD symptom levels. All continuous variables were standardized prior to entry. In Step 1, main effects for motive (sleep or coping) and PTSD group were simultaneously entered. In step 2, the interaction between motive (sleep or coping) and PTSD group was entered. In step 3, alcohol use (AUDIT total score) and depressive symptoms (IDAS General Depression sub-score) were entered as covariates. Variables were entered in this fashion to test whether the obtained results remained after adjusting for relevant covariates, while ensuring that interaction effects were not significant merely due to suppression effects of covariates (Simmons et al., 2011).

3. RESULTS

Results of t-tests indicated that individuals with probable PTSD reported greater motivation to use cannabis for sleep and coping reasons compared to those without PTSD. No associations were found between PTSD and any other motives (see Table 1). In the hierarchical regressions (see Table 1), a significant main effect for sleep motives, but not PTSD group, was observed in predicting past 30-day cannabis use. Furthermore, as predicted, the interaction between sleep motives and group was associated with past 30-day cannabis use, accounting for 3% of unique variance. After adjusting for covariates in Step 3, the interaction remained significant with the entire model accounting for 25.2% of variance in past 30-day cannabis use. In terms of coping motives, there was a main effect for coping, but not PTSD group. In addition, the interaction of PTSD group and coping was non-significant.

Consistent with recommendations for examining interactions (Aiken and West, 1991), post-hoc probing of the significant interaction indicated that sleep motives was positively associated with past 30-day cannabis use among individuals with probable PTSD, but not among individuals without PTSD (see Figure 1).

Analyses were also run using a continuous index of PTSD symptoms (total PCL score). Results remained consistent. A significant interaction of sleep motive and PTSD symptoms

emerged both before, $\beta = .70, p = .008$, and after, $\beta = .69, p = .009$, accounting for covariates. In addition, analyses related to coping motives still yielded a non-significant interaction, $\beta = -.07, p = .80$.

4. DISCUSSION

The present study sought to extend prior work by determining motivation for cannabis use among individuals who report elevated PTSD symptoms and use medical cannabis. First, the present study replicated prior work (e.g., Bonn-Miller et al., 2007a; 2013) by documenting that individuals with probable PTSD used cannabis for negative affect reduction (i.e., coping motives). Consistent with hypotheses, the present study also provided the first empirical evidence for cannabis use for sleep reasons among those with probable PTSD, with these two motives (i.e., coping, sleep) being the only motives observed to differ between those with probable PTSD and those without.

Also consistent with expectation, PTSD group was found to interact with sleep motives in terms of cannabis use frequency. These findings extend prior work that documented an interactive relation between PTSD symptoms and sleep problems in terms of coping motives (Bonn-Miller et al., 2010) by showing that those with probable PTSD (and those with greater PTSD symptom severity) who used cannabis to improve sleep reported more frequent cannabis use. Indeed, no association was observed between sleep motives and use frequency among the non-PTSD group. Though coping-oriented use was elevated among those with probable PTSD, no interaction was observed for frequency of cannabis use, providing strong evidence for the uniqueness of the association between PTSD symptoms and sleep motives in terms of cannabis use frequency. Finally, all of the aforementioned associations were observed above and beyond co-occurring alcohol problems and depressive symptoms, and among a sample of medicinal cannabis users, a group heretofore unexamined in terms of PTSD and associated use motivation.

Though the present study provides strong empirical evidence for the unique role of sleep-motivated cannabis use among medicinal cannabis users with probable PTSD, it is not without limitation. First, the present study was cross-sectional in nature. Additionally, it was conducted within one cannabis dispensary in San Francisco, and the sample was primarily male. So as to improve our understanding of the observed associations and generalizability of findings, future work should employ prospective assessment among samples more representative of the medicinal cannabis using population. Another limitation of the present study was that no interview-based or objective measures were employed (all data were self-report). Though the employed measures were well validated and have been used extensively in prior literature, future work would benefit from including biochemical verification of cannabis use status as well as behavioral (e.g., cue exposure) and/or interview-based (e.g., Clinician Administered PTSD Scale; Blake et al., 1995) measures of PTSD status and symptomatology.

Limitations notwithstanding, the present study provides empirical evidence to suggest that individuals with high levels of PTSD symptoms use medicinal cannabis for coping and sleep motives, and that sleep-motivated use, specifically, is associated with more frequent cannabis use. Interventions shown to improve sleep quality (e.g., Cognitive Behavioral Therapy for Insomnia; Morin et al., 2006) may be useful in terms of providing an alternative to cannabis for individuals with PTSD who are reporting significant difficulties with sleep. It is unknown whether the high rate of cannabis use among this sub-population is associated with adverse health outcomes relative to those with PTSD who do not use cannabis.

Acknowledgments

Role of Funding Source. Funding for this study was provided by A VA Clinical Science Research and Development (CSR&D) Career Development Award-2 (Bonn-Miller), a donation from the San Francisco Patient and Resource Center (Bonn-Miller), Health Services Research and Development Service funds (Babson), and a grant from the National Institute on Drug Abuse (U01-DA031784; Vandrey). The funding sources had no further role in study design; in the collection, analysis and interpretation of data; in the writing of the report; or in the decision to submit the paper for publication.

An Analysis of Applicants Presenting to a Medical Marijuana Specialty Practice in California

Helen Nunberg, MD, MPH, Beau Kilmer, PhD, Rosalie Liccardo Pacula, PhD, and James Burgdorf

Abstract

For more than a decade, medical marijuana has been at the forefront of the marijuana policy debate in the United States. Fourteen states allow physicians to recommend marijuana or provide a legal defense for patients and physicians if prosecuted in state courts; however, little is known about those individuals using marijuana for medicinal purposes and the symptoms they use it for. This study provides descriptive information from 1,655 patients seeking a physician's recommendation for medical marijuana, the conditions for which they seek treatment, and the diagnoses made by the physicians. It conducts a systematic analysis of physician records and patient questionnaires obtained from consecutive patients being seen during a three month period at nine medical marijuana evaluation clinics belonging to a select medical group operating throughout the State of California. While this study is not representative of all medical marijuana users in California, it provides novel insights about an important population being affected by this policy.

I. INTRODUCTION

As of December 2010, 15 states and the District of Columbia provide allowances for medical marijuana (National Conference of State Legislatures, 2010).¹ There is a small literature about whether these laws influence the overall demand for marijuana (Gorman and Charles, 2007; Pacula et al., 2010), and a tremendous amount of discussion about how medicinal marijuana is distributed, especially in California (see e.g., Hoeffel, 2010a; 2010b). What remains largely missing from the literature and policy discussions is a good understanding of the individuals who seek a medical allowance for marijuana.

This paper helps fill this gap by systematically evaluating the characteristics, ailments, and medical histories of a large group of applicants seeking a medicinal marijuana recommendation. Data are collected from medical charts and doctor interviews with 1,655 individuals seen in June, July and August of 2006 from nine medical marijuana specialty practices dispersed throughout California. The results provide some interesting insights as to the characteristics of those seeking medicinal allowances nearly a decade after the policy was introduced in California.

The remainder of this paper is organized as follows. In Section 2 we briefly review the literature on the therapeutic value of cannabinoids, provide details of the specific allowances provided for within California state law, and review previously published surveys of populations of medical marijuana users. In Section 3 we discuss the methods that were used in the current study, including our data collection procedures, and in Section 4 we present

¹This excludes Maryland. While Maryland does allow those arrested for marijuana possession to use a medical necessity defense, those found to be using for medical purposes are still convicted and can be fined up to \$100.

our results. A general discussion of these findings and the limitations of our study are presented in Section 5.

II. BACKGROUND AND LITERATURE REVIEW

Research on the therapeutic value of cannabinoids

Cannabinoids are compounds related to tetrahydrocannabinol (THC) found in the cannabis plant (phytocannabinoids), in animals (endocannabinoids), and synthesized in laboratories (e.g., THC analogues, cannabinoid receptor agonists and antagonists) (Pertwee, 2006). Cannabinoid receptors are found in all animals; in humans, cannabinoid receptors are concentrated in the brain but are also found in other parts of the body.

The use of cannabis as a medicine originated thousands of years ago. After being introduced to the West in the mid-nineteenth century, cannabis-based medicines were popular through the early decades of the twentieth century (Grinspoon, 2005; Zuardi, 2006). The virtual disappearance of cannabis-based medicines by the mid-1900s was due to the introduction of new pharmaceuticals (e.g., aspirin, chloral hydrate, barbiturates) for the same conditions, such as pain, migraines, menstrual cramps, and sedation, as well as the legal restrictions associated with the 1937 Marijuana Tax Act (Fankhauser, 2002; Grinspoon).

The Institute of Medicine's (IOM) 1999 report *Marijuana and Medicine: Assessing the Science Base*, concluded that "Scientific data indicate the potential therapeutic value of cannabinoid drugs, primarily THC, for pain relief, control of nausea and vomiting, and appetite stimulation; smoked marijuana, however, is a crude THC delivery system that also delivers harmful substances" (4). The report further noted that, "For the most part, the logical categories for the medical use of marijuana are not based on particular diseases but on symptoms...[that] can be caused by various diseases or even by treatments for diseases" (IOM, 1999; pp. 137–138). Based on these findings, the panel recommended that "clinical trials of cannabinoid drugs for symptom management should be conducted with the goal of developing rapid-onset, reliable, and safe delivery systems" (4). In addition to focusing on pain relief, control of nausea and vomiting, and appetite stimulation, the IOM report also called recommended that clinical trials focus on the suitability of cannabinoid drugs to address anxiety reduction and sedation.

Reviews published since the IOM report also highlight the potential therapeutic value of cannabinoid drugs; however, few of the studies focus on inhaled marijuana. A review of 72 randomized, double-blind, placebo-controlled studies from 1975 to 2004 evaluating the therapeutic effects of cannabinoids concludes that "Cannabinoids present an interesting therapeutic potential as antiemetics, appetite stimulants in debilitating diseases (cancer and AIDS), analgesics, and in the treatment of multiple sclerosis, spinal cord injuries, Tourette's syndrome, epilepsy and glaucoma" (Ben Amar, 2006). A more recent review focusing on clinical studies published from 2005 to 2009 (Hazekamp and Grotenhermen, 2010) concluded that cannabinoids have "therapeutic potential mainly as analgesics in chronic neuropathic pain, appetite stimulants in debilitating diseases (cancer and AIDS), as well as in the treatment of multiple sclerosis." For both reviews, a minority of the trials evaluated inhaled marijuana (six and eight studies, respectively). The others used a synthetic THC isomer or analog for oral administration, or plant extract in oral or sublingual preparations.²

²Hazekamp and Grotenhermen included recent studies of nabilone, a prescription drug that is a THC analog. Skrabek et al. (2008) performed a randomized, controlled trial to assess the benefit of nabilone on pain reduction and quality of life improvement in patients with fibromyalgia. They found significant decreases in pain and anxiety. Similarly, Ware et al. (2010) concluded that nabilone "is effective in improving sleep in patients with fibromyalgia and is well tolerated." Finally, in a more recent observational study (Bestard and Toth, 2010), nabilone was found to be as effective as gabapentin, a first line medication for peripheral neuropathy, in measures of pain, sleep, depression and anxiety.

In February 2010, the Center for Medicinal Cannabis Research (CMCR) at the University of California San Diego submitted a report to the Legislature and Governor of California describing five completed clinical trials with inhaled marijuana (Grant et al., 2010). Four demonstrated pain relief effects in conditions secondary to injury or disease of the nervous system (Abrams et al., 2007; Wallace et al., 2007; Wilsey et al., 2008; Ellis et al., 2009), and one suggested a reduction of spasticity in multiple sclerosis (Corey-Bloom et al., 2008).

Medicinal Marijuana in California

In California, patients with a physician's recommendation, along with their designated caregivers and recommending physicians, are exempted from state criminal laws against marijuana. Although provision and use remain illegal under federal law, U.S. Attorney General Eric Holder made a statement in March 2009 suggesting that the federal government would not target those who complied with state medical marijuana laws. This was made more official in an October 2009 memo to U.S. Attorneys which noted that: "As a general matter, pursuit of these priorities should not focus federal resources in your States on individuals whose actions are in clear and unambiguous compliance with existing state laws providing for the medical use of marijuana."

The California medical marijuana law, passed through voter referendum (Proposition 215) in 1996, permits the use of marijuana for "cancer, anorexia, AIDS, chronic pain, spasticity, glaucoma, arthritis, migraine, *or any other illness for which marijuana provides relief*" [emphasis added]. California Senate Bill 420, signed into law on October 12, 2003, named additional ailments such as severe nausea, cachexia, seizures, and persistent muscle spasms (regardless of whether they are associated with multiple sclerosis). In an effort to provide better guidance to law enforcement agencies, SB 420 allowed patients and primary caregivers to possess up to six mature plants (or 12 immature plants) and eight ounces of marijuana; however, it granted local governments the authority to establish larger maximum quantities.

Many of the early studies about medicinal marijuana users in California focused on individuals with HIV or AIDS (e.g., Harris et al., 2000; Sidney, 2001; de Jong et al., 2005; Prentiss et al., 2004). Based on analyses of several unpublished surveys of clients entering cannabis buyer clubs in the San Francisco Bay Area, Gieringer (2002) found that the share of clients that were AIDS and cancer patients declined after the passage of Proposition 215. More recent research in California shows that medicinal marijuana patients are largely men who present with pain and/or emotional/mental health concerns (O'Connell and Bou-Matar, 2007; Reiman, 2007; Reiman, 2009). An informal survey of several California medical marijuana specialty physicians revealed that more than 95% of the patients of each physician were already "self-medicating" prior to the receipt of their recommendation, leading Mikuriya et al. (2007) to conclude that the physicians were really "approving" the medical use of marijuana as opposed to "recommending" it.

III. DATA AND METHODS

The data used in this study come from medical records of 1,745 applicants consecutively presenting to one of nine MediCann clinics located in large and small cities throughout California.³ The sample is based on visits in June, July, and August 2006, roughly ten years after the original law was enacted. Medical charts were reviewed and data entered within a few weeks of the visit. Our final sample excludes 90 individuals who are either missing diagnosis information (N=35) or did not report using marijuana before seeking a

³Since 2006, MediCann has expanded to 21 locations throughout California.

recommendation (N=55).⁴ There are no statistically significant differences in terms of age, race/ethnicity, and gender between those included and excluded in the analysis sample.

We drew on consecutive visits from all nine clinics in hopes of approximating a representative sample of applicants seeking recommendations at these medical marijuana specialty practices. The sample is not generalizable to all individuals applying for a medical marijuana recommendation as it only represents those individuals selecting this particular network of physicians.

In general, the MediCann policy was to provide a 12-month recommendation to those with an acceptable medical condition who had supporting medical record documentation.⁵ Those without medical record documentation received a provisional three-month recommendation conditional upon them providing the MediCann physician with a copy of the relevant supporting medical record, or, if not currently under the care of a medical professional, seeking care and providing those records. Applicants were only denied if they did not report having an eligible medical condition or if they refused to be under the care of a medical professional. For our sample the denial rate was less than 2%.

MediCann's medical records include two standard forms specifically created for MediCann. One form is filled out by the applicant and includes demographic information, medical history, and marijuana use history. The second form is filled out by the evaluating physician and contains clinical information related to the health problem and symptoms for which the applicant is seeking help. Clinic physicians relied on medical histories, physical exams, and the supporting medical documents when they assigned diagnoses. The supporting medical documents included laboratory and radiological evaluations to validate applicant claims of use of marijuana for relief of symptoms due to a medical condition. Over two-thirds of applicants (67.8%) brought medical record documentation with them at the time of the visits analyzed in our study.

In light of the limited information on this population of interest, we examine simple means or sample proportions for several variables of interest, including patient characteristics and stated therapeutic needs, physician diagnoses, and medical history. Results are provided for the entire sample and then broken down by gender.

IV. RESULTS

Applicant Characteristics

Applicant demographic information is shown in Table 1 both for the full sample and by gender, since almost 73% of the applicants seeking a recommendation were male. This is not much different than the share of those in the 2006 National Household Survey on Drug Use and Health who reported purchasing marijuana in the previous month (70%). Female applicants seeking recommendations were, on average, older and more likely than men to be African American, have some college education, have Medicaid (MediCal) health insurance, or to be unemployed and disabled (19.5% of women reported being unemployed due to disability). In general, those seeking recommendations were insured (73.0% currently insured, of whom 24.2% were covered through Medicare or Medicaid), have at least a high school degree (only 8.8% have less than a high school degree), and are generally employed (68.7%).

⁴While in many ways the applicants who report not using marijuana prior to seeking this recommendation are perhaps the most interesting, there are an insufficient number of these individuals in our sample for robust comparisons.

⁵Qualifying patients would be given a recommendation and would be reassessed periodically to review the course of treatment and any new information about their health, as well as to monitor response to treatment as indicated by a decrease in symptoms, an increase in level of function, or an improvement in quality of life.

As for the age distribution, at least half of the population seeking medical recommendations through this physician group was over the age of 35. For comparison, the median age for those 18 and older in the 2006 NSDUH who reported purchasing marijuana in the previous month was in the 26–29 year old category (those over 21 are placed into age categories).

Applicants' Self Reports of the Therapeutic Benefits of Marijuana

In light of the IOM's argument that the "logical categories for the medical use of marijuana are not based on particular diseases but on symptoms (IOM; pp. 137–138), we examined the self-reported therapeutic benefit received from marijuana and the symptoms it helped relieve. Applicants were asked "Which of the following best describe the therapeutic benefit you receive from medicinal cannabis? (Check the most important reasons you use cannabis.)" The results are presented in Table 2.

Applicants most frequently reported using medical marijuana for pain relief (82.6%), improved sleep (70.6%), and relaxation (55.6%). The next most frequently reported benefits included relief of muscle spasms (41.3%), headache (40.8%), relief of anxiety (38.1%), improved appetite (38.0%), relief of nausea and vomiting (27.7%), and relief of depression (26.1%). Half the applicants (50.8%) reported using marijuana as a substitute for prescription medication and 13.2% reported using marijuana as a substitute for alcohol.

Interestingly, women were statistically more likely than men to report that they used marijuana to relieve most of the indications listed, including headaches, anxiety, nausea, depression, panic, and medication side-effects. The only indication for which men were more likely than women to report use of marijuana was to help with focus. One in four men reported that marijuana improved focus.

Physician Diagnosis

Table 3 presents the highest frequency diagnoses and the diagnoses specifically listed in the Compassionate Use Act. Recall that treating physicians make their diagnoses based on a review of applicant's history, the medical records from treating physicians (in two-thirds of the cases), and on their own physical examination. Evaluating physicians were then asked to "circle only diagnoses related to patient's medicinal marijuana use" from a list of 162 diagnoses.

In general, chronic pain disorders were the most common diagnoses made by physicians, with nearly 60 percent (58.2%) of applicants being diagnosed with some sort of musculoskeletal or neuropathic chronic pain condition. Low back pain was diagnosed for over one quarter (26.2%) of patients seen during this three month period, with lumbar and cervical degenerative disc disease (together 21.8%) and arthritis (18%) the next most common diagnoses in the chronic pain group. Mental health disorders were the next largest group of diagnoses made (22.9%), followed closely by sleep disorders (21.3%). Diagnoses in the grouping "neurological disorders," including migraine and other headache, were made in 16.6% of applicants. Only 3% of the applicants were diagnosed with either cancer or HIV/AIDS.

Previous Treatments and Physician's Recommendations for Additional Treatment

Because self-reported information was collected from applicants and most provided medical documentation from their treating physician that could be reviewed by the evaluating physician, it was possible to consider the extent to which previous therapies had been used to cope with or treat the primary symptoms for which they were seeking a medical allowance. In Table 4 we provide a list of therapies or approaches that were previously tried or currently being used. Almost half of the applicants (47.6%) reported taking prescription

medication at the time of their evaluation, and nearly 4 out of 5 (79.5%) reported having taken prescription medication in the past for their problems. As chronic pain was the leading diagnosis for which marijuana was being recommended, we were curious to see what percent of applicants had used opioids or opiate medication to deal with their problem. On the physician evaluation form, evaluating physicians were asked to check yes or no if the applicant was currently using or had used in the past opioids or opiate medication prescribed by another physician for their chronic pain. Evaluating physicians determined that almost half of all applicants (48.0%) experiencing chronic pain either currently or in the past had been prescribed opioids or opiate medication.

Non-prescription therapies tried by applicants seeking medicinal marijuana allowances included physical therapy (48.6%), chiropractic services (37.2%), surgery (21.9%), psychological counseling (20.7%), and acupuncture (19.6%). Thus, these data do not suggest that applicants immediately seek marijuana recommendations as the first strategy to deal with their symptoms. In many cases, these individuals tried more traditional forms of medicine.

V. DISCUSSION

This study provides descriptive information from 1,655 applicants seeking a physician's recommendation for medical marijuana in California, the conditions for which they sought treatment, and the diagnoses made by the physicians. The most common diagnoses reported were for chronic pain, mental health conditions (primarily anxiety and depression), and sleep disorders (insomnia). For physicians who make medical marijuana recommendations, the risk of being deceived is not dissimilar to the risk of deception faced by those who prescribe oxycodone and other painkillers; however, those prescribing the latter can limit the number of pills and refills.⁶ For medical marijuana, existing laws and policies only allow physicians to distribute recommendations, they cannot control the number of purchases, what is purchased (e.g., % THC or other cannabinoid content), where it is purchased, or the route of administration (e.g., inhale smoke or vapor, ingest an edible, apply topically).

The majority of applicants reported that they tried other therapies, including prescription drugs, to manage their symptoms prior to seeking the medicinal allowance. Fifty percent of the sample reported that they used marijuana as a substitute for prescription medicine. This is consistent with other studies (e.g., Reiman, 2007; 2009) and raises important questions about the specific drugs they are replacing. Future research with this population should focus on previous and concurrent prescription medication use to examine claims that marijuana enables people to reduce or eliminate their use of prescription medications. These data could also be useful for understanding whether there could be cost-savings associated with substituting certain prescription medicines with marijuana.

This also raises the issue about whether the legalization of marijuana for non-medicinal purposes would influence the consumption of prescription drugs. Not only would legalization increase availability and reduce the price of marijuana (Kilmer et al., 2010), but the reduced stigma may increase the likelihood that some individuals try it for medicinal purposes. It could also be the case that doctors may be more willing to discuss marijuana use with patients if it was not prohibited.

Less than 5% of the applicants in our sample were diagnosed with HIV/AIDS, cancer, or glaucoma. While these were not the only diseases/conditions discussed when Proposition

⁶However, doctors prescribing oxycodone cannot prevent patients from crushing the pill to deactivate the time-release functionality and then snorting or injecting it.

215 was on the ballot, they did receive a lot of attention. This is not surprising; we would expect the number of applicants presenting with HIV/AIDS, cancer, or glaucoma to be relatively low compared to the number presenting with pain, anxiety, and insomnia, due to the relative prevalence of these conditions in the general population. However, it is also important to note that many of those receiving recommendations did so for conditions other than those listed by the IOM (pain relief, control of nausea and vomiting, and appetite stimulation).

Finally, the age profile observed in the sample of applicants is intriguing, especially when compared with those who report purchasing marijuana in the previous month in the 2006 NSDUH. One should not assume the larger median age for these applicants is statistically meaningful in light of the potential non-representativeness of our sample and the fact that it is drawn exclusively from California. However, if these age differences appear in future studies, it could offer important insights about age-related risk aversion and/or age-specific access to distribution networks—each with different policy implications. Thus, future work should explore the robustness of these differences and consider their implications for policy.

We conclude by reminding readers that we did not examine randomly-selected representative sample of all individuals in California seeking a medical recommendation for the use of marijuana. We were merely able to collect data from a sample of individuals who presented themselves within a three month window to a group of doctors that they most likely expected would be willing to provide them with a recommendation. The applicants receiving recommendations from these doctors may differ from those in the general population in important ways that we are unable to know. As applicants receiving physician recommendations are not required by law to register with county or state health officials, we have no way of knowing the extent to which the population served by this particular physician group might differ from that served by other medical marijuana specialists or by primary care physicians. Knowledge about the number and type of individuals that receive recommendations from other specialists or from primary care physicians would improve our understanding medical marijuana users in California.

Since California law allows for medical marijuana use for any “illness for which marijuana provides relief,” we have an enormous opportunity to further our understanding of the risks and benefits of marijuana with careful questioning of some of the thousands of patients willing to discuss their use of marijuana. Detailed information about the doses, frequency, methods, and forms of marijuana consumed, as well as information about past and present alcohol, illicit drug, and prescription drug consumption would be of great interest.

Use and effects of cannabinoids in military veterans with posttraumatic stress disorder

KEVIN BETTHAUSER, JEFFREY PILZ, AND LAURA E. VOLLMER

Cannabis and its synthetic derivatives are commonly used around the world to treat a variety of disease states.¹ However, controversy continues to surround cannabis and cannabinoid use as a primary or adjunctive therapy in the treatment of stress disorders. Conflicting results of published studies further blur the distinction between cannabis as a potentially beneficial alternative to conventional pharmacotherapy and behavioral therapies and cannabis as a substance that might worsen patient outcomes when used for self-medication.²⁻⁵ This article reviews published evidence regarding the use of cannabis to address symptoms of posttraumatic stress disorder (PTSD) among military veterans.

PTSD prevalence and pathophysiology

Prevalence. PTSD is defined as chronic activation of the stress response as a result of experiencing a traumatic event.^{6,7} It has been estimated that 60% of male and 50% of female persons will experience at least one traumatic experience in their lifetime, with a high rate of

Purpose. Published evidence regarding the use of cannabis and cannabis derivatives by military veterans with posttraumatic stress disorder (PTSD) is reviewed.

Summary. When inhaled or delivered orally or transdermally, cannabinoids (the psychoactive components of unrefined marijuana and various derivative products) activate endogenous cannabinoid receptors, modulating neurotransmitter release and producing a wide range of central nervous system effects, including increased pleasure and alteration of memory processes. Those effects provide a pharmacologic rationale for the use of cannabinoids to manage the three core PTSD symptom clusters: reexperiencing, avoidance and numbing, and hyperarousal. A literature search identified 11 articles pertaining to cannabis use by military veterans who met standard diagnostic criteria for PTSD. Cross-sectional studies have found a direct correlation between more severe PTSD symptomatology and increased motiva-

tion to use cannabis for coping purposes, especially among patients with difficulties in emotional regulation or stress tolerance. Data from 4 small studies suggested that cannabinoid use was associated with global improvements in PTSD symptoms or amelioration of specific PTSD symptoms such as insomnia and nightmares. Large well-designed controlled trials are needed in order to better delineate the potential role of cannabinoids as an adjunct or alternative to conventional approaches to PTSD management.

Conclusion. While further research into cannabinoid treatment effects on PTSD symptoms is required, the evaluated evidence indicates that substantial numbers of military veterans with PTSD use cannabis or derivative products to control PTSD symptoms, with some patients reporting benefits in terms of reduced anxiety and insomnia and improved coping ability.

dom and Enduring Freedom, 10% of veterans of the Persian Gulf War, and 30% of those serving during the Vietnam War have had PTSD symptoms to varying degrees.

Furthermore, patients with PTSD are at risk for other psychological disorders, including but not limited to generalized anxiety disorder, major depressive disorder, and substance use disorder, and for physical problems such as chronic pain, hypertension, and asthma.⁶

Diagnosis. PTSD symptoms are often grouped into three subgroups defined by *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)*, criteria and often assessed in veterans using the PTSD Checklist—Military Version (PCL-M): reexperiencing (also termed intrusion), avoidance and numbing, and hyperarousal.^{9,10} Reexperiencing refers to the cluster of PTSD symptoms associated with flashbacks and vividly reliving the traumatic experience. Avoidance–numbing symptoms are those that involve the patient trying to avoid emotional feelings; such behavior disrupts personal relationships. Finally, hyperarousal symptoms include irritability, difficulty concentrating, increased worrying about safety, and reduced tolerance to startling stimuli.¹⁰ PTSD diagnosis is based on patients experiencing these symptoms for at least one month to a degree that interferes with activities of daily living or reduces quality of life.

Pathophysiology. The pathophysiology of these symptoms, while not fully understood, is thought to

be related to increased sympathetic nervous system activity due to a traumatic experience compounded by changes in memory processing. Physical manifestations of PTSD are linked to increased levels of norepinephrine but also activity at α_2 -adrenergic receptors, which counteractively impede the release of neurotransmitters from adrenergic presynaptic neurons.⁶ Alteration in memory processing is hypothesized by several sources to be the cause of psychological reliving and continued response to triggering stimuli.^{6,10,11} Involved in central processing of fear and anxiety processes as well as sympathomimetic stimulation, the amygdala and hypothalamic structures are thought to be key components of PTSD symptomatology, although their roles are not fully understood.^{10,12}

The changes in memory function associated with PTSD differ from those seen in other forms of stress.¹³ The significant difference is the lack of increased cortisol levels in persons with PTSD. One group of researchers hypothesized that the changes in neural functioning seen in patients with PTSD reduce the ability to remove traumatic memories and the remembered response to those stimuli.¹¹

Cannabinoid pharmacology

Endogenous cannabinoid ligands, or endocannabinoids, exist naturally in the body to stimulate activity at cannabinoid receptors. Drugs delivering cannabinoid compounds also activate these receptors. Specifically, cannabinoid-1 (CB-1) and cannabinoid-2 (CB-2) G-coupled protein receptors are activated by cannabis compounds, leading to the production of secondary messengers that modulate the release of neurotransmitters from presynaptic sites through both excitatory and inhibitory actions.¹⁴ CB-1 receptors are diffusely distributed within the central nervous system, which helps to explain the wide range of effects seen

with cannabinoid receptor activation; CB-1 receptors are the primary target for modification of PTSD symptoms. With cannabinoid use, pleasure is increased, while memory and concentration can be inhibited, due to the release of acetylcholine, norepinephrine, dopamine, serotonin, and glutamate neurotransmitters. CB-2 receptors are concentrated in the peripheral nervous system and elicit immunosuppressive and antiinflammatory responses when activated. Cannabinoids are highly lipophilic compounds that rapidly cross lipid membranes and the blood-brain barrier, leading to a fast onset of effect, especially when cannabinoids are inhaled. In murine models, it was demonstrated that correcting a deficiency of endogenous cannabinoids enabled mice subjected to traumatic shock treatments to overcome their conditioned response by allowing removal of the harmful stress-inducing memories through inhibition of γ -aminobutyric acid pathways in the amygdala. This mechanism is thought to explain human responses to cannabinoids as well.

Cannabinoid classification and legal status

Perhaps the most known connotation of the term *cannabinoid* to the layperson pertains to marijuana, which can deliver cannabinoids via respiratory, transdermal, and oral routes. Formally, marijuana refers to the unrefined leaves and flowers of *Cannabis sativa*, which contain over 460 active substances and no fewer than 60 cannabinoids.¹⁴ Delta-9-tetrahydrocannabinol (δ -9-THC) is the cannabinoid responsible for the majority of effects seen with marijuana use. The active compounds in marijuana produce the same activity in the messenger systems linked to cannabinoid receptors as that produced by endocannabinoids.

Cannabinoid-containing substances differ in terms of route of administration and active chemical

ingredients. Marijuana and select synthetic cannabinoids are classified by the Drug Enforcement Administration as Schedule I drugs under the Controlled Substances Act of 1970.¹⁵ This is largely due to the effects of δ -9-THC, which causes a “high” sensation and impaired cognition when inhaled or absorbed via the gastrointestinal tract. However, cannabinoids synthesized for specific disease therapies or available in other dosage forms, such as a hard-shell capsule, may be subject to other legal classifications. As of January 2014, 19 states and the District of Columbia allowed medicinal use of cannabis in select patients with certain disease states, most commonly seizure disorders and chronic pain.¹⁴

The addiction potential and stigma of marijuana use are important considerations, and the benefits of cannabinoid therapies for PTSD must be weighed against the associated adverse drug events (some of which can be life-threatening).¹⁴ The purpose of this review is to analyze current relevant literature surrounding the use of cannabis and cannabinoids for PTSD symptom control by military veterans, with the goal of providing insights on whether these treatments improve or worsen patient outcomes.

Methods and results of literature review

During the period February 10–October 1, 2014, a comprehensive literature search covering the period January 1, 1995, to October 1, 2014, was conducted using PubMed (MEDLINE) and Academic Search Complete (EBSCO Industries, Inc., Ipswich, MA). Both Medical Subject Headings (MeSH) terms and the subheadings feature of PubMed were used. Keywords were searched separately in combination with appropriate Boolean operators.

Keywords in searches included *PTSD*, *post traumatic stress disorder*, *medical marijuana*, *cannabis*, *medical cannabis*, *marijuana*, and *combat vet-*

erans (appendix). For the purposes of this review, the term *cannabinoid* was considered to apply to endocannabinoids. On identification of articles that met the inclusion criteria, the references cited therein were analyzed for additional relevant articles not identified in the original keyword and MeSH term searches.

The article/study inclusion criteria that were applied to each item retrieved in the search were as follows:

- Reported outcome(s) related to the general use of cannabinoids among persons with a diagnosis of PTSD associated with military experience or the use of cannabinoids for the amelioration of PTSD symptoms associated with military experience
- Pertained to research in humans
- Was written in the English language
- Pertained to individuals with PTSD diagnosed via a standard scale (e.g., *DSM-IV* or *DSM-5* criteria, Impact of Event Scale—Revised)

Editorials and opinion pieces were excluded from the review.

Each article identified for inclusion in the review was analyzed by the authors individually and collaboratively in order to determine its clinical relevance and relative standing in the realm of data supporting or militating against medicinal cannabis use for PTSD symptoms.

A total of 59 articles were identified through PubMed and the EBSCO database. Pursuant to application of the inclusion and exclusion criteria, 11 articles were included in this review. A variety of study designs were represented in the list of selected articles, and all evaluated research supported two general concepts: (1) many people suffering from PTSD use cannabis for symptom alleviation, and (2) some people find it of benefit in that regard.

Cannabinoids and coping mechanisms

Several studies supported the

relationship between cannabinoid use and coping behavior, with usage tending to increase with PTSD symptom severity.^{2,5,16-18} Bonn-Miller et al.¹⁶ conducted a cross-sectional study that examined the relationship between PTSD symptom severity and motives for marijuana use among 103 young adult marijuana users who reported at least one traumatic event in their lifetime. The study concluded that symptom severity was significantly related to coping-oriented marijuana use motives. Furthermore, levels of post-traumatic stress were not related to other motives for marijuana use, providing evidence of “discriminant validity” (a construct aimed at showing that things that should not be related are, in fact, not related) and empirical evidence of coping motives for marijuana use.

In other research, Bonn-Miller and colleagues⁵ used a cross-sectional study design to examine the correlation between difficulty in emotional regulation and use of cannabis as a coping mechanism in patients who have experienced traumatic life events. The study surveyed a fairly homogeneous sample of adults who reported marijuana use within the previous 30 days. A multitude of surveys were used to determine marijuana use, the presence of PTSD symptoms, and each participant’s level of difficulty with emotional regulation. The investigators found that PTSD symptom severity and difficulty in emotional regulation were both significantly predictive of coping-oriented marijuana use. Furthermore, PTSD symptom severity predicted the degree of difficulty in emotional regulation even when the frequency of marijuana use was controlled.

Bonn-Miller et al.¹⁷ subsequently hypothesized that patients with PTSD using medical marijuana for sleep might increase their use in an attempt to cope with more severe symptoms. As in their previous research, the investigators chose a

cross-sectional study design, evaluating coping-use motivations, cannabis and alcohol use, and other outcomes in a convenience sample of male and female adult patients buying cannabis from a licensed dispensary. Based on PCL-M scores, two groups were formed: patients without PTSD (defined as a PCL-M score of ≤ 30 [$n = 95$]) and patients with PTSD (defined as a score of >30 [$n = 75$]). The study results showed that patients with PTSD had a greater motivation to use cannabis for sleep and coping reasons than the non-PTSD group regardless of comorbid alcoholism or depressive symptoms. This study was limited by its narrow focus on patients who were already using medical marijuana. As the researchers noted, the fact that tolerance to marijuana's sleep-inducing effects can develop seemed inconsistent with the finding that PTSD led to increased use of cannabis.

Potter et al.¹⁸ conducted a cross-sectional study ($n = 142$) of adults in Vermont with PTSD to investigate the role of distress tolerance in relation to PTSD symptom severity and marijuana use. The researchers found that PTSD symptom severity was positively correlated with marijuana-use coping motives ($r = 0.37, p < 0.01$) and negatively correlated with distress tolerance ($r = -0.47, p < 0.01$). Their overall conclusion was that distress tolerance may play a partial role in mediating the relationship between PTSD symptom severity and coping-oriented marijuana use.

Cannabinoids, worsening of PTSD symptoms, and substance abuse

Studies included in this review examined the possible link between cannabis use and worsening of PTSD symptoms or concomitant substance abuse.^{2,19} Bonn-Miller et al.² used a prospective cohort study design to analyze cannabis use in relation to PTSD symptom severity in a population of 432 male military veterans (mean \pm S.D. age, 51 ± 4

years) admitted to a VA residential treatment program for patients with PTSD. Cannabis use four months after the completion of the rehabilitation program was significantly more likely in program participants with lower levels of improvement from intake to discharge in PCL-M scores for avoidance–numbing and hyperarousal symptom clusters ($p < 0.05$). The researchers concluded that lower improvement in PCL-M scores at program completion was significantly predictive of an increased risk of cannabis use within the four months after discharge.

Although this study lacked generalizability (i.e., it involved only patients seen in a VA residential rehabilitation program), it suggested that specific symptoms have more influence than others on PTSD patients' desire to use cannabis. A major limitation of this study was that patients in the rehabilitation program were required to quit marijuana use for the duration of their treatment, but the effect of cannabinoid withdrawal was not included in the analysis. Furthermore, the study involved a nonrandomized sample, raising the possibilities of high subjectivity and bias.

Bremner et al.¹⁹ conducted a similar cross-sectional study of Vietnam War military veterans ($n = 61$) in the northeastern United States. This study aimed to measure the progression of some PTSD symptoms and related alcohol and substance abuse symptoms, as well as the effects of abused substances on those PTSD symptoms. The researchers found that PTSD symptoms were increased among veterans using substances such as alcohol, heroin, cocaine, and marijuana. Further, the study showed that veterans using said substances reported benefits with regard to PTSD symptoms.

Cannabinoids and reduction of PTSD symptoms

Research also has examined the reduction of PTSD symptom sever-

ity after treatment with cannabis products.^{3,4} A study by Mashiah⁴ examined the use of medical cannabis in Israeli military veterans ($n = 29$) with diagnosed chronic PTSD. Study participants were given no more than 100 g of cannabis per month and instructed to smoke the cannabis daily at frequencies and amounts of their own choosing. Patients were reassessed three times throughout one year by their psychiatrists. At each reassessment, the study found that the average total Clinician-Administered PTSD Scale (CAPS) score was reduced relative to previously assessed and baseline scores. However, all patients still met the criteria for moderate-to-severe PTSD. This report did not describe the baseline cannabis-use characteristics of the evaluated patients. Additionally, only 10 participants were reassessed after the second follow-up, with no explanation provided by the study author.

Greer et al.³ performed a chart review–based study of 80 patients with PTSD participating in New Mexico's Medical Cannabis Program. The total CAPS score and CAPS symptom-cluster scores for reexperiencing, avoidance–numbing, and hyperarousal symptoms were significantly reduced ($p < 0.0001$) when patients were using cannabis relative to scores obtained under the no-cannabis condition. Overall, patients reported more than 75% reductions in all three areas of PTSD symptoms while using cannabis. It should be noted that participants in this study had already found cannabis to reduce their PTSD symptoms and, partly for that reason, sought entry into the cannabis program (they also sought to avoid criminal penalties for marijuana possession); as a result, they might have been predisposed to report reduced symptoms. Further, it is possible that subjects exaggerated their PTSD symptoms during initial CAPS assessment in hopes of qualifying for the program. While this study

sheds some light on the possibility of medical cannabis being an effective treatment for PTSD, it lacked a control sample of PTSD sufferers with no prior experience with cannabis and involved a large potential and motives for bias.

Nabilone, a synthetic endocannabinoid receptor agonist, has been studied for potential usefulness in mitigating PTSD symptoms, particularly insomnia and nightmares.^{20,21} Cameron et al.²⁰ conducted a retrospective chart review–based study of patients with mental illness ($n = 104$) who received nabilone while admitted to a correctional and treatment facility in Canada (90% of the patients had PTSD). The researchers looked at indications for nabilone use, effectiveness and safety outcomes, and medications discontinued when cannabinoids were added to patients' regimens. Nabilone was used to treat a mean of 3.5 indications per patient, most commonly nightmares, insomnia, and chronic pain. Improvement in PTSD symptoms was assessed via analysis of scores on the PTSD Checklist—Civilian (PCL-C), which is very similar to the PCL-M, and the Global Assessment of Functioning (GAF). On average, posttreatment PCL-C scores were significantly decreased ($p = 0.001$) from pretreatment scores, allowing many cases initially classified as moderate-severity PTSD to be reclassified as borderline or mild cases; the mean GAF score increased significantly ($p = 0.001$), indicating improved functioning and decreased symptoms. Thirty-one patients reported adverse events during treatment with nabilone, the most serious being psychosis; of those 31 patients, 10 chose to abandon the study. The authors concluded that nabilone can potentially decrease PTSD symptoms, including insomnia and nightmares, in patients with diagnosed cannabis dependence.

Another investigator conducted an open-label clinical trial to

evaluate the effects of nabilone on treatment-resistant nightmares in patients ($n = 47$) with PTSD.²¹ Patients were reviewed after adjunctive treatment with 0.5 mg of nabilone one hour before bedtime. Thirty-four patients (72%) receiving nabilone experienced either cessation of nightmares or a significant reduction in nightmare intensity. The researcher also found subjective improvements in terms of sleep time and daytime flashbacks. The results of the study indicated the potential benefits of nabilone in patients with PTSD experiencing poor control of nightmares with standard pharmacotherapy.

Discussion

All articles evaluated in this review indicated that individuals suffering from PTSD symptoms related to military experiences often use cannabis or cannabinoids as a means of coping, with some reporting benefits. The studies also suggested that the pathogenesis of PTSD—and, most likely, effective treatment—is multifactorial.

Of note, the research described in the reviewed articles was generally limited by the use of small nonrandomized and/or self-selected samples that lacked control groups and carried a high potential for recall bias and type II error. These limitations should be the catalyst for further research through large, randomized, placebo-controlled trials. With growing evidence that patients with PTSD use cannabis and its derivatives as a means of symptom alleviation, it is becoming necessary for the healthcare community to better understand this phenomenon.

There is a growing need for research comparing the effects of cannabinoids with those of conventional pharmacotherapies currently used in PTSD (e.g., prazosin, selective serotonin reuptake inhibitors, second-generation antipsychotics) and cognitive-behavioral therapy. Head-to-head comparisons of the

conventional therapies with cannabinoids are needed in order to demonstrate whether one treatment is superior to another in terms of safety or efficacy. Like cannabinoids, all current pharmacotherapies used for PTSD carry known risks that potentially outweigh benefits from use. With the rising number of veterans returning from recent conflict zones, and a subsequent rise in PTSD cases, the need for quality research in this area is great.

Conclusion

While further research into cannabinoid treatment effects on PTSD symptoms is required, the evaluated evidence indicates that substantial numbers of military veterans with PTSD use cannabis or derivative products to control PTSD symptoms, with some patients reporting benefits in terms of reduced anxiety and insomnia and improved coping ability.

THE USE OF INDIAN HEMP IN THE TREATMENT OF CHRONIC CHLORAL AND CHRONIC OPIUM POISONING.

BY EDWARD A. BIRCH, M.D., M.R.C.P.,

HONORARY MEMBER OF THE CALCUTTA MEDICAL SOCIETY; PHYSICIAN TO THE GENERAL HOSPITAL, CALCUTTA.

IN 1887, at Calcutta, at nearly the same time, I met with two cases, both of them distressing and interesting. The first was that of a European gentleman, who I remembered to have met some two years previously, when he brought his wife from a distant district with a view to placing her under a physician in consequence of her habits as a confirmed chloral drinker. At that time I discovered that she was also a sufferer from valvular cardiac disease; but I need allude no further to her than to state that no power of persuasion or fear of consequences produced any effect. She made no real effort to overcome her vice. When denied her regular dose on two occasions, she became so outrageous, and, in her husband's opinion, so alarmingly ill, that she remained but a few days in town. Her husband then stated that his wife had continued her habit, and that she ultimately died. The object of his visit was, he stated, to consult me about his heart. A very careful examination of that organ enabled me to assure him that it was healthy, though it certainly was in an irritable condition. Thus encouraged, he went on, to my amazement, to tell me that he had followed in his wife's footsteps, that he could not live without chloral, that he was utterly miserable, and that he took about forty grains daily. His depression of spirits he described as being terrible; he had frequently contemplated suicide; insomnia was almost complete, no sleep whatever being obtained without the aid of chloral, and then but little. He could take scarcely any food. The patient was a fresh, healthy-looking man, whose occupation was out-door and health-giving. He neither drank nor smoked. Change of air and scene had proved useless, but then he had never been able to release himself from his habit. I could not ascertain, with any certainty, how long he had been addicted to chloral, but I suspected he commenced it long before his wife's death, though that event was the excuse he offered in extenuation. His organs were healthy, and worked healthily, except the functionally deranged heart. I prescribed a sea trip, a mixture containing tinct. cannabis indica (ten minims), tinct. strophanth., and tinct. chlorof. co., with a bitter infusion, and appealed to him in the strongest language to abandon his vice. Six weeks later he returned, in much the same state, and reported that at first he had improved, but soon became intermittent in the use of his medicine, and he had not given up his chloral. He now agreed voluntarily to place himself under circumstances which admitted of surveillance and restraint. His chloral was peremptorily stopped, and he was prescribed a pill containing half a grain of ext. cannabis ind. with a few grains of the compound colocynth pill, to be taken three times a day. The result was an *immediate* improvement. The craving for the chloral had almost vanished in twenty-four hours, natural sleep returned after a few days, and he began to enjoy his food. Eventually he returned to his home and work, a happy man; but much disappointed because the name of the drug used was not communicated to him.

The second case was briefly this: I was requested by his friends to see a young Eurasian gentleman, whom I found to be a most miserable object, aged about twenty-four years, yellow, intensely anæmic, and extremely emaciated—an "exhumed corpse," in fact, lying upon a couch, suffering acute agony in every limb. His liver and spleen were both materially enlarged. His history was shortly this. Occupying a position of considerable responsibility, and compelled to reside in one of the most desolate and depressing regions of Bengal, he became a confirmed and very excessive spirit drinker, till, fearing the consequences, he resolved to conquer the habit, and he did so most thoroughly, but with the frightful assistance of opium. Laudanum was the form selected, and for at all events four months prior to his coming under my notice he admitted having consumed not less than two ounces daily. His friends, who had only just rescued him from his isolated position, were quite hopeless

of the possibility of recovery. Here there was the well-known train of symptoms—insomnia, anorexia, disordered bowels, conscious delusions, though there was no confusion of ideas in conversation, and so forth. Again I resorted to cannabis, commencing with only a quarter of a grain of the extract, gradually increasing it to half a grain, one grain, and one grain and a half three times a day, with the happiest result. Ability to take food and retain it soon returned, and after a time an appetite appeared; he began to sleep well; his pulse, which could not be counted at first, exhibited some volume; flesh rapidly accumulated; and after three weeks he was able to take a turn upon the verandah with the aid of a stick. After the lapse of six weeks he spoke of returning to his post, and I never saw him again.

I have never before or since had such typical cases of this class to deal with, but I have lost no opportunity of testing the cannabis in the direction indicated as far as possible, and I am satisfied of its immense value. The chief point that struck me was the *immediate* action of the drug in appeasing the appetite for the chloral or opium, and in restoring the ability to appreciate food. It seems to supply the place of the poison, to stimulate the appetite, to increase the heart's power, and thus to procure sleep indirectly, as well as directly, by its own sedative effect. Moreover, I am convinced that it is a diuretic, and that this action helped in the above cases. I prescribed the cannabis simply with a view to utilising a well-known remedy for insomnia, but it did much more than procure sleep. I think it will be found that there need be no fear of peremptorily withdrawing the deleterious drug, if hemp be employed. I know that the mere withdrawal of chloral will effect a cure, but at the expense of an interval of suffering which need not be incurred; and the same in a different degree holds true of opium. Upon one point I would insist—the necessity of concealing the name of the remedial drug from the patient, lest in his endeavour to escape from one form of vice he should fall into another, which can be indulged with facility in any Indian bazaar in the forms of gunjah (the dried flowering tops), churrus (the resinous exudation), bang or subzee (the larger leaves and capsules), or majoon (a compound of bang, butter, and flour). Hence the prescription should be made as complex as possible, and at the earliest moment the dose of the extract should be diminished gradually till eventually it is withdrawn altogether from the prescription.

Calcutta.

A SUCCESSFUL CASE OF PROCTOTOMY FOR MALIGNANT DISEASE.

BY C. STONHAM, F.R.C.S. ENG.,

ASSISTANT SURGEON TO THE WESTMINSTER HOSPITAL.

GEORGE B—, aged sixty-one, a platelayer, came under my care on Jan. 24th, 1887, with the following history. About a year previously he first noticed pain during defecation, with frequent loss of blood. At first he did not attach much importance to these symptoms, but they gradually became more severe and the pain was more or less constant. Latterly he had had frequent attacks of diarrhoea, accompanied by pain of a burning character. There had not been any irritability of the bladder or any difficulty in micturition. The patient had always been a spare man, weighing at this time 10st.; he did not think he had lost flesh lately. Family history good.

State on admission.—About one inch from the margin of the anus there was a hard nodulated mass extending all round the circumference of the gut, and upwards for about two inches, the finger just reaching its upper limit, but when coughing the whole growth slipped over the finger like a ring. The edge of the mass was rounded. There was no involvement of surrounding parts, the whole gut being freely movable. Examination caused considerable hæmorrhage. The patient said that he felt in perfect health, and was merely seeking relief from the constant local annoyance.

Operation.—On Jan. 29th, the patient's bowels having been previously thoroughly opened by castor oil and enemata, about fifteen ounces of warm boracic acid lotion

Cannabis for chronic pain: Case series and implications for clinicians

Mark A Ware MBBS MRCP(UK) MSc¹, Ann Gamsa PhD¹, Jan Persson MD PhD²,
Mary-Ann Fitzcharles MD FRCPC¹

MA Ware, A Gamsa, J Persson, M-A Fitzcharles. Cannabis for chronic pain: Case series and implications for clinicians. *Pain Res Manage* 2002;7(2):95-99.

BACKGROUND: Chronic pain is one of the most common reasons for therapeutic cannabis use.

OBJECTIVES: To describe therapeutic cannabis use among patients with chronic pain.

METHODS: Patients with chronic pain who voluntarily indicated that they used cannabis therapeutically completed a questionnaire about the type of cannabis used, the mode of administration, the amount used and the frequency of use, and their perception of the effectiveness of cannabis on a set of pain-associated symptoms and side effects. The study was approved by the McGill University Health Centre Research Ethics Board.

RESULTS: Fifteen patients (10 male) were interviewed (median age 49.5 years, range 24 to 68 years). All patients smoked herbal cannabis for therapeutic reasons (median duration of use six years, range two weeks to 37 years).

Seven patients only smoked at night-time (median dose eight puffs, range two to eight puffs), and eight patients used cannabis mainly during the day (median dose three puffs, range two to

eight puffs); the median frequency of use was four times per day (range one to 16 times per day).

Twelve patients reported improvement in pain and mood, while 11 reported improvement in sleep. Eight patients reported a 'high'; six denied a 'high'. Tolerance to cannabis was not reported.

CONCLUSIONS: The results of this self-selected case series must be interpreted with caution. Small doses of smoked cannabis may improve pain, mood and sleep in some patients with chronic pain. Clinical trials are warranted to test these effects. Further prospective studies should examine the patterns and prevalence of cannabis use among chronic pain populations.

Le cannabis contre la douleur chronique : Une série de cas et les répercussions pour les cliniciens

HISTORIQUE : La douleur chronique est l'une des principales causes d'utilisation du cannabis pour des raisons thérapeutiques.

OBJECTIFS : Décrire l'usage du cannabis pour des raisons thérapeutiques chez des patients souffrant de douleur chronique.

Telephone 514-934-2222, fax 514-934-8096, e-mail mark.ware@muhc.mcgill.ca

Received for publication March 5, 2002. Accepted May 15, 2002

MÉTHODOLOGIE : Des patients souffrant de douleur chronique qui ont volontairement indiqué utiliser du cannabis pour des raisons thérapeutiques ont répondu à un questionnaire sur le type de cannabis utilisé, le mode d'administration, la quantité utilisée et la fréquence d'utilisation, ainsi que sur leur perception de l'efficacité du cannabis sur un ensemble de symptômes et d'effets secondaires associés à la douleur. L'étude a été approuvée par le conseil de recherche déontologique du Centre universitaire de santé McGill.

RÉSULTATS : Quinze patients (10 hommes) ont été interrogés (âge moyen : 49,5 ans, plage de 24 à 68 ans). Tous les patients fumaient du cannabis végétal pour des raisons thérapeutiques (durée moyenne de six ans, plage de deux semaines à 37 ans).

Sept patients ne fumaient que le soir (dose moyenne de huit bouffées, plage de deux à huit bouffées), et huit patients utilisaient le cannabis

surtout le jour (dose moyenne de trois bouffées, plage de deux à huit bouffées). La fréquence moyenne d'utilisation correspondait à quatre fois par jour (plage de une à 16 fois par jour).

Douze patients ont fait état d'une diminution de leur douleur et d'une amélioration de leur humeur, tandis que 11 ont déclaré mieux dormir. Huit patients ont affirmé ressentir un état d'euphorie, et six l'ont nié. Aucune tolérance au cannabis n'a été déclarée.

CONCLUSIONS : Les résultats de cette série de cas par autosélection doivent être interprétés avec prudence. De petites doses de cannabis fumé pourraient réduire la douleur et améliorer l'humeur et le sommeil chez certains patients atteints de douleur chronique. Des essais cliniques s'imposent pour vérifier ces effets. Des études prospectives supplémentaires devraient porter sur les schémas et la prévalence d'utilisation de cannabis au sein des populations souffrant de maladie chronique.

The use of *Cannabis sativa* in the treatment of pain has been described in the literature since 3000 BC (1). The recent discovery of specific cannabinoid receptors (2,3) and endogenous cannabinoid ligands (4,5) that play an important role in pain transmission (6) has renewed interest in natural and synthetic cannabinoids as therapeutic agents. This recent scientific activity has occurred in parallel with rising popular support in Canada and elsewhere for the use of herbal cannabis as a medicinal agent (7). Health Canada has issued a call for research into the medicinal uses of cannabis, including the evaluation of smoked cannabis in clinical trials (8).

Dose-response considerations are among the first issues to be considered in designing a study of a new drug in humans. Currently, data on cannabis dose requirements for therapeutic effect are limited to oral preparations of delta-9-tetrahydrocannabinol (THC) and cannabis extracts. There are few data on the doses of smoked cannabis used by medicinal users, but such information may be useful in estimating starting doses for clinical trials and for developing other modes of cannabinoid drug delivery.

Chronic pain often involves a complex constellation of symptoms, including pain, anxiety, fatigue, limitation of activity and depression, all of which contribute to a reduced quality of life. Preclinical research provides compelling evidence that cannabinoids exhibit antinociceptive effects in animal models of acute pain and chronic inflammatory and neuropathic pain (9). Oral THC has been found to have some analgesic effect in cancer pain (10). Oral preparations of whole cannabis containing several cannabinoids have been found to reduce opioid requirements in a single patient trial (11). Smoked cannabis has never been studied in a clinical trial of chronic pain, but anecdotal reports of patients who have smoked cannabis for pain relief suggest that the effects are varied, and include relaxation, reduced anxiety, improved sleep and improved concentration (12). The effects of smoked cannabis on chronic pain may, therefore, be more complex than simple analgesia.

We present a case series of 15 patients with chronic pain who reported having used cannabis for symptom relief. The

objectives of the study were to determine the main reasons for using cannabis, the dose size and frequency, the desired and adverse effects, and the experience of tolerance to these effects.

PATIENTS AND METHODS

Patients were recruited from two sites – the McGill Pain Centre and a university-affiliated rheumatology clinic. The McGill Pain Centre is a tertiary referral centre for the multidisciplinary management of chronic pain. The clinic sees over 250 new patients per year and has over 1000 patients on the register. The rheumatology clinic is staffed by three academic rheumatologists and is located about 20 km from the downtown centre of Montreal. As part of the routine assessment of new patients, patients are asked about the previous use of pain management techniques, including conventional and unconventional therapies, and the degree of benefit or side effects derived from these treatments. They are not asked specifically about cannabis use. Over a six-month period from February to July 2001, 15 patients chose to report cannabis use for symptom management. These patients were invited to participate in the present study. A structured questionnaire was administered in the presence of the primary caregiver. The diagnosis was provided by the primary care giver. Cannabis use was described by the type of material used (herbal, resin, oil) and method of administration (smoked, eaten, tea). A single dose was defined as the number of puffs or joints taken at any discrete point in time, and frequency was defined as the number of such doses per day. A joint was assumed to be equivalent to eight puffs (13). Patients were asked to indicate which symptoms were present and to categorize the perceived effectiveness of cannabis on each symptom (improved, no change, worse). Because some side effects of cannabis use may be considered by patients to be desirable (eg, the 'high' associated with use), they were asked to rate the side effects qualitatively.

For statistical analysis, perceived effectiveness and side effects were handled as ordered categorical variables and assigned rank scores. Correlations between dose (single and

68	Female	Rheumatoid arthritis

total daily) and effectiveness or side effect scores were examined by one-way ANOVA using Stata version 6.0 (Stata Corporation, USA).

Approval for the study was obtained from the McGill University Health Centre Research Ethics Board, and all patients provided written informed consent.

RESULTS

Fifteen patients (10 male) – 10 from the pain centre and five from the rheumatology clinic – participated in the survey. The median age of the participants was 49.5 years (range 24 to 68 years). The chronic pain syndromes are listed in Table 1. Three patients had spinal radiculopathy (one cervical, two lumbar); two patients had rheumatoid arthritis; two patients had fibromyalgia; two patients had complex regional pain syndrome; and one patient each had phantom limb pain, ankylosing spondylitis, multiple sclerosis, chronic pancreatitis, seronegative spondyloarthropathy and a musculoskeletal pain that was not otherwise specified.

All patients smoked herbal cannabis from the flowering heads of the plant – 10 in joints, three in pipes and two in both forms. Additionally, cannabis was eaten by two patients and was taken as a tea by one. The median duration of therapeutic cannabis use was six years (range two weeks to 37 years).

Dose size and frequency exhibited wide variability, and could be divided into two main categories: night-time users, who only smoked at night (seven patients), and daytime users (eight patients), who smoked at intervals during the day and night. The median single dose for nighttime users

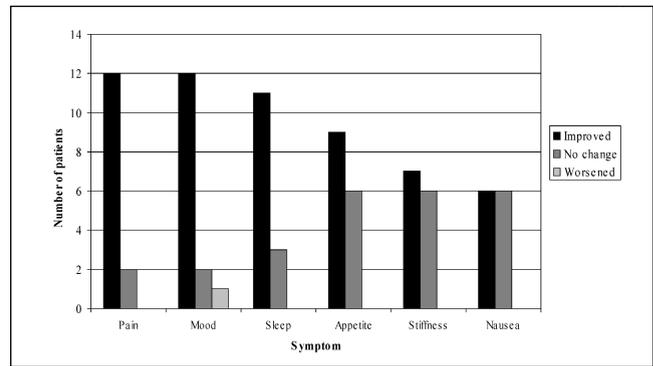

Figure 1) Perceived effectiveness of cannabis on symptoms among 15 patients with chronic pain who used cannabis

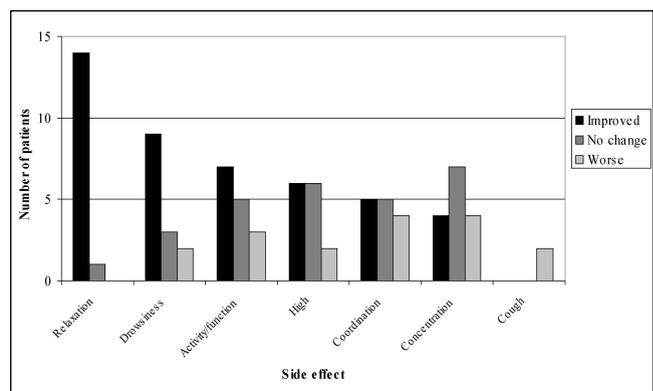

Figure 2) Perception of the side effects of smoked cannabis among 15 patients with chronic pain

was eight puffs (range two to eight puffs). The median single dose for daytime users was three puffs (range two to eight puffs), with a median frequency of four times per day (range one to 16 times per day).

The perceived effectiveness of cannabis on selected symptoms is shown in Figure 1. All 15 patients reported effects on mood (12 reported an improvement, two reported no change and one reported a worsened mood) and appetite (nine reported an improvement and six reported no change). Fourteen patients reported effects on pain (12 reported an improvement and two reported no change) and sleep (11 reported an improvement and three reported no change). Thirteen patients reported effects on stiffness (seven reported an improvement and six reported no change). Twelve patients reported effects on nausea (six reported an improvement and six reported no change).

The experience of side effects of cannabis among the 15 patients is shown in Figure 2. Fifteen patients reported effects on relaxation (14 reported an improvement and one reported no change), change in level of activity (seven reported an improvement, five reported no change and three reported a decrease) and ability to concentrate (four reported an improvement, seven reported no change and four reported a worsening). Fourteen patients reported effects on drowsiness (nine reported an improvement, three

reported no change and two reported a worsening), 'high' (six reported an improvement, six reported no change and two reported a worsening) and coordination (five reported an improvement, five reported no change and four reported a worsening). Two patients reported having a cough.

Neither single nor total daily dose was related to the perceived effectiveness of any of the symptoms. For all patients, 'high' was significantly associated with individual dose size ($F=18.49$, $P=0.001$) but not with total daily dose ($F=0.64$, $P=0.44$). After excluding daytime users, the relationship between single dose and 'high' remained significant for the nighttime users ($F=24.11$, $P=0.0044$).

DISCUSSION

This survey of 15 patients with chronic pain who reported using cannabis for therapeutic purposes is limited by its small size, inherent self-selection bias and lack of control group and should, therefore, be interpreted with considerable caution. We are cognizant of the fact that our data came mainly from those who had tried cannabis and found it tolerable and effective; only one subject in our case series reported that cannabis use was completely unhelpful and associated with debilitating side effects. Despite these limitations, we believe that our study raises some interesting points.

The first point is that pain relief is only one outcome to be addressed in trials of cannabis or cannabinoids for pain. The patients with chronic pain in this survey reported effects of cannabis on pain, sleep and mood. Some patients also reported that cannabis improved their functional status, and their ability to concentrate and relax. This finding is contrary to reported behavioural changes such as the amotivational syndrome (14) and cognitive impairment (15) in long term recreational users. This paradox has been observed in patients with chronic cancer pain whose responses to morphine in performance tasks were different from those of healthy subjects (16). Pain itself may reduce the ability to concentrate on task performance; therefore, while cannabis may impair concentration in healthy subjects, pain patients might experience a different effect. We also note that the 'high' associated with cannabis use may be perceived as a beneficial effect by patients rather than an undesirable side effect. Therefore, we recommend that, in addition to pain, a range of objective, subjective and functional outcomes including mood, quality of life and sleep should be assessed in both short term and long term studies of cannabis and cannabinoids in chronic pain states.

A second point that arises from this survey is the difficulty in estimating therapeutic dose sizes. In this series, most patients reported using herbal cannabis smoked as a joint, with doses ranging from two puffs at night to several joints per day. There are several potential sources of variability to be considered in estimating doses from such survey data. First, individual patients have different ideas of what constitutes a joint (including size, tobacco admixture and presence of a filter), and may have different puff sizes; the cannabis that they use comes from different sources,

which may independently influence the amount of cannabinoid delivered. Second, the type of cannabis preparation used must be considered in deriving dose estimates from such patient data. While cannabis potency is usually measured in terms of THC content, herbal cannabis is known to contain a mixture of other cannabinoids in addition to THC. While THC is the most abundant cannabinoid in drug-type cannabis, nonpsychoactive cannabinoids such as cannabidiol may possess anti-inflammatory, antispasticity and sedative properties that offer potential benefit in disorders such as arthritis (17). Cannabidiol may also modify the anxiety provoked by pure THC administration (18). It is well known that herbal cannabis originating from different geographical regions may contain different profiles of cannabinoids (19), and hashish, the compressed resins synthesized on the flowering heads, may also contain cannabinoid profiles that are different from those of herbal cannabis (20). Thus, the source of the cannabis used by patients may affect not only the dose but also the response. Third, it is not known whether the dose used for therapeutic effect is associated with the severity of pain or with other behavioural or biological factors. Many patients may have had prior experience with cannabis use recreationally (21), which may change their expectation of the drug's effect (22).

Despite this variability, the doses used among the patients in this survey tended to be modest. Some patients used cannabis at a dose of one joint at night, while daytime users smoked fewer puffs more frequently. A total daily dose of one joint per day, either as one dose or in divided doses, appeared to be most common in our patients. The long term effects of this level of exposure to smoked cannabis on the respiratory and other systems are not well known.

In summary, many pain practitioners across Canada will have encountered patients who are either already using cannabis for pain relief or who, in light of recent media interest in medical cannabis issues, will present to their physicians requesting advice or further information. A useful background on cannabinoids has appeared in a previous issue of *Pain Research & Management* (23). With the belief that some information is better than none, we hope that this series of 15 patients with a variety of pain syndromes who reported their experience of cannabis use for symptom management will be of some use in guiding the sort of questions to ask. Our data suggest that dose sizes may be measured in puffs, and that pain relief is one of several possible outcomes that chronic pain patients are seeking to achieve with cannabis use.

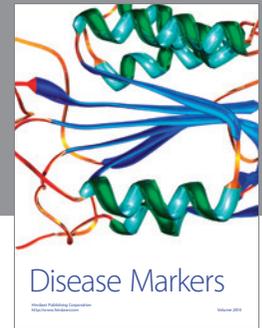

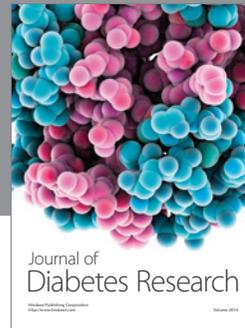

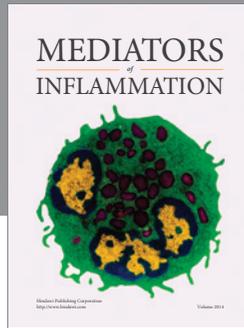

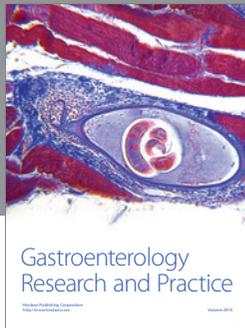

We would like to make three suggestions for further research. First, large, prospective questionnaire studies are required to determine the prevalence of cannabis use among patients with chronic pain, and to ascertain the number of patients who have tried cannabis but not found it useful. Second, more detailed data on the dose (size and frequency), and the perceived benefits and side effects of cannabis use are required. We believe that therapeutic cannabis users are a useful potential source of this information, and we suggest that these data may be collected with

the help of the Compassion Club community, where thousands of Canadians are currently obtaining cannabis for therapeutic purposes. Third, the cohort of patients using cannabis under the Medical Marijuana Access Regulations offers a unique opportunity to collect prospective dose and outcome data. Once a standardized cannabis material is available to these patients, some of the inherent variability in dose estimates may be minimized.

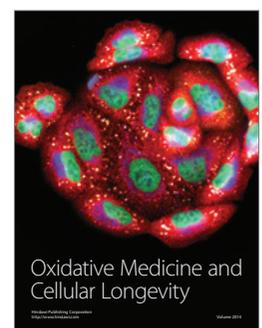

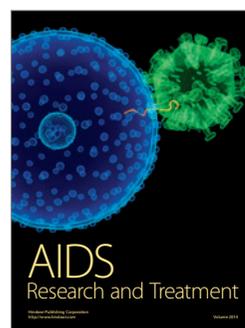

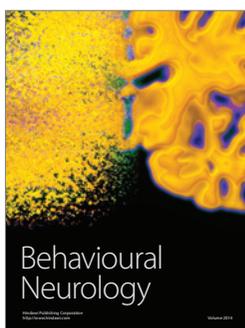

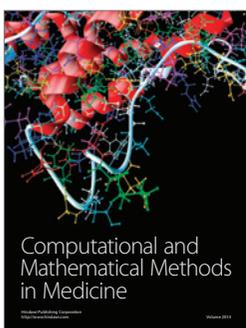

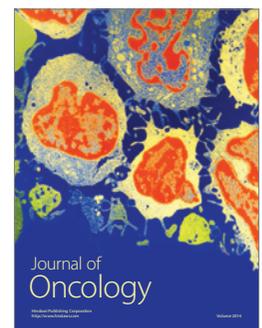

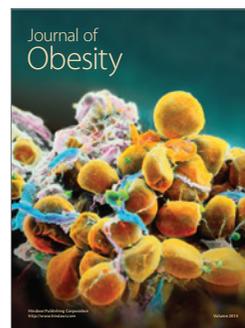

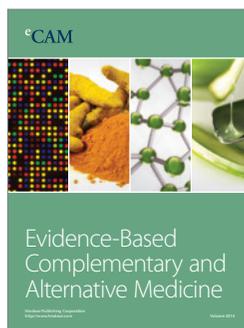

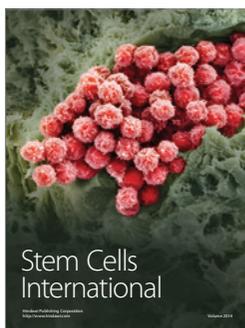

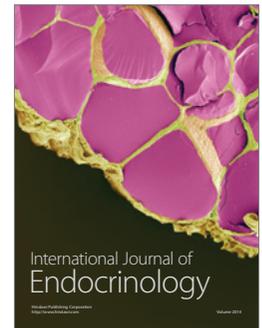

ACKNOWLEDGEMENTS: The authors wish to thank Bev Rowat for her assistance in administering their survey and to Anneli Vainio for her support in this project. Mark Ware was supported by a stipend from the McGill University Health Centre-Montreal General Hospital Pain Centre.

The Effects of Nabilone on Sleep in Fibromyalgia: Results of a Randomized Controlled Trial

Mark A. Ware, MBBS, MSc,
MRCP*†

Mary-Ann Fitzcharles, MBBS,
FRCPC‡

Lawrence Joseph, PhD§

Yoram Shir, MD*†

BACKGROUND: Sleep disorders affect many patients with chronic pain conditions. Cannabis has been reported by several patient populations to help sleep. We evaluated the safety and efficacy of nabilone, a synthetic cannabinoid, on sleep disturbance in fibromyalgia (FM), a disease characterized by widespread chronic pain and insomnia.

METHODS: We conducted a randomized, double-blind, active-control, equivalency crossover trial to compare nabilone (0.5–1.0 mg before bedtime) to amitriptyline (10–20 mg before bedtime) in patients with FM with chronic insomnia. Subjects received each drug for 2 wk with a 2-wk washout period. The primary outcome was sleep quality, measured by the Insomnia Severity Index and the Leeds Sleep Evaluation Questionnaire. Secondary outcomes included pain, mood, quality of life, and adverse events (AEs).

RESULTS: Thirty-one subjects were enrolled and 29 completed the trial (26 women, mean age 49.5 yr). Although sleep was improved by both amitriptyline and nabilone, nabilone was superior to amitriptyline (Insomnia Severity Index difference = 3.2; 95% confidence interval = 1.2–5.3). Nabilone was marginally better on the restfulness (Leeds Sleep Evaluation Questionnaire difference = 0.5 [0.0–1.0]) but not on wakefulness (difference = 0.3 [–0.2 to 0.8]). No effects on pain, mood, or quality of life were observed. AEs were mostly mild to moderate and were more frequent with nabilone. The most common AEs for nabilone were dizziness, nausea, and dry mouth.

CONCLUSIONS: Nabilone is effective in improving sleep in patients with FM and is well tolerated. Low-dose nabilone given once daily at bedtime may be considered as an alternative to amitriptyline. Longer trials are needed to determine the duration of effect and to characterize long-term safety.

(Anesth Analg 2010;110:604–10)

Fibromyalgia (FM) is a chronic pain syndrome characterized by diffuse body pain with associated pressure allodynia. The diagnosis is clinical with no confirmatory test and is based on a history of widespread pain and the presence of tenderness at 11 of 18

specific tender point sites.¹ This condition, predominantly affecting adult women, is worldwide and common with a prevalence of 2% in North America.^{2–4}

Although the pathophysiology of FM is not clearly understood, evidence is emerging of widespread central nervous system sensitization,⁵ which may be mediated by dopaminergic,⁶ serotonergic,⁷ and glutamatergic⁸ mechanisms. Autonomic dysregulation has also been postulated in FM.^{9–11}

In addition to the report of pain, patients with FM experience numerous other somatic symptoms such as fatigue, mood disorder, and sleep disturbance that have an important effect on well-being. Insomnia has been reported in >75% of patients with FM.¹² Unique sleep patterns have been identified in patients with FM, for example, increased α non-rapid eye movement (REM) spindles on electroencephalogram recordings.¹³ The use of antidepressant therapy has been shown to improve sleep quality in patients with FM.¹⁴

Pregabalin has been shown to be effective for pain in FM¹⁵ and was recently approved by the United States Food and Drug Administration for the management of pain associated with FM. Before this, standard treatment for FM has included low-dose tricyclic antidepressants such as amitriptyline, cardiovascular

exercise, cognitive behavioral therapy, and patient education.^{16,17} Nabilone, a synthetic cannabinoid, has been observed in a small case series to improve sleep in patients with chronic pain.¹⁸ A recent small randomized controlled trial of nabilone in FM was shown to reduce pain, but sleep changes were not reported.¹⁹ To our knowledge, no study has specifically evaluated sleep quality as a primary outcome in FM. This study was therefore designed to investigate the effects of nabilone on sleep in patients with FM.

METHODS

We conducted a randomized, active-control, equivalence clinical trial using a 2-period crossover design. Each period was of 2 wk duration separated by a 2-wk washout phase. The total study period was for 10 wk, including the initial and final 2-wk washout periods.

Participants

Subjects were recruited from the Pain Clinic of the McGill University Health Centre. Eligible subjects were adult men and nonpregnant women aged 18 yr or older with a diagnosis of FM¹ who had self-reported chronic insomnia. Insomnia was defined as disturbed sleep either every night or every other night for the past 6 mo.²⁰ Subjects remained on stable analgesic therapy and had to have a negative urine screen for cannabinoids at the baseline visit. Subjects who were using a cannabinoid or amitriptyline at screening underwent a 2-wk washout period before entering the study. Subjects were excluded if they had cancer pain, unstable cardiac disease, a history of psychotic disorder, schizophrenia, or recent manic episode (within the past year), seizure disorder, glaucoma, urinary retention, hypersensitivity to cannabinoids, amitriptyline, or related tricyclic antidepressants, or were taking monoamine oxidase inhibitors.

Eligible and consenting subjects underwent a medical history, physical examination, and chart review. Vital signs and concomitant medications were recorded, and urinary drug screening, full blood counts, and renal and liver function tests were performed and required to be negative or normal. At the baseline visit, eligible subjects completed questionnaires on pain, mood, and quality of life (see below), and underwent a urine drug test before randomization.

Study Drug

Doses of nabilone 0.5 mg or amitriptyline 10 mg were prepared by an independent pharmacy in sealed opaque capsules. Subjects received either nabilone 0.5 mg or amitriptyline 10 mg at the start of the treatment cycle of the study according to the randomization schedule. On Day 7 of each treatment cycle, the study physician evaluated whether the subject might benefit from an increase in dose. If an increase was indicated, the dose of the assigned medication was doubled (to either nabilone 1 mg or amitriptyline 20 mg) for the second week. At the end of the second week, subjects

stopped the study medication for a 2-wk washout period and began the second treatment cycle on the other study drug following the same procedures as above.

Objectives

The primary objective of this study was to determine whether nabilone is equivalent to amitriptyline in improving quality of sleep in patients with FM. The secondary objective was to describe the effects of nabilone on the other clinical variables of pain, mood, quality of life, and global satisfaction. Adverse events (AEs) were recorded.

Study Outcomes

Primary Outcome

The primary outcome was the quality of sleep. Two measures were used to assess sleep, the Insomnia Severity Index (ISI) and the Leeds Sleep Evaluation Questionnaire (LSEQ). The ISI is a reliable and valid instrument used to quantify perceived insomnia severity and is used as an outcome measure in insomnia treatment research.²¹ A score of <8 on the ISI implies no clinical insomnia, 8–14 implies moderate insomnia, and >15 implies severe insomnia. The LSEQ is a well-validated instrument that has been used to monitor subjectively perceived changes in sleep during psychopharmacological investigations with a variety of psychoactive drugs including sedative hypnotics, anxiolytics, central nervous system stimulants, and antihistamines.²² The LSEQ comprises ten 100-mm visual analog scales measuring 4 characteristics of sleep: getting to sleep, quality of sleep, awakening from sleep, and behavior after wakefulness. We used the full LSEQ at clinic visits and in a study diary. During telephone interviews, patients responded to the questions on a 0–10 numerical scale. Sleep diaries were completed daily and returned at the end of each 2-wk cycle. Sleep data were also collected on 3 occasions by telephone during each week of the study including the washout period.

Secondary Outcomes

The secondary outcomes were pain, mood, quality of life, global satisfaction with treatment, and AEs. Pain was measured with the McGill Pain Questionnaire, a widely used and validated instrument frequently used in clinical trials of analgesic medications.²³ Mood was assessed using the short-form Profile of Mood States.²⁴ Quality of life was assessed using the Fibromyalgia Impact Questionnaire, a validated and disease-specific questionnaire for FM.²⁵ Patient global satisfaction was assessed using the question “Would you wish to continue with this medication?” (Y/N). Data on pain, mood, quality of life, and satisfaction were collected on Days 1 and 14 of each treatment cycle. At the end of the third and last washout phase, patients were asked to give their preference (if any) for 1 of the study

medications. Vital signs were recorded at each clinic visit. AEs were recorded throughout the study.

Urine samples were obtained at the screening visit and on Days 1 and 14 of each treatment cycle and tested by semiquantitative assay for the principal urinary metabolite (9-COOH-THC) of tetrahydrocannabinol (THC) to ensure that no other cannabinoid was used during the study.

Sample Size Estimation

The LSEQ has demonstrated differences in sleep quality from baseline of >1.5 on a 10-cm scale with samples of 30 subjects or fewer.²² An equivalence study comparing the analgesic efficacy of amitriptyline with gabapentin concluded equivalence with 24 subjects. There are no specific data on sleep scores after amitriptyline therapy. We therefore estimated that a sample of 30 subjects would be sufficient to conclude equivalence based on within-subject *SD* of 1.0 around the primary outcome, because this would provide a confidence interval (CI) width for the between-treatment difference of approximately ± 0.7 on the LSEQ scale. To account for a dropout rate of up to 25%, we aimed to recruit 40 subjects for this trial for a final sample size of at least 30 subjects. No interim analyses were planned.

Randomization

The randomization schedule was prepared (ralloc procedure, Stata version 8.0, Houston, TX) using randomly assigned block sizes ranging from 2 to 8. The schedule was kept by the study pharmacist away from the investigators. Study subjects were consecutively assigned to treatment order by the study nurse based on the randomization schedule. A coded script was given to the subject with instructions on the use of the allocated treatment. The subject then collected the medication from the study pharmacy and began taking the medication the same night.

Blinding

The study physician, study nurse, and subjects were blinded to the allocated treatment order. At the end of the study, the subjects were asked to estimate the order of allocated drugs as a means of estimating the success of blinding.

Statistical Analyses

The principal hypothesis for this study was that nabilone at a dose of 0.5–1 mg is equivalent to amitriptyline at a dose of 10–20 mg in improving sleep quality in patients with FM. The primary outcome of sleep quality was derived from the average scores obtained during the second week of each cycle of the ISI and of the sleep quality items (questions 4 and 5 on restfulness and wakefulness, respectively) from the LSEQ. The sleep scores during nabilone therapy were compared with those during amitriptyline using CIs of the within-subject difference in scores. Regression models were created with treatment, period, and

order as terms in the model. Examination of treatment by period interactions was included to assess potential carryover effects. For inferences, 95% CIs were generated for all parameters. Secondary outcomes were assessed using similar procedures for each variable. AEs were tabulated by severity and study drug.

Ethics and Trial Registration

Ethics approval was obtained from the McGill University Health Centre Research Ethics Board; all subjects provided written informed consent. Approval to use the study drugs was obtained through a Clinical Trial Application to the Therapeutic Products Directorate of Health Canada (Clinical Trial Application number 099547). The trial was conducted following Good Clinical Practice guidelines and was registered at www.clinicaltrials.gov (registration number NCT00381199).

RESULTS

One hundred fourteen subjects were screened, 39 were enrolled, and 32 were recruited and randomized to study drug (Fig. 1). Enrollment began in August 2005 and the last enrolled subject completed follow-up

Note the Leeds Sleep Evaluation Questionnaire is not measured at baseline because it requires a comparison with normal sleep.

in January 2007. Three subjects withdrew after randomization, 1 for noncompliance with study protocol, 1 for lack of effect, and 1 because of side effects after a single dose (edema of arms and legs, decreased concentration, dizziness, nausea, hyper-alert state, and insomnia). Twenty-nine subjects completed the study per protocol; there were no dropouts. All randomized subjects' data were included in the safety analysis.

Of the 32 randomized subjects, 26 were women and 5 were men (1 missing data). The mean age was 49.5 yr (SD 11.2) with a range of 26–76 yr. Baseline demographic and clinical data of recruited subjects are shown in Tables 1 and 2. Five subjects were taking

tricyclic antidepressants at screening (4 amitriptyline and 1 nortriptyline), and all successfully withdrew from these medications before randomization. No subject was taking cannabinoid medications at screening, and all baseline urine tests were negative for THC.

Primary Outcome

Although both drugs improved sleep, after controlling for period effects, nabilone was found to have a greater effect on sleep than amitriptyline on the ISI (adjusted difference = -3.25 ; CI, -5.26 to -1.24) (Fig. 2). Based on the LSEQ sleep quality outcomes, there was no evidence of superiority of either drug, although subjects had a more restful sleep taking nabilone compared with amitriptyline (difference = 0.48 ; CI, 0.01 – 0.95) (Fig. 3). There were no marked differences in other scales of the LSEQ between the 2 drugs, although there was a suggestion of nabilone performing better than amitriptyline for ease (difference = -0.7 ; CI, -1.4 to 0.02) and speed (difference = -0.7 ; CI, -1.36 to 0.03) of falling asleep.

Other Outcomes

No differences were noted between treatments for pain (McGill PPI difference = -0.1 ; 95% CI = -0.3 to 0.2 ; other scales of McGill Pain Questionnaire also not significant), mood (Profile of Mood States difference = 1.4 ; 95% CI = -4.3 to 7.2), or quality of life (Fibromyalgia Impact Questionnaire difference = -0.7 ; 95% CI = -7.3 to 5.8).

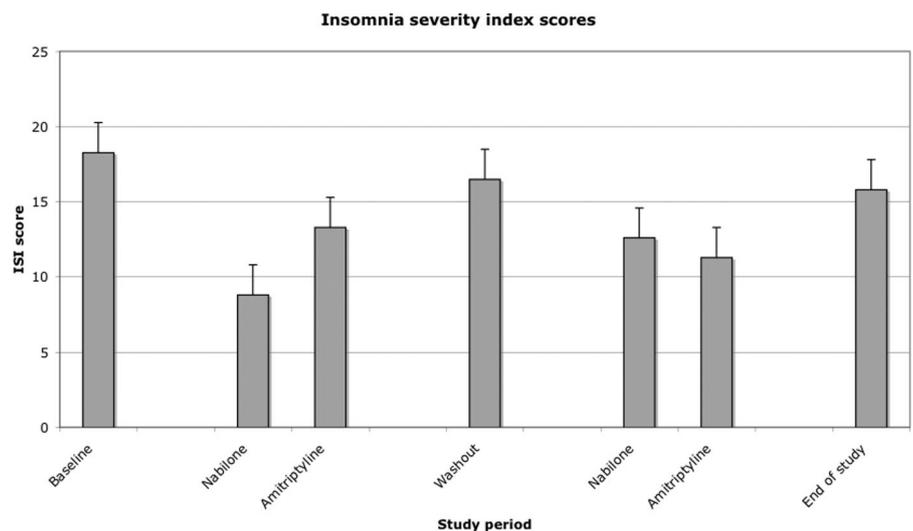

Satisfaction and Preference

At the completion of the trial, preference for nabilone was reported by 41% (12 of 29) and for amitriptyline by 32% (9 of 28) of subjects (difference = 9%; 95% CI = -16% to 32%).

Dose Adjustment

The dose of amitriptyline was more frequently increased at 1 wk (26 of 28; 92%) compared with nabilone (21 of 29; 72%) (difference = 20%; 95% CI = -2% – 43%).

Figure 2. Effects of nabilone and amitriptyline on the Insomnia Severity Index (ISI).

Treatment Effect [LSEQ]

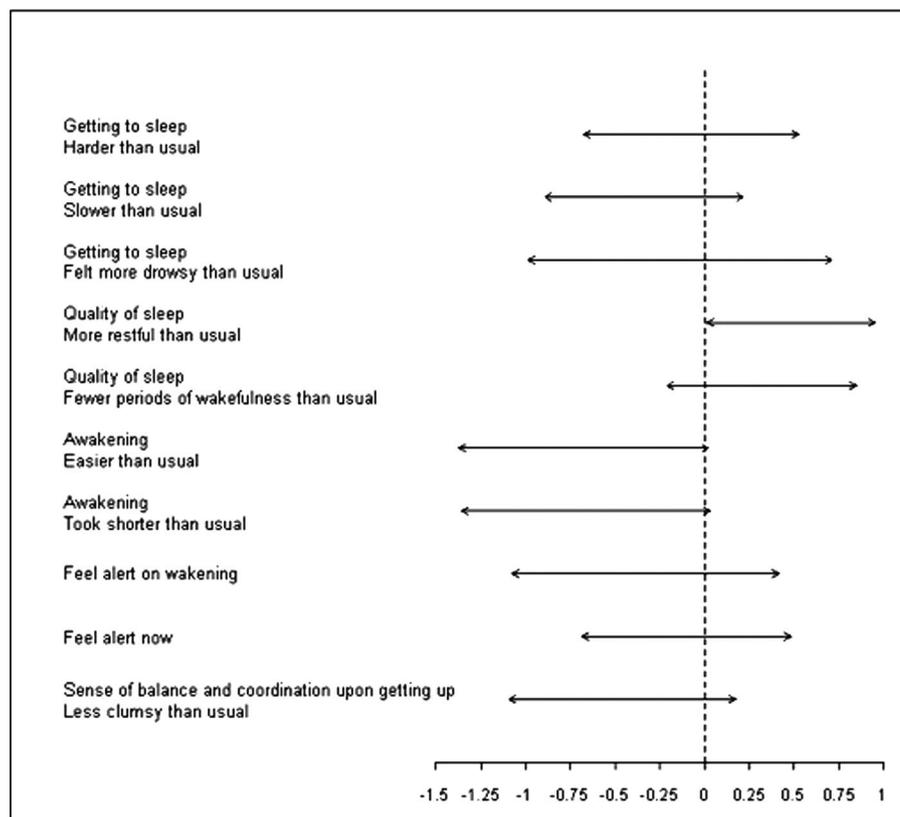

Figure 3. Treatment effects of nabilone compared with amitriptyline on sleep items in the Leeds Sleep Evaluation Questionnaire (LSEQ). Note that treatment effects shifted to the right favor nabilone, whereas effects shifted to the left favor amitriptyline. The *x* axis is the magnitude of the effect on a scale from 0 to 10. Shifts to the right represent improvements on the sleep subscales (shown on the *y* axis).

Table 3. Absolute Number of Adverse Events Occurring on >1 Occasion During the Trial

Description	Nabilone	Amitriptyline	Total
Dizziness	10	4	16
Headache	4	6	14
Nausea	9	1	14
Dry mouth	7	3	10
Drowsiness	6	1	7
Constipation	4	1	5
Diarrhea	2	2	4
Insomnia	3		3
Vomiting	3		3
Blurred vision	2	3	5
Fatigue	2	1	3
Cognitive impairment	2		2
Disorientation	2		2
Migraine	2		2

Discernment

When asked at the end of the study to guess which treatment had been administered, 8 subjects (29%) correctly identified the period in which they received amitriptyline, and 12 (41%) correctly identified the period in which they received nabilone.

Adverse Events

A total of 187 AEs were reported during the trial of which 120 were mild, 64 were moderate, and 3 severe. Of the 3 severe AEs, 2 occurred during amitriptyline therapy (headache and insomnia) and 1 occurred

during nabilone (drowsiness). No serious AEs occurred during the trial. Fifty-three AEs were deemed possibly or probably related to amitriptyline therapy, and 91 AEs were deemed possibly or probably related to nabilone therapy. The most common AEs reported for nabilone and amitriptyline are shown in Table 3. AEs occurring in >2 subjects, which were more common for nabilone, were dizziness (10 subjects), nausea (9), dry mouth (7), drowsiness (6), constipation (4), insomnia (3), and vomiting (3).

DISCUSSION

We have observed that both the synthetic cannabinoid nabilone and the tricyclic antidepressant amitriptyline had a favorable effect on sleep in patients with FM, with nabilone showing overall superiority to amitriptyline for sleep quality. The effects of nabilone on pain, mood, and quality of life were similar to those seen with amitriptyline. Adverse effects were more common with nabilone, particularly drowsiness and dizziness, although global satisfaction with both drugs was similar.

The effects of cannabinoids on sleep have been recognized for many years. The hypnotic effects of THC were evaluated in the 1970s, and it was shown that THC increased Stage 3 sleep and reduced REM sleep²⁶; amitriptyline has not been found to have any effect on non-REM sleep in patients with FM.²⁷

Researchers conducting clinical trials of cannabinoids for other chronic pain disorders have reported improved sleep as secondary outcomes.²⁸ Endogenous cannabinoids have also been postulated to have an effect on normal sleep induction.²⁹ To our knowledge, this is the first study to evaluate sleep as a primary outcome for a chronic noncancer pain condition.

Our study has several important strengths. First, because both drugs cause similar side effects (e.g., drowsiness and dry mouth), we postulated that amitriptyline would be a suitable active control for nabilone, and therefore would preserve the blinded nature of the trial. Our data on blinding suggest that blinding was preserved, suggesting that amitriptyline is a good active control for further trials of nabilone. Second, because amitriptyline is frequently used for promoting sleep in FM, and because we have observed improvement of sleep among subjects taking amitriptyline, we believe that the study has demonstrated internal and external validity and was sufficiently powered to show clinically meaningful sleep improvements. For these reasons, we believe that the effects of nabilone on sleep quality are valid.

There are a number of limitations to this study that require comment. First, because the exposure to each drug was for a single 2-wk period, we are unable to extrapolate any conclusions regarding the long-term safety and efficacy of nabilone for sleep disturbance in FM. Because FM is a chronic condition, favorable treatments will likely require prolonged administration. Second, because both study drugs were used in relatively low dosage, this may have influenced the final outcome either favorably for nabilone (if nabilone was more effective at lower doses) or unfavorably for amitriptyline (if amitriptyline was more effective at higher doses). Because no other equivalency studies have previously been conducted with these drugs, the selected doses of the study drugs were based on clinical experience. Further dose-finding studies, specifically for nabilone, may be needed to explore safety and efficacy if higher doses are to be considered.

The mainstay of management for FM remains a multidisciplinary treatment approach, which includes exercise, education, pharmacological interventions, and behavioral therapies.^{17,30} Sleep disturbances in FM are associated with poor quality of life and function, and increased pain and fatigue.³¹ Although nabilone has been shown to have analgesic effects on pain in FM,¹⁹ the effects of nabilone on sleep have not hitherto been addressed in this population.

In conclusion, we report that the synthetic cannabinoid nabilone is an effective drug in promoting sleep in patients with FM who have chronic insomnia and may be superior to amitriptyline, which is currently widely used for this purpose. Further studies on

the effects of nabilone on sleep architecture and long-term safety and efficacy in FM and other pain conditions are warranted.

ACKNOWLEDGMENTS

The authors thank Lynda Oliveros, Laura Pallett, Linda Ferguson, and Nicole Poitras for administrative and nursing support during this trial. They also thank the subjects for their generous participation.

Executive Summary

In May 2014, Minnesota became the 22nd state to create a medical cannabis program. Distribution of extracted cannabis products in liquid or oil form to qualified, enrolled patients began July 1, 2015. Minnesota's medical cannabis program is distinct from those in nearly all other states as the Minnesota Department of Health's Office of Medical Cannabis is required to study and learn from the experience of participants. This report draws on data from enrollment, purchasing and related health information, and survey results to describe the experience of patients who enrolled during the first year of the program's operation: July 1, 2015 through June 30, 2016.

The Office of Medical Cannabis anticipates performing additional analyses of data for the first year cohort of enrolled patients, as well as initiating analyses of data from patients who enrolled in the program later. Of particular interest are patients who enrolled after intractable pain became a qualifying condition on August 1, 2016. A report is planned for the end of 2017 that will give a preliminary look at the experience of the first several hundred patients certified for intractable pain. It is possible that focused projects will be developed in the future that will draw on medical record information to answer specific questions raised by analyses of the kinds of program data described in this report.

Participation

Between July 1, 2015 and June 30, 2016 a total of 1660 patients enrolled in the program and 577 health care practitioners registered themselves in order to certify that patients have a medical condition that qualifies them for the program. The most common qualifying conditions were severe and persistent muscle spasms (43%), cancer (28%), and seizures (20%). Each of the remaining six qualifying conditions during the first year – Crohn's Disease, Terminal illness, HIV/AIDS, Tourette Syndrome, glaucoma, and ALS – accounted for less than 10% of patients. Ten percent (167 patients) were certified for more than one qualifying condition. Most patients were middle-aged (56% between ages 36-64), 11% were <18, and 11% were ≥65. Distribution by race/ethnicity generally matched the state's demographics, with 90% of patients describing themselves as white.

The legislation that established the program specified there would be one location for purchasing medical cannabis (called Cannabis Patient Centers; CPCs) in each of the state's eight congressional districts. Patients who enrolled in the program during the first year came from throughout the state, with the average distance from the patient's home to the nearest CPC 29 miles (median distance=16 miles). Some patients were a considerable distance from the nearest CPC, however, with 13% over 60 miles from the nearest one. The program allows patients to have one or more parents or non-parent caregivers who register with the program, who are then allowed to transport and administer a patient's medical cannabis. Only 11%

of patients had a registered caregiver, 17% had a registered parent or guardian, and 26% had either a registered parent/legal guardian or a registered caregiver.

Among the 577 health care practitioners who registered with the program 82% were physicians, 13% were advanced practice registered nurses, and 5% were physician assistants.

Medical Cannabis Purchasing Patterns

Most patients make their first medical cannabis purchase within 14 days of program approval. Subsequent purchases typically follow a roughly monthly periodicity. However, intervals between purchases are sometimes less than a month, especially during the first months of program participation as the patient experiments with small amounts of different products. And intervals between purchases are sometimes much longer than a month. Using a cutoff of six months without any medical cannabis purchases as a surrogate for program discontinuation, 51% of patients who enrolled and made a purchase within the first six months of the program discontinued participation in the program as of December 31, 2016.

Medical Cannabis Use Patterns

Each patient's medical cannabis purchasing transactions during their first enrollment year (or through early March if still within their first enrollment year) were analyzed. A total of 16,238 products were purchased during 10,898 transactions, with 38% of all transactions consisting of two or more products. For analytic purposes, products were classified according to the ratio of delta-9-tetrahydrocannabinol (THC) to cannabidiol (CBD) as follows: Very High THC:CBD (100:1 or higher), High THC:CBD (>4:1 up to 99:1), Balanced THC:CBD (1:1 up to 4:1), High CBD:THC (\geq 1:1 up to 99:1), and Very High CBD:THC (100:1 or higher).

Products for enteral administration (swallowed – includes capsules and oral solutions) and products for inhalation (vaporized oil) each accounted for 45% of product purchases. Products for oromucosal administration (absorption through cheek) accounted for 9%. Nearly 50% of all purchases were Very High THC:CBD products, followed by Balanced THC:CBD (30%) and High CBD:THC (15%). Very High THC:CBD products were most commonly oil for vaporization or for oromucosal absorption, while Balanced THC:CBD and High CBD:THC products were most often for enteral administration.

Examining purchasing history across all patients is very complex for reasons that include experimentation with different products over time. As a first approach to assessing routine use of products, most frequently purchased products were examined for each patient. For 28% of patients, two or more products were purchased the same number of times. The product types that emerged as most frequently purchased were Very High THC vaporization oil (25%), High CBD:THC enteral preparations (14%), and Balanced enteral preparations (13%). Most frequently purchased product types varied considerably across medical conditions.

Benefits

Information on patient benefits comes from the Patient Self-Evaluations (PSE) completed by patients prior to each medical cannabis purchase and from patient and health care practitioner surveys. Results of analysis of PSE and survey data indicate perceptions of a high degree of benefit for most patients.

Patients responded to a survey question asking them how much benefit they believe they received from using medical cannabis on a scale from 1 (no benefit) to 7 (great deal of benefit). Across all patients 64% indicated a benefit rating of 6 or 7 and this degree of benefit was indicated by at least half of the patients with each medical condition. A small but important proportion of patients indicated little or no benefit: 9% gave a rating of 1, 2, or 3. Benefit ratings varied somewhat by qualifying medical condition. When patients were asked what the most important benefit was for them, two-thirds indicated a reduction in symptoms directly related to their qualifying medical condition and most of the remainder indicated more general quality of life benefits.

An important part of this report is the verbatim comments written by patients, and the reader is encouraged to review these comments, presented in an Appendix. Examples of these comments include:

- “Almost all muscle spasm and pain associated with spasms are gone. I used to have constant nerve triggered pain that is minimal now. Results were almost immediate. I am sleeping way better now also.”
- “[NAME] has passed away. I am her daughter and was her care giver. She was open to trying medical cannabis and we got the liquid form. It was a saving grace. She was in a lot of pain and when prescribed medications did NOT work – we started this and it kept her calm and relaxed. I am very thankful that we were able to have this option available. It helped to make her last months more bearable and truly it would have been miserable without it.”
- “I am getting enough sleep for the first time since about 2011. My absence seizures have gone from 3-4 a day to almost 0. It also has lessened the severity of grand mal seizures. The recovery time after has gone from around 12 hours to around 4.”
- “At first it helped a lot but my seizures have returned.”
- “Spasms – only a little better.”

Health care practitioners were somewhat more conservative in assessment of benefit to their patients. Across all the benefit ratings by health care practitioners, 38% indicated a rating of 6 or 7 and 23% indicated little or no benefit (rating of 1, 2, or 3). Similarity in benefit assessment between health care practitioners and patients appears to vary by medical condition, with highest discrepancy among seizure patients. Descriptive comments suggest at least part of the difference is driven by perspective of what constitutes benefit. The patients cite quality of life

benefits more often than the health care practitioners, who appear to focus more on objective measures such as seizure counts.

The symptom scores provided in the Patient Self-Evaluation data have the advantage of completeness, since they are required prior to each medical cannabis purchase. In this report a reduction of $\geq 30\%$ was applied to most symptoms to indicate clinically meaningful symptom reduction. Results show patterns similar to those in the survey benefits rating, but usually somewhat smaller in size. For most symptoms between half and two-thirds of patients who achieve clinically meaningful improvement retained that degree of improvement over the next four months.

Examples of proportion of patients achieving and retaining $\geq 30\%$ symptom reduction include:

- Among seizure patients, 68% reported $\geq 30\%$ reduction in seizure frequency and 49% both achieved that level of reduction and retained it, on average, for at least four months
- Among patients with Tourette syndrome, 61% reported $\geq 30\%$ reduction in tic frequency and 46% both achieved that level of reduction and retained it, on average, for at least four months
- Among patients with Crohn's disease, 51% reported $\geq 30\%$ reduction in number of liquid stools per day and 29% both achieved that level of reduction and retained it, on average, for at least four months
- Among patients with severe, persistent muscle spasms, 48% reported $\geq 30\%$ reduction in spasm frequency and 28% both achieved that level of reduction and retained it, on average, for at least four months
- Among cancer patients with at least moderate levels of nausea when they started using medical cannabis, 38% reported $\geq 30\%$ reduction of nausea and 23% both achieved that level of reduction and retained it, on average, for at least four months
- Among cancer patients with at least moderate levels of pain when they started using medical cannabis, 29% reported $\geq 30\%$ reduction of pain and 12% both achieved that level of reduction and retained it, on average, for at least four months

Moderate to severe levels of non-disease-specific symptoms such as fatigue, anxiety, and sleep difficulties were common across all the medical conditions. And the reductions in these symptoms was often quite large. These findings support the understanding that some of the benefit perceived by patients is expressed as improved quality of life.

The type(s) of medical cannabis used at the time patients achieved clinically significant improvement was analyzed for each symptom assessed within each category of medical condition. Full results of these analyses are presented in an Appendix and summaries are in the Benefits chapter.

Adverse Side Effects

At this point, the safety profile of the medical cannabis products available through the Minnesota program seems quite favorable. Approximately 20-25% of enrolled patients report negative physical or mental side effects of some kind, with the majority – around 60% - reporting only one and 90% reporting three or fewer. The vast majority of adverse side effects, around 90%, are mild to moderate in severity. An assessment of the 30 patients reporting severe side effects, meaning “interrupts usual daily activities,” found no apparent pattern of patient age, medical condition, or type of medical cannabis used. The most common adverse side effects are dry mouth, drowsiness, and fatigue. Fortunately, up to the present no serious adverse events (life threatening or requiring hospitalization) have been reported.

Affordability and Suggestions for Improving the Program

Unlike traditional pharmaceuticals whose costs are often covered through insurance reimbursement, medical cannabis purchased through the Minnesota program is currently not covered by insurance and must be purchased out of pocket. The patient survey asked for a rating of product affordability on a scale of 1 (very affordable) to 7 (very prohibitive). More than half (51%) responded with a 6 or a 7 and 86% responded with a score of 4 or higher. “Bring the costs down” was a frequent response when patients and certifying health care practitioners were asked how the program could be improved. Some patients indicated on surveys they used less medical cannabis than they knew was helpful to them because they could not afford it.

1. Introduction

In May 2014, Minnesota became the 22nd state to create a medical cannabis program. Distribution of cannabis products to qualified, enrolled patients began July 1, 2015. Minnesota's medical cannabis program is distinct from those in nearly all other states due to the fact that the Minnesota Department of Health's Office of Medical Cannabis is required to study and learn from the experience of participants. Minnesota's online registry, which integrates information from patients, certifying health care practitioners and manufacturers, continuously captures program data. Data elements from the Registry have been selected to create a de-identified research data set for reporting and research. This report draws on aspects of that research data set to describe the experience of patients who enrolled during the first year of the program's operation: July 1, 2015 through June 30, 2016.

Data in this report come from several aspects of the program's operations:

- Information from registration or enrollment of patients, health care practitioners, and caregivers;
- Information patients provide each time they visit a cannabis patient center for purchase of cannabis products, including information on symptom severity and side effects;
- Details about each cannabis product purchased; and
- Information is derived from responses to periodic surveys of patients and their certifying health care practitioners.

Though there is certainly imprecision in some of the data collected by the program, this report provides important details that can be found in few other states. A notable part of the report is a set of statements regarding benefits, negative effects, and comments about the program made by patients and health care practitioners. These are redacted to protect privacy, but otherwise presented as was written on the surveys. The comments have been coded by type but the verbatim comments have a power of their own, reminding us that each enrollee is a unique individual, not just a number. A few comments are included elsewhere, but the reader is encouraged to spend time reviewing the full listing of responses in the appendices.

The Office of Medical Cannabis anticipates performing additional analyses of data for the first year cohort of enrolled patients, as well as initiating analyses of data from patients who enrolled in the program later. Of particular interest are patients who enrolled after intractable pain became a qualifying condition on August 1, 2016. A report is planned for the end of 2017 that will give a preliminary look at the experience of the first several hundred patients certified for intractable pain. It is possible that focused projects will be developed in the future that will

MINNESOTA MEDICAL CANNABIS PROGRAM: PATIENT EXPERIENCES FROM THE FIRST
PROGRAM YEAR

draw on medical record information to answer specific questions raised by analyses of data derived from the program registry.

2. Patients and Caregivers Registered in the First Program Year

DESCRIPTION OF PATIENTS ENROLLED IN THE FIRST PROGRAM YEAR

Qualifying Condition

During the first year of the Minnesota Medical Cannabis program (July 2015-June 2016), 1,660 patients were certified by registered healthcare practitioners and subsequently enrolled in the program (Figure 2.1). The healthcare practitioners certified the patients as having one or more of the following qualifying conditions: severe and persistent muscle spasms (n=713), cancer (n=468), seizures, including those characteristic of epilepsy (n=328), Crohn's disease (n=108), terminal illness (n=94), HIV/AIDS (n=54), Tourette syndrome (n=30), glaucoma (n=24), and amyotrophic lateral sclerosis (ALS) also known as Lou Gehrig's disease (n=22) (Table 2.1, Figure 2.2). Of the 1660 patients from the first program year, 167 (10.1%) were certified as having more than one qualifying condition; these patients are represented more than once in Table 2.1 and Figure 2.2.

Figure 2.1. Patient enrollment in the first program year.

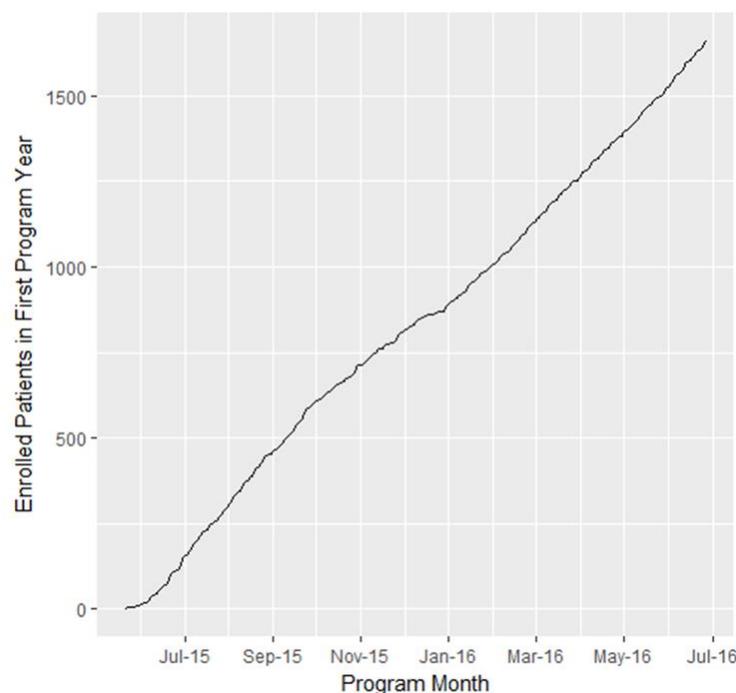

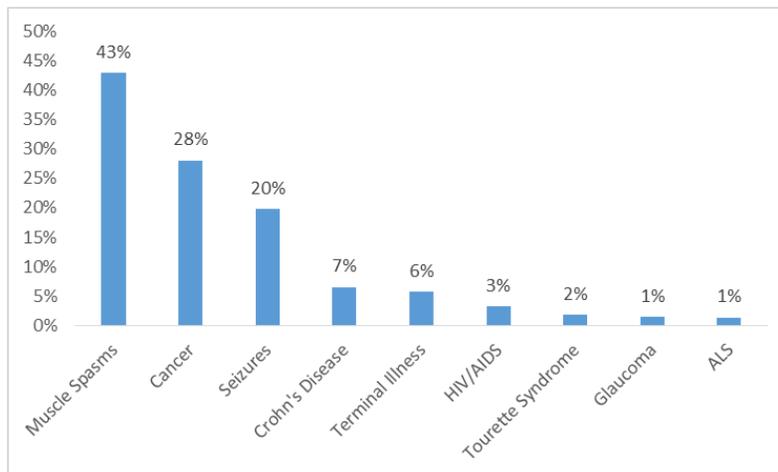

Table 2.1. Patient counts by qualifying condition.

Condition	Count	%
<i>Muscle Spasms</i>	713	43%
<i>Cancer</i>	466	28%
<i>Seizures</i>	328	20%
<i>Crohn's Disease</i>	108	7%
<i>Terminal Illness</i>	94	6%
<i>HIV/AIDS</i>	54	3%
<i>Tourette Syndrome</i>	30	2%
<i>Glaucoma</i>	24	1%
<i>ALS</i>	22	1%

Note: Percentages sum to more than 100 percent because among the 1660 patients enrolled during the first year, 167 (10.1%) were certified for more than one qualifying condition.

Figure 2.2. First year cohort patients by qualifying medical condition.

Note: Percentages sum to more than 100 percent because among the 1660 patients enrolled during the first year, 167 (10.1%) were certified for more than one qualifying condition.

Age and Gender

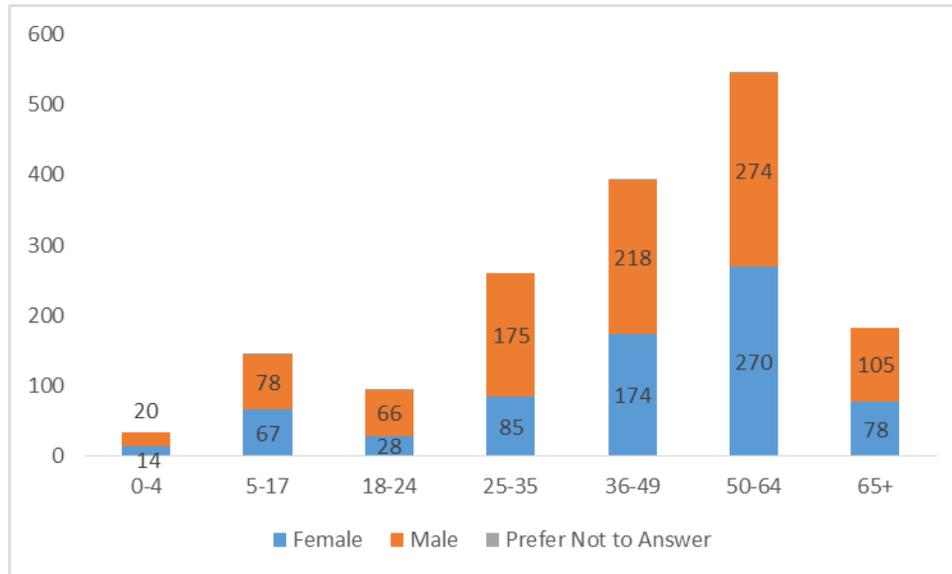

At the time of certifying that a patient has a medical condition qualifying them for the medical cannabis program, the certifying healthcare practitioner enters the patient’s date of birth. Additionally, during registration, patients are asked to report gender and race/ethnicity but are not required to do so. Table 2.2 shows the breakdown of patients by age category and gender at the time of initial program enrollment. The gender breakdown of patients in the first program year was 57% male and 43% female, with <1% of patients declining to report gender. Patients tended to be middle-aged, with 56.3% of the cohort falling between ages 36-64. However, the cohort also included a notable proportion of pediatric patients (10.7%) and patients over 65 years (11.0%).

Table 2.2. Patient counts by age and gender.

	0-4	5-17	18-24	25-35	36-49	50-64	65+
Female	14 (41%)	67 (46%)	28 (29%)	85 (33%)	174 (44%)	270 (49%)	78 (43%)
Male	20 (59%)	78 (53%)	66 (69%)	175 (67%)	218 (55%)	274 (50%)	105 (57%)
Prefer Not to Answer	0 (0%)	1 (1%)	2 (2%)	0 (0%)	2 (1%)	3 (1%)	0 (0%)
Total	34 (2%)	146 (9%)	96 (6%)	260 (16%)	394 (24%)	547 (33%)	183 (11%)

Note: Percentages are calculated based on the total count of patients in each age category.

Figure 2.3. Age and gender breakdown of first year cohort.

Age by Qualifying Condition

Breakdown of age category within each qualifying condition is shown in Table 2.3. Among the first year cohort, average age was 44.3 ± 18.9 years. Age distribution varied substantially across qualifying medical condition groups; patients certified for glaucoma or ALS tended to be older in general (average age of 60.4 ± 14.0 and 61.5 ± 9.6 , respectively); patients certified for seizure disorders or Tourette syndrome generally were younger (23.4 ± 16.0 and 25.3 ± 11.7 , respectively).

Table 2.3. Patient age by qualifying medical condition.

	0-4	5-17	18-24	25-35	36-49	50-64	65+	Mean Age (SD)	Total
Muscle Spasms	3 (0%)	6 (1%)	33 (5%)	124 (17%)	216 (30%)	268 (38%)	63 (9%)	47.3 (14.5)	713
Cancer	3 (1%)	15 (3%)	11 (2%)	33 (7%)	83 (18%)	217 (47%)	104 (23%)	54.6 (16.2)	466
<i>Pain</i>	1 (0%)	3 (1%)	8 (3%)	26 (8%)	65 (20%)	151 (47%)	66 (21%)	54.3 (15.3)	320

MINNESOTA MEDICAL CANNABIS PROGRAM: PATIENT EXPERIENCES FROM THE FIRST PROGRAM YEAR

	0-4	5-17	18-24	25-35	36-49	50-64	65+	Mean Age (SD)	Total
<i>Nausea/Vomiting</i>	1 (0%)	12 (4%)	10 (4%)	18 (7%)	50 (18%)	130 (48%)	52 (19%)	53.4 (16.5)	273
<i>Cachexia/Wasting</i>	1 (1%)	6 (3%)	5 (3%)	8 (4%)	16 (9%)	90 (50%)	54 (30%)	57.9 (16.5)	180
Seizures	30 (9%)	114 (35%)	43 (13%)	68 (21%)	52 (16%)	18 (6%)	3 (1%)	23.4 (16.0)	328
Crohn's Disease	0 (0%)	0 (0%)	9 (8%)	35 (32%)	35 (32%)	22 (20%)	7 (7%)	41.4 (13.8)	108
Terminal Illness	2 (2%)	9 (10%)	3 (3%)	8 (9%)	20 (21%)	38 (40%)	14 (15%)	48.7 (20.1)	94
<i>Pain</i>	0 (0%)	7 (11%)	1 (2%)	6 (9%)	16 (24%)	27 (41%)	9 (14%)	48.7 (20.1)	66
<i>Nausea/Vomiting</i>	1 (2%)	4 (9%)	2 (4%)	3 (7%)	9 (20%)	21 (47%)	5 (11%)	48.7 (20.3)	45
<i>Cachexia/Wasting</i>	1 (3%)	4 (11%)	2 (5%)	1 (3%)	3 (8%)	19 (50%)	8 (21%)	48.9 (20.3)	38
HIV/AIDS	0 (0%)	0 (0%)	0 (0%)	8 (15%)	20 (37%)	26 (48%)	0 (0%)	47.0 (9.7)	54
Tourette Syndrome	0 (0%)	11 (37%)	3 (10%)	12 (40%)	3 (10%)	1 (3%)	0 (0%)	25.3 (11.7)	30
Glaucoma	0 (0%)	0 (0%)	1 (4%)	0 (0%)	4 (17%)	11 (46%)	8 (33%)	60.4 (14.0)	24
ALS	0 (0%)	0 (0%)	0 (0%)	0 (0%)	2 (9%)	12 (55%)	8 (36%)	61.5 (9.6)	22

Race and Ethnicity

Table 2.4 shows patient-reported race and ethnicity. Patients were given the option to select multiple race and ethnicity categories, so the counts reflect some patients more than once. Ninety-one patients selected more than one race/ethnicity and 95 patients declined the question. Compared to 2014 Census Bureau estimates of race/ethnicity in Minnesota, the distribution of responding members of the first program year cohort is generally similar, with a slightly higher proportion of American Indians (2.7% versus 1.9%) and lower proportion of Hispanics (2.4% versus 4.9%) and Asians (1.7% versus 5.0%).

Table 2.4. One-year cohort patient race and ethnicity compared to overall state demographics.

Race/Ethnicity	Medical Cannabis Registry	2014 Census Bureau Estimates
American Indian	42 (2.7%)	1.9%
Asian	27 (1.7%)	5.0%
Black	101 (6.5%)	6.5%
Hawaiian	3 (0.2%)	0.1%
White	1410 (90.1%)	87.5%
Hispanic	37 (2.4%)	4.9%
Other	26 (1.7%)	1.7%

Race and ethnicity estimates for Minnesota can be found at the following website:
<http://factfinder.census.gov/faces/nav/jsf/pages/index.xhtml>

Registered Caregivers and Parents/Legal Guardians

If a patient is unable to pick up their medication from a cannabis patient center or is unable to administer the medication, their certifying health care practitioner may also certify the patient's need for a designated caregiver. This allows the enrolled patient to have a caregiver who then undergoes a background check and registers with the program. Registered caregivers can then legally obtain and possess the patient's medical cannabis on their behalf. Additionally, parents or legal guardians of patients can register with the program to act as caregiver and pick up or possess medication on behalf of the patient. Table 2.5 shows the proportion within each

qualifying condition group of patients who have registered caregivers or parents or legal guardians registered to pick up medication on behalf of the patient. Patients certified for ALS, cancer, or terminal illness have the highest proportions of patients with registered caregivers (32%, 15% and 15%, respectively). Patient certified for seizure disorders or Tourette syndrome, who are also generally younger than the cohort at large, have the highest proportion of patients with registered parents or legal guardians in the program (65% and 53%, respectively). Patients with seizures or Tourette syndrome also have the highest proportion of either registered caregivers or registered parents/legal guardians. Table 2.6 shows the absolute number of registered caregivers associated with a patient in the first year cohort, reported by condition. Most patients with registered caregivers have only one caregiver able to pick up medication on their behalf (n=157); 21 patients have two caregivers and one patient has three caregivers.

Table 2.5. Proportion of patients with registered caregivers, parents or legal guardians authorized to pick up medication, or both.

CONDITION	Number of Enrolled Patients	Patients with Registered Caregiver(s)	Patients with Registered Parent(s)/Legal Guardian(s)	Patients with Registered Caregiver(s) or Parent(s)/Legal Guardian(s)
All Conditions	1660	179 (11%)	279 (17%)	430 (26%)
Cancer	466	71 (15%)	23 (5%)	92 (20%)
Terminal Illness	94	14 (15%)	10 (11%)	22 (23%)
Glaucoma	24	3 (13%)	0 (0%)	3 (13%)
HIV/AIDS	54	1 (2%)	0 (0%)	1 (2%)
Tourette Syndrome	30	2 (7%)	16 (53%)	16 (53%)
ALS	22	7 (32%)	1 (5%)	8 (36%)
Seizures	328	32 (10%)	213 (65%)	225 (69%)
Muscle Spasms	713	72 (10%)	26 (4%)	96 (13%)
Crohn's Disease	108	6 (6%)	3 (3%)	8 (7%)

Table 2.6. Count of registered caregivers associated with patients enrolled in the first program year, by qualifying condition.

Condition	Registered Caregiver Count
All Conditions	202
Cancer	83
Terminal Illness	19
Glaucoma	4
HIV/AIDS	1
Tourette Syndrome	2
ALS	7
Seizures	37
Muscle Spasms	79
Crohn's Disease	6

Geographic Distribution and Distance to Nearest Cannabis Patient Center

At the time of registration, patients provide their home address for verification of Minnesota residency. Home addresses are retained in the patient’s online registry account but are not retained in the research database; in lieu of home address, patient ZIP codes and calculated distances from each address to the nearest cannabis patient center are accessible for research purposes. The general geographic distribution of patients was examined using patient-reported ZIP codes; the first three digits of ZIP codes compose a prefix which corresponds to an approximate geographic region¹. The U.S. Postal Service assigns to each prefix labels that match

¹ <http://pe.usps.com/Archive/HTML/DMMArchive20050106/print/L002.htm>

MINNESOTA MEDICAL CANNABIS PROGRAM: PATIENT EXPERIENCES FROM THE FIRST
PROGRAM YEAR

the major city within the region and approximate surrounding cities; these region labels are shown in Table 2.7, along with the count of patients living in the corresponding ZIP codes.

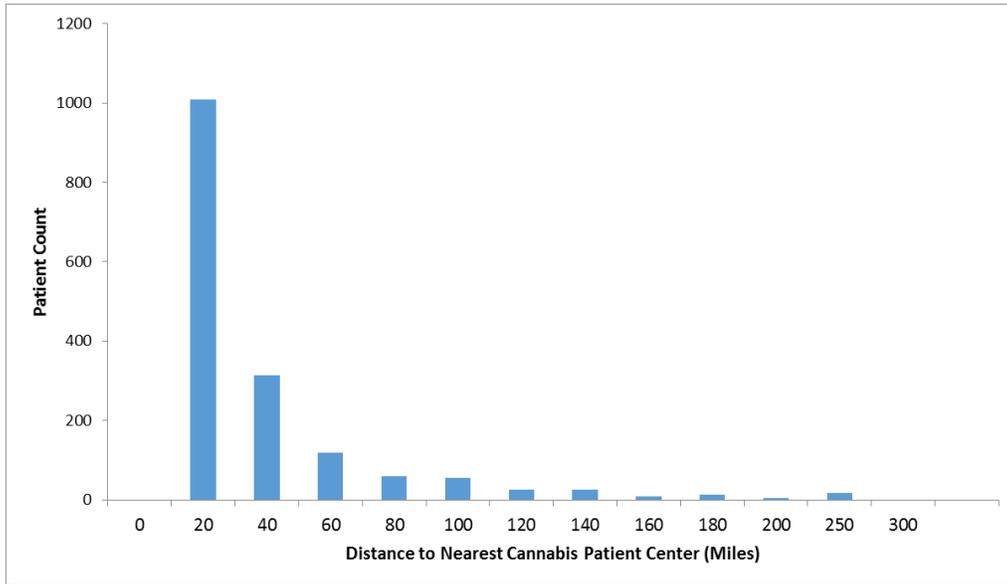

Table 2.7. Geographic distribution of patients by ZIP code prefix.

Region	ZIP Code Range	Patient Count (%)
St Paul	55000-55199	561 (34%)
Minneapolis	55300-55599	671 (40%)
Duluth	55600-55899	59 (4%)
Rochester	55900-55999	104 (6%)
Mankato	56000-56199	63 (4%)
Willmar	56200-56299	49 (3%)
St Cloud	56300-56399	80 (5%)
Brainerd	56400-56499	27 (2%)
Detroit Lakes	56500-56599	28 (2%)
Bemidji	56600-56699	11 (1%)
Grand Forks*	56700-56799	7 (0%)

Note: The Grand Forks region, corresponding to ZIP codes with a 567 prefix, refers to a region including Grand Forks, South Dakota, as well as several ZIP codes located in Minnesota near the western border. Patients living in this region reside in Minnesota.

Two medical cannabis manufacturers each operate four cannabis patient centers where patients can purchase medical cannabis following consultation with pharmacy staff at the center. Minnesota law required that one cannabis patient center be open in each of Minnesota’s eight legislative districts by July 1, 2016 (one year after the program start date). Figure 2.4 shows the distribution of calculated one-way distance from each patient’s home address to the nearest cannabis patient center location as of July 1, 2016, when all eight centers were operational. Average one-way distance is 28.9 ± 36.9 miles; median one-way distance is 15.5 miles. The majority of patients (n=1441; 86.8%) live within 60 miles of the nearest cannabis patient center.

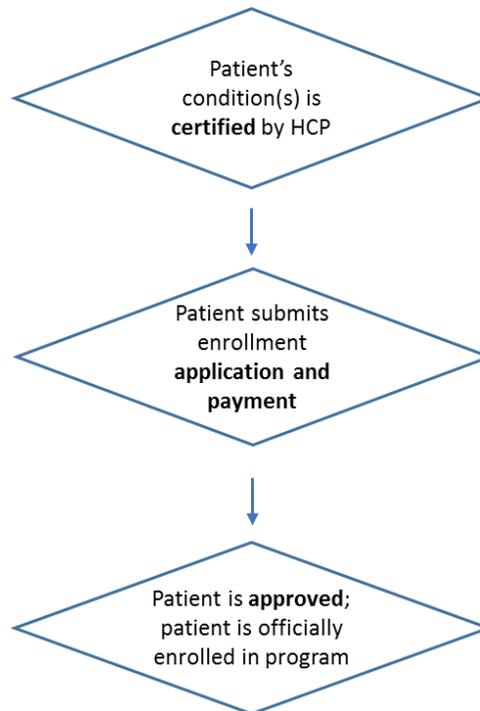

Figure 2.4. Distribution of one-way distance from patient home to nearest cannabis patient center.

From Certification to Program Approval: How Long Does it Take for Patients?

A sequential series of steps are followed in order to move patients from certification by a healthcare practitioner to their enrollment in Minnesota’s Medical Cannabis program. First, patients must have at least one medical condition that qualifies for the program and must have that condition certified by a registered health care practitioner (HCP). After their medical condition is certified, patients have 90 days to submit a complete application to enroll in the program. Patients must also submit payment to cover the annual enrollment fee along with their application materials. Once the application and enrollment fee are submitted, Office of Medical Cannabis (OMC) staff reviews and verifies all submitted materials and can approve the patient for the program. Figure 2.5 depicts the process flow from certification to program approval:

Figure 2.5. Flow chart of enrollment events.

To give current and prospective patients some idea of the time it takes to go from certification to program approval, records from patients in the first program year cohort (n = 1660) were analyzed at different time points: 1) time between certification to program approval, 2) time between certification to enrollment payment, and 3) time between enrollment payment and program approval.

Time from Certification to Program Approval

Just over half of all patients (54.7%) in the cohort (n = 1660) were approved/enrolled in the program within 3 days of having their condition(s) certified. Close to 90% (1484 out of 1660 patients) were enrolled in the program within a month of being certified.

Time from Certification to Annual Enrollment Fee Payment

Records of enrollment fee payments were unavailable for patients who did not make an electronic payment; therefore, calculations of time between certification and enrollment fee payment was restricted to 1579 patients (95.1% of patients in the cohort represented) who paid the enrollment fee electronically. Of these patients, 57.2% of them (n = 903) submitted payment within 1 day of getting their qualifying condition(s) certified by their HCP. More than 90% of patients (n = 1452) submitted payment within one month of certification.

Time from Annual Enrollment Fee Payment and Program Approval

Records of enrollment fee payments were not available for all patients in the cohort; therefore, calculations of time between enrollment fee payment and program approval was restricted to 1579 patients (95.1% of patients in the cohort represented). Of these patients, 72.7% of them (n = 1148) were approved for the program (officially enrolled in the program) within a day of submitting their annual enrollment fees. Close to all patients (99.3%) were enrolled in the program within a month of submitting their annual enrollment fees. The small proportion of patients who do not get approved within a month of their fee submission generally reflects patients who submitted inadequate or incomplete information during the enrollment submission process (meaning that the Office of Medical Cannabis is waiting for additional information to approve them for the program).

From Certification to Program Approval: Conclusions

Just over half of all patients in the cohort were officially enrolled in the program within three days of being certified. Within a week of certification, 70% of patients were enrolled in the program. This suggests that the majority of patients move relatively quickly from certification to enrollment in the program.

When breaking down the process flow between certification and program approval, it typically took longer for patients to move from certification to paying the enrollment fee than it did from their paying the enrollment fee to getting approved. This generally reflects the nature of the process flow going from certification to paying the enrollment fee: after patients are certified, the patient must self-initiate and complete the submission of all application materials along with payment (involves variable amounts of time to gather all materials and to ensure sufficient funds to make fee payment). This is in contrast to the step between enrollment fee payment and getting approved for the program: patient has submitted all materials and payment by this

point and – unless they are directed otherwise by OMC staff – will get approved for the program in the order their materials were received in the queue.

Re-Enrollment

The Minnesota medical cannabis program requires by statute that once a patient becomes certified as having a qualifying condition and enrolled in the program, the patient's enrollment lasts for one year; therefore each year a patient must be re-certified as having at least one qualifying condition and must re-enroll in the program and pay an annual enrollment fee. If a patient is not re-certified as having a qualifying condition and does not re-enroll in the program by the anniversary date of the most recent enrollment, their account is deactivated and they are no longer able to purchase medical cannabis from a cannabis patient center or retain the protections of the program. To investigate the rate at which enrolled patients who approach their expiration dates re-enroll in the program, patients who enrolled in the program during the first program month (including those who were approved early, prior to the program start in July 2015) were examined. A total of 253 patients were enrolled in the first program month; these patients' enrollments expired in July 2016. Re-enrollment activity for these patients was examined six months following expiration of the first enrollment year. Within six months following the expiration of the first year of enrollment, 115 (45%) among these patients re-enrolled in the program. Of the remaining 138 patients who did not re-enroll during this period, 24 patients (17%) died within 18 months of initial enrollment. Additionally, patients can re-enroll at any time following expiration, and some patients who did not re-enroll immediately may do so at a later time.

Most patients who re-enrolled within six months of expiration did so prior to expiration (44%) or within the first month after enrollment expiration (40%). Only 3% of these patients re-enrolled beyond three months post expiration. Timing of re-enrollment for patients who initially enrolled during the first program month are shown in Table 2.8.

Table 2.8. Timing of program re-enrollment for patients enrolled in the first program month.

Time Re-Enrollment Occurred	Patient Count (%)
Prior to Expiration	51 (44%)
1st Month After Expiration	46 (40%)
2nd Month After Expiration	0 (0%)
3rd Month After Expiration	15 (13%)
4th Month After Expiration	1 (1%)
5th Month After Expiration	2 (2%)
6th Month After Expiration	0 (0%)
<i>Total Count of Patients Re-enrolled Within 6 Months of Annual Expiration Date</i>	<i>115</i>

Note: Among the 253 patients who enrolled in the program in July 2015, 115 (45%) re-enrolled within six months of expiration. Percentages are based on a total number of re-enrollments within this period (n=115).

At the time of enrollment expiration, a patient can allow their enrollment to lapse without any action or communication with the Office of Medical Cannabis. Currently OMC does not collect information systematically on why patients chose to either re-enroll or let their current enrollment expire. However, some insight into program discontinuation is available from a Continued Use survey, which asks patients who have not purchased medical cannabis for 60 days whether they have decided to stop the treatment, whether they received any benefits from the treatment, and what their reasons are for either stopping or pausing the treatment. Early results looking at patients who purchased medical cannabis within the first three program months but discontinued purchasing for 60 days showed that 62% (n=10) of patients who indicated they planned to stop using medical cannabis (n=16) found little or no benefit from the treatment. Among 59 patients who indicated they were unsure of whether they would continue or that they intended to continue the treatment, 35 (73%) cited cost as a barrier to continuing. These results do not directly answer the question of why some patients do not re-enroll but give some indication of potential reasons for doing so. (For methodology and preliminary results from the Continued Use survey, see [“Early Results of Office of Medical Cannabis Surveys: May 2016”](#) on the [Office of Medical Cannabis](#) website).

3. Health Care Practitioners Registered in the First Program Year

The Minnesota Medical Cannabis program outlines a set of qualifying medical conditions which make a patient eligible for enrollment in the program. By Minnesota statute, a patient must be certified by a Minnesota-licensed physician, physician assistant (PA), or advanced practice registered nurse (APRN) as having one or more of the qualifying conditions. A Minnesota practitioner with appropriate credentials must first register with the Minnesota Medical Cannabis program before they can certify patients for the program: practitioners complete a short online form with their name and clinic information to register. Office of Medical Cannabis staff verify the provider's entered information and their Drug Enforcement Agency (DEA) license prior to approving the practitioner to certify patients. This chapter will describe the certifying healthcare practitioners who registered in the first program year.

Healthcare Practitioner Count, Age and Gender

From July 2015- June 2016, 577 healthcare practitioners licensed in Minnesota registered in the medical cannabis program, including 473 physicians (82%), 77 APRNs (13%) and 27 PAs (5%). Table 3.1 shows the breakdown of healthcare practitioner (HCP) type, gender and average age, based on publicly available data from the Boards of Medical Practice and Nursing. Physicians registered in the program were predominantly male (72%) and were generally older than registered APRNs and PAs, who were predominantly female (88% and 78%, respectively).

Figure 3.1. Count of registered healthcare practitioners during the first program year.

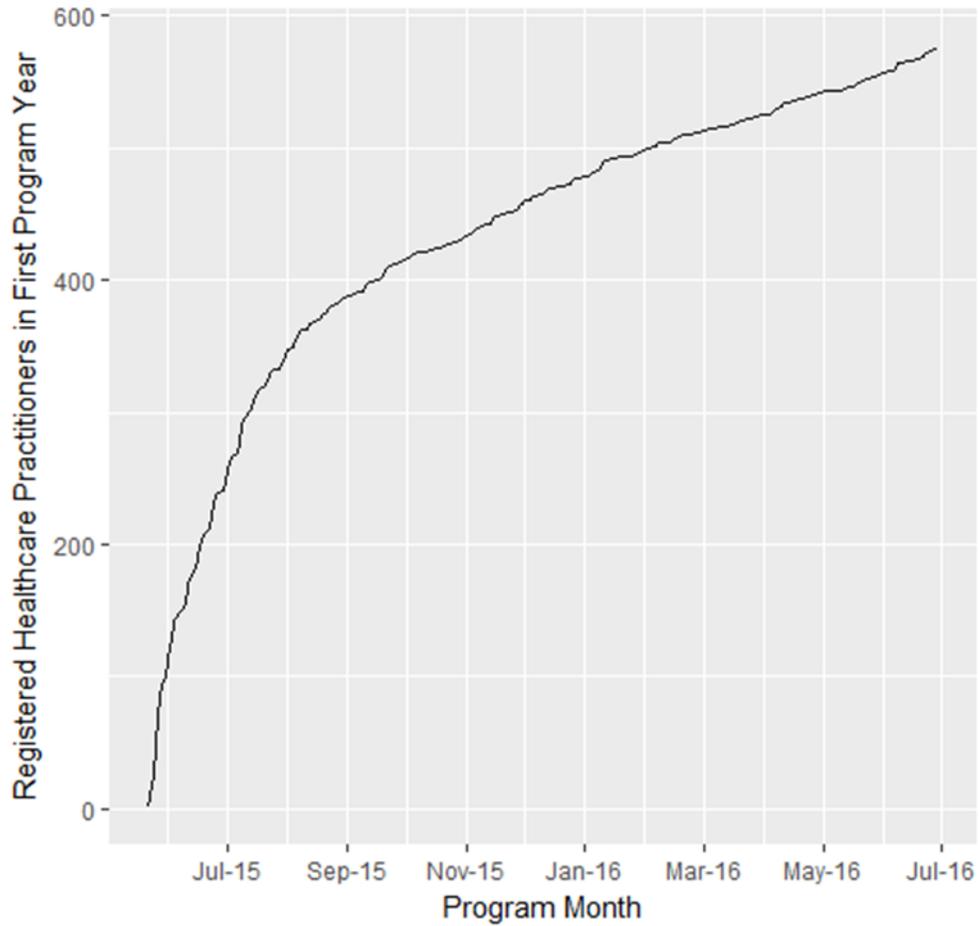

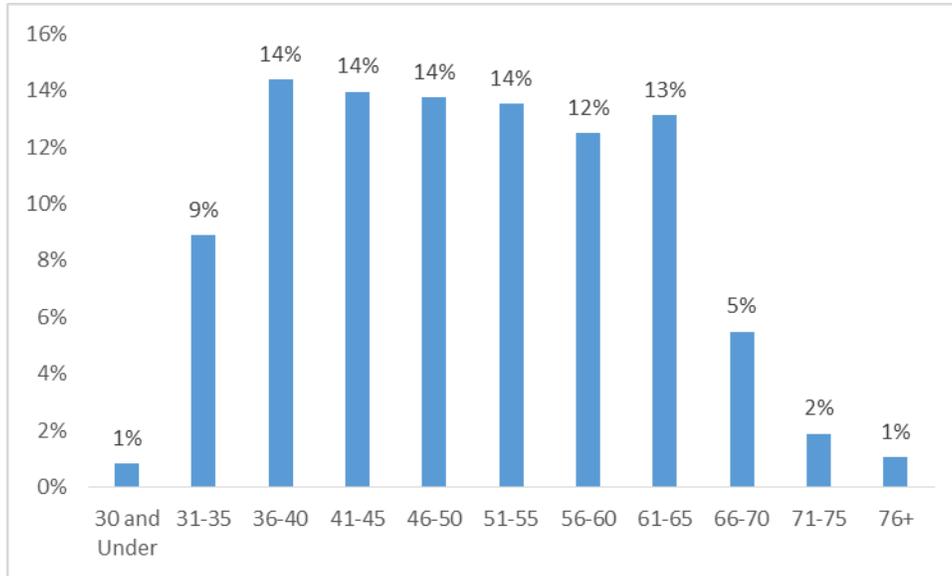

Table 3.1. Healthcare practitioner by type, with gender and average age.

HCP TYPE	N	%	MALE: N (%)	MEAN AGE (SD)
Physician	473	82%	341 (72%)	50.3 (11.3)
APRN	77	13%	9 (12%)	47.0 (9.4)
PA	27	5%	6 (22%)	39.9 (9.5)
Total	577	100%	356 (62%)	49.4 (11.2)

Note: Age data was unavailable for 17 APRNs and three physicians.

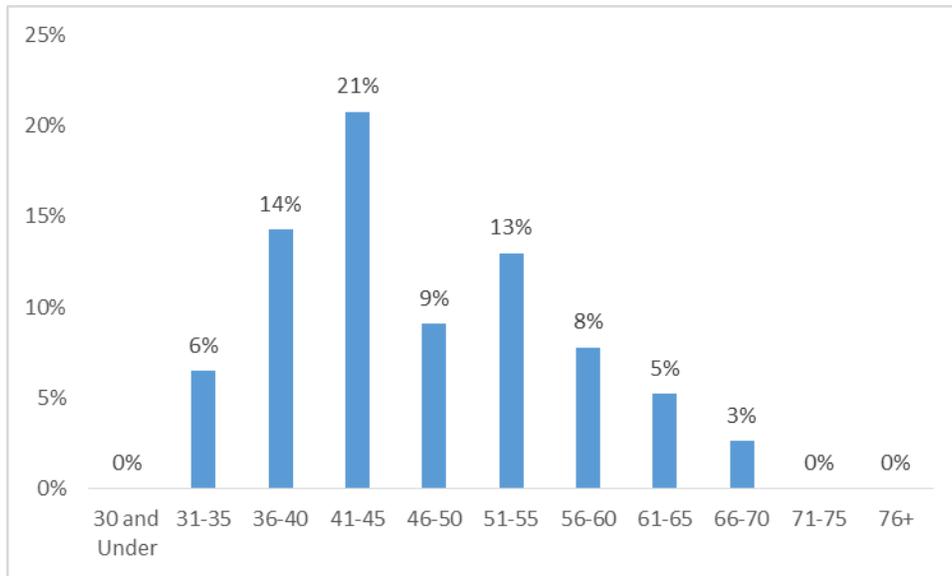

More detailed representations of age distribution among registered physicians, PAs and APRNs are available in Figures 3.2-3.4. Figure 3.2 shows the age distribution in 5 year increments of physicians enrolled in the first program year; most physicians fall between ages 36-65 years (81%) with relatively even distribution of numbers across this range. Figure 3.3 shows the age distribution for APRNs; 51% of APRNs are 50 years or under. Figure 3.4 shows the age distribution for PAs registered in the program; most PAs fall between ages 31-45 (78%).

Figure 3.2. Age distribution of physicians registered in the medical cannabis program (n=473).

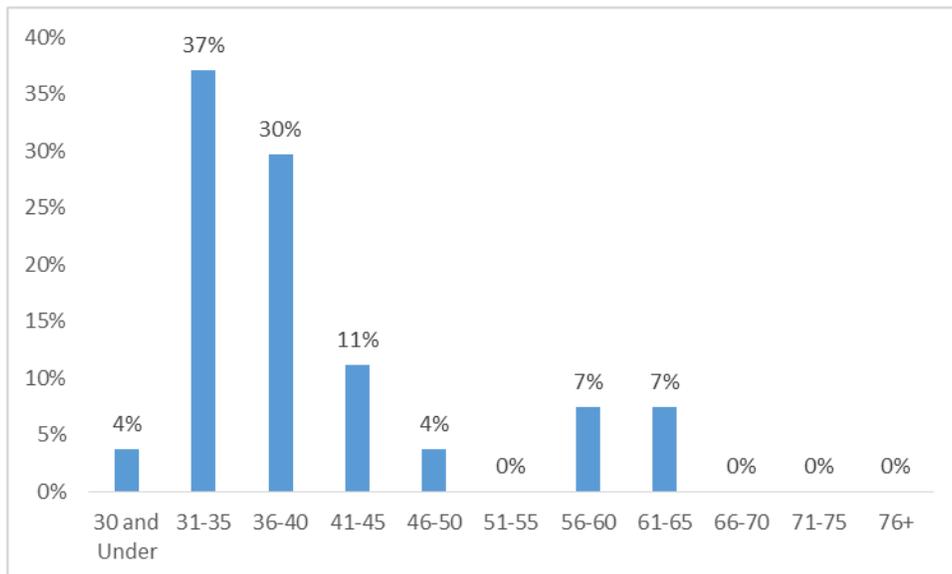

Note: Age data was not publicly available for three physicians registered in the first program year.

Figure 3.3. Age distribution of advanced practice registered nurses registered in the medical cannabis program (n=77).

Note: Age data was not publicly available for 17 APRNs registered in the first program year.

Figure 3.4. Age distribution of physician assistants registered in the medical cannabis program (n=27).

Registered Physician Specialties and Licensures

The Minnesota Board of Medical Practice lists information on Minnesota-licensed physicians and physician assistants. Included is self-reported “Area of Specialty” information indicating a physician’s (or physician assistant’s) certifications from the American Board of Medical Specialties or American Osteopathic Specialty Boards. While physician assistant specialty information is infrequently provided, physicians often list certifications in more than one area of specialty. For example, physicians practicing as oncologists may list certifications in the areas of Internal Medicine, Hematology, and Medical Oncology. A variety of specialties were represented among physicians registered in the first program year, including subspecialties of neurology (neurology with special qualifications in child neurology, clinical neurophysiology, and epilepsy), pediatrics (pediatric hematology-oncology) and internal medicine or family medicine (gastroenterology, geriatric medicine, hospice and palliative medicine, sports medicine, nephrology, and infectious disease). Specialties including ophthalmology, dermatology, radiology and surgery were also represented. In cases where a physician listed an area of specialty and subspecialty, such as Internal Medicine and Gastroenterology, the subspecialty was chosen to represent the physician’s practice (in this case, Gastroenterology). Table 3.2 shows the distribution of physician specialties; each physician is represented only once. Two physicians who are licensed in Minnesota and registered in the program do not have any listed specialties with the Board of Medical Practice; they are therefore excluded from Table 3.2. The most common specialty category for physicians registered in the first program year was primary care (38%), which included internal medicine (13%), family medicine (23%) and pediatrics (2%). Physicians with specialization in oncology (17%) and neurology (14%) were also common.

Table 3.2. Registered physician specialty categories.

Registered Physician Specialties	N (%)
Primary Care	179 (38%)
<i>Internal Medicine</i>	<i>61 (13%)</i>
<i>Family Medicine</i>	<i>109 (23%)</i>
<i>Pediatrics</i>	<i>8 (2%)</i>
Oncology	81 (17%)
Neurology	65 (14%)
Pediatric Specialty	29 (6%)
Hospice/Palliative Medicine	25 (5%)
Physical Medicine and Rehabilitation	21 (4%)
Gastroenterology	11 (2%)
Psychiatry	10 (2%)
Ophthalmology	9 (2%)
Surgery	8 (2%)
Infectious Disease	6 (1%)
Radiology/Radiation Oncology	5 (1%)
Pain Medicine	5 (1%)
Nephrology	3 (1%)
Geriatric Medicine	3 (1%)
Emergency Medicine	2 (0%)
Rheumatology	2 (0%)

Obstetrics and Gynecology	2 (0%)
Sports Medicine	2 (0%)
Anesthesiology	2 (0%)
Dermatology	1 (0%)
Public Health and Preventive Medicine	1 (0%)
Pulmonary Disease	1 (0%)
Sleep Medicine	1 (0%)

Advanced Practice Registered Nurse Licensures

Advanced practice RNs include licensed Clinical Nurse Specialists (CNS), Certified Registered Nurse Anesthetists (CRNA), Certified Nurse-Midwives (CNM) or Certified Nurse Practitioners (CNP). Among the 77 APRNs who registered in the first program year, 75 held CNP certification, 1 held CNS certification, and 1 held both CNP and CNS certifications.

Summary

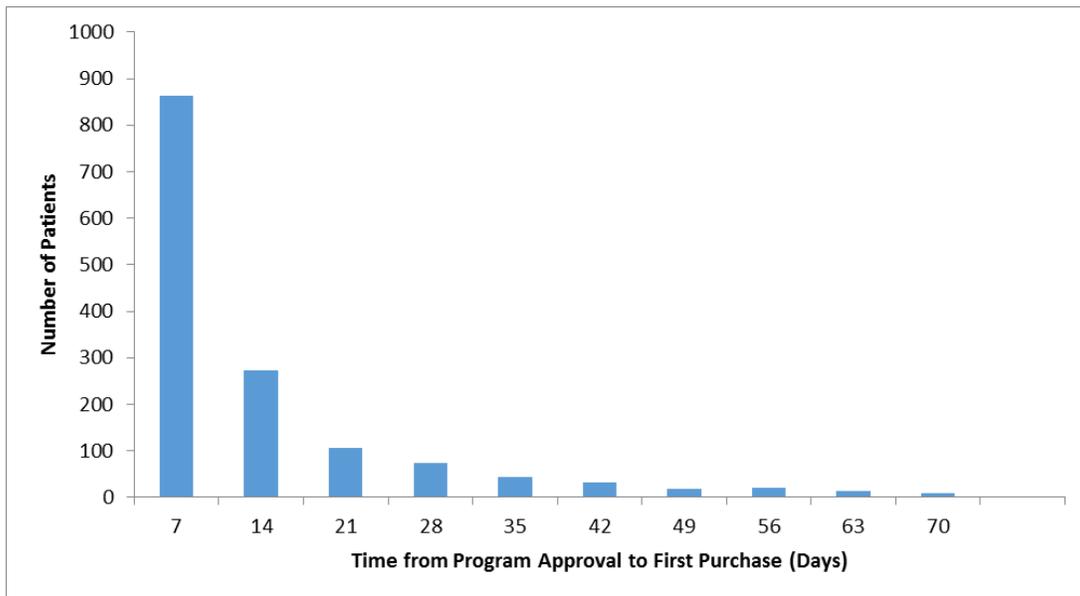

In the first year of the Minnesota Medical Cannabis program, 577 licensed healthcare practitioners registered as certifying providers with the program, predominantly physicians (82%). There were age and gender differences across the HCP types; physicians tended to be older and male; PAs and APRNs tended to be younger and female. Physician licensure information showed that physicians from a diversity of clinical practices are involved in certifying patients for the medical cannabis program, but the majority of these providers are primary care providers or specialties that typically manage patients with the Minnesota program’s qualifying conditions (i.e. severe muscle spasms, seizure disorders, Tourette syndrome and ALS are typically managed by neurologists; cancer is often managed by oncologists).

4. Frequency and Duration of Medical Cannabis Purchases

Time from Program Approval to First Medical Cannabis Purchase

Once a patient is approved for the medical cannabis program, the patient and/or their registered caregiver(s) or parent(s)/legal guardian(s) can visit any of the eight cannabis patient centers and purchase medical cannabis. Figure 4.1 shows the distribution of time from program approval to first medical cannabis purchase for patients enrolled during the first program year who purchased medical cannabis before December 31, 2016 (n=1528). Many patients (n=196; 13%) made a first purchase within one day of program approval; over half (n=864; 57%) made a first purchase within seven days and most patients (n=1137; 74%) made a first purchase within 14 days of program approval.

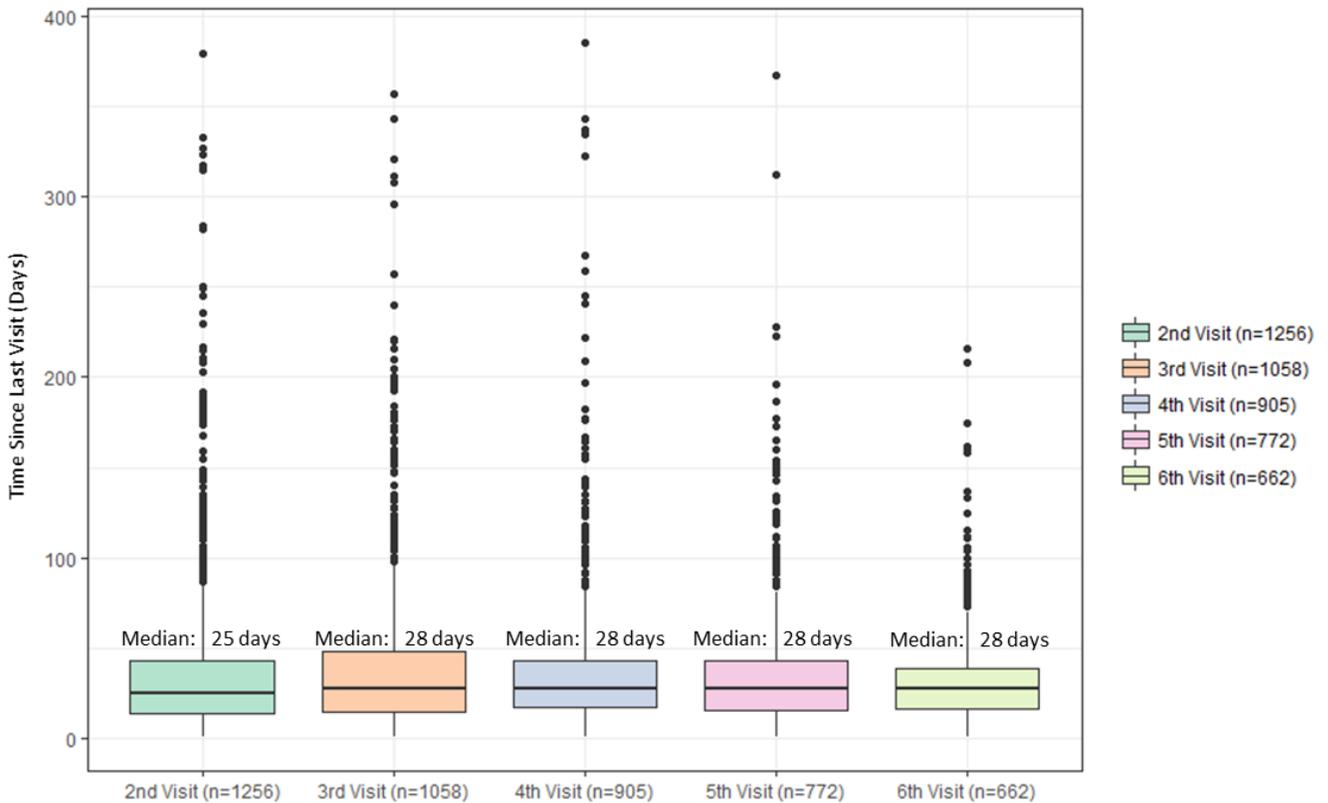

Figure 4.1. Time from patient approval to first medical cannabis purchase.

Time Between Purchases

According to Minnesota statute, patients can purchase up to a 30-day supply of medicine at a cannabis patient center. However, visits to a cannabis patient center vary from 30-day intervals for several reasons. Figure 4.2 shows the intervals between purchases for patients from the one-year cohort with at least two purchases (n=1256). Patients must purchase medical cannabis with cash and many patients report that the medicine's cost is prohibitive; for these reasons, patients may purchase smaller quantities than a month's supply and visit cannabis patient centers more frequently than once a month. On the other hand, many patient responses to the Continued Use Survey (see ["Early Results of Office of Medical Cannabis Surveys: May 2016"](#) on the [Office of Medical Cannabis](#) website) indicated a quantity of medicine intended to be a 30-day supply lasted longer than 30 days, or the patient chose to use the medicine sparingly as a cost-saving measure and therefore the supply lasted longer than anticipated. However, the median times between visits for the first consecutive six visits were close to the expected interval of one month (median time since last visit: 25, 28, 28, 28, and 28 days for the second, third, fourth, fifth and sixth visits, respectively).

Figure 4.2. Time between visits for patients with two or more visits from July 2015-December 2016.

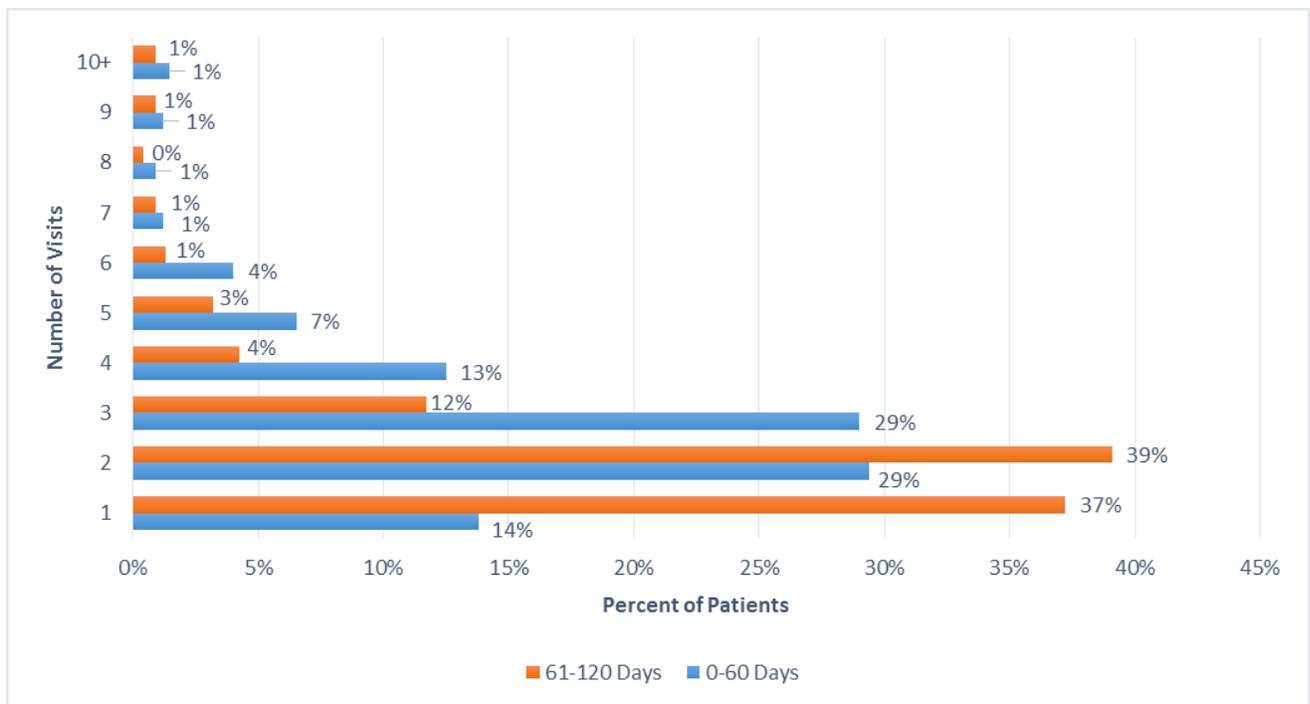

Note on boxplots: upper and lower hinges for each boxplot correspond to the 75th and 25th percentiles of each distribution, respectively. The upper and lower whiskers extend to the highest and lowest values that are within 1.5 x the interquartile range from the upper and lower hinges, respectively. Data beyond the whiskers, plotted as individual points, are outliers.

Purchasing Activity in First Four Months of Program Participation

Patients beginning medical cannabis treatment often try different types of products with varying ratios of THC:CBD and routes of administration to achieve optimal symptom management; therefore patients may be more likely to make more visits to cannabis patient centers at the beginning of treatment and fewer visits in later times once the patient’s regimen had been established. As seen in Figure 4.2, frequency of visits (represented as time between consecutive visits) varies widely across patients. To compare purchasing activity in the first two months versus the second two months of program activity, the number of visits for each patient with continuous enrollment was examined in the first and second 60 days of program activity (day 0 defined as the date of first medical cannabis purchase). Patients who made no

purchases between days 61 and 120 or beyond day 120 were excluded to eliminate patients who had atypical purchasing activity or quit the program during this time window. Figure 4.3 shows the distribution of number of visits per patient which occurred in the first and second 60 days of program activity (n=752). During the first 60 days of program activity, median number of visits was 3 and 543 of 752 patients in this group (72%) made three or fewer purchases. During days 61-120 of program activity, median number of visits was 2 and 662 of 752 patients (88%) made three purchases or less. While the distributions of purchasing activity in the first 60 days and second 60 days is roughly similar, they indicate that purchasing activity is slightly greater during the first 60 days of program activity.

Figure 4.3. Number of visits in first 60 days and second 60 days of program activity, for patients with one or more purchases in both 60 day intervals.

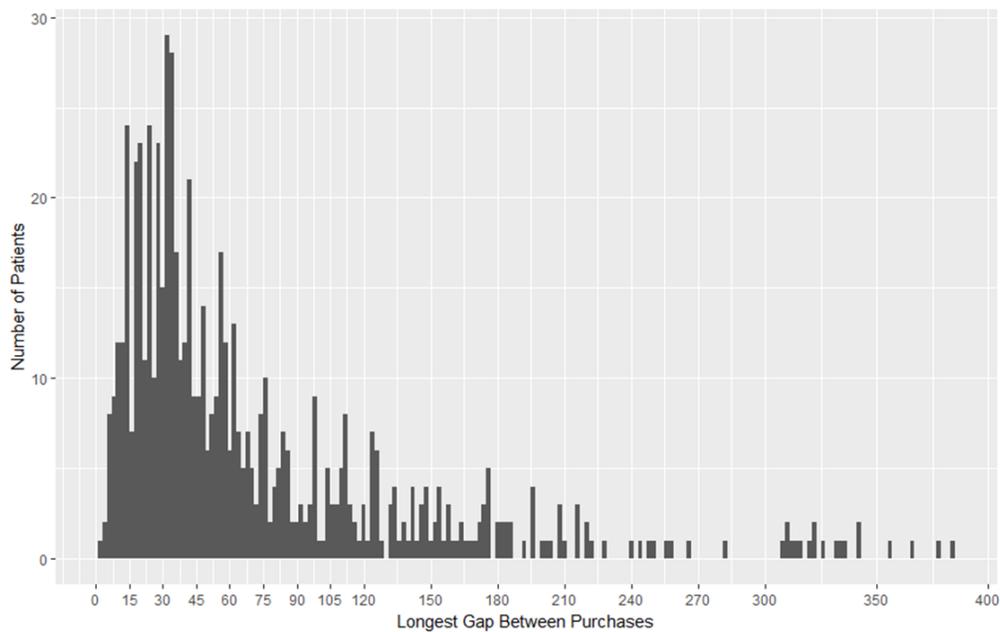

Patients Who Stopped Purchasing Medical Cannabis

Since patients make an annual payment to be enrolled in the medical cannabis program, if they decide at some point during the following year to discontinue medical cannabis treatment, it is unlikely they will request to be withdrawn from the program, as there is no financial incentive to do so. Therefore, to understand discontinuation in the program, a functional definition was created based on purchasing patterns. For each patient in the one year cohort enrolled with a first purchase prior to December 31, 2015 and making at least two purchases before December 31, 2016 (n=669), the longest gap between consecutive purchases from July 2015-December 2016 is shown in Figure 4.4; median longest gap in this group was 47 days. Among these

patients, 546 (82%) had a longest gap between purchases of 120 days or less; 616 (92%) had a longest gap between purchases of 180 days or less. Median longest gap for each patient is significantly longer than median time between visits for patient's first six visits; this suggests that there may be a great deal of variability within a patient's inter-visit times. Early patient responses to the Continued Use survey point to factors which may impact purchasing frequency: unexpectedly low rate of product usage, cost-motivated reduction or temporary cessation of product usage, unrelated medical treatment changes which interfered with cannabis usage, or out-of-state travel.

Figure 4.4. Distribution of longest gap between visits per patient, July 2015-December 2016.

Since most patients (92%) enrolled and purchasing within the first six program months who made two or more purchases by December 31, 2016 had no inter-visit gaps longer than 180 days, program discontinuation was defined for this analysis as ceasing purchasing activity for six months or longer during the period included in this analysis (July 2015-December 2016). This definition was applied to all patients enrolled in the first six program months who made at least one purchase (n=774) to find the proportion of patients (regardless of duration enrolled in the program) who did not make any purchases for at least six months, through the end of 2016. Of these 774 patients making at least one medical cannabis purchase, 398 patients (51%) made no purchases for at least six months, as of December 2016. Based on the distribution of longest gaps between purchases in this subset of the one-year cohort, it is likely that this proportion is

a rough estimate of the proportion of patients who quit the program within 18 months after trying medical cannabis.

Using a six month window with no purchases as a surrogate for program discontinuation has limitations. For example, our analysis did not account for duration of enrollment and any effect it may have on purchasing patterns. However, it gives an approximation of patients who abandon medical cannabis treatment and roughly aligns with the re-enrollment rate of 45% in patients enrolled in the first program month (see “Re-Enrollment” in Chapter 2: Description of Patients and Designated Caregivers).

Frequency and Duration of Medical Cannabis Purchases: Conclusions

Most patients make their first medical cannabis purchase within 14 days of program approval. Subsequent purchases often follow a roughly monthly periodicity, with median inter-visit gap at 25 days for the gap between the first and second visit and 28 days for the next four inter-visit gaps. Additionally, patients tend to make purchases slightly more frequently in the first 60 days of program activity compared to the second 60 days of program activity (median number of visits is 3 from 0-60 days and 2 from 61-120 days). Finally, most patients (92%) do not have an inter-visit gap longer than 180 days; using 6 months or more of no purchasing activity as a surrogate for program discontinuation, 51% of patients who enrolled and made a purchase within the first six months of the program ceased purchasing medical cannabis as of December 31, 2016.

5. Medical Cannabis Use Patterns

Medical cannabis purchasing records were extracted from the registry in early March 2017 for patients enrolled in the 1st program year. From this data, all transactions that occurred within a patient's first enrollment year were retained. For those patients whose first enrollment year had not yet ended at the time of data extraction, all purchasing transactions were retained. This resulted in a dataset with the following:

- 10,898 purchasing transactions consisting of:
- 16,238 products within these transactions (37.9% of all purchasing transactions consisted of two or more products), which
- Represented 1529 patients (92.1% of the first program year cohort).

For analytical purposes, all 16,238 product transactions were classified according to the ratio of delta-9-tetrahydrocannabinol (THC) to cannabidiol (CBD) found in the medical cannabis products. Products ranged from containing very high THC to CBD content to those with very high CBD to THC, as well as everything in between (products with relatively balanced amounts of THC and CBD). For definitions on THC:CBD ratio classifications, see Box 5.1.

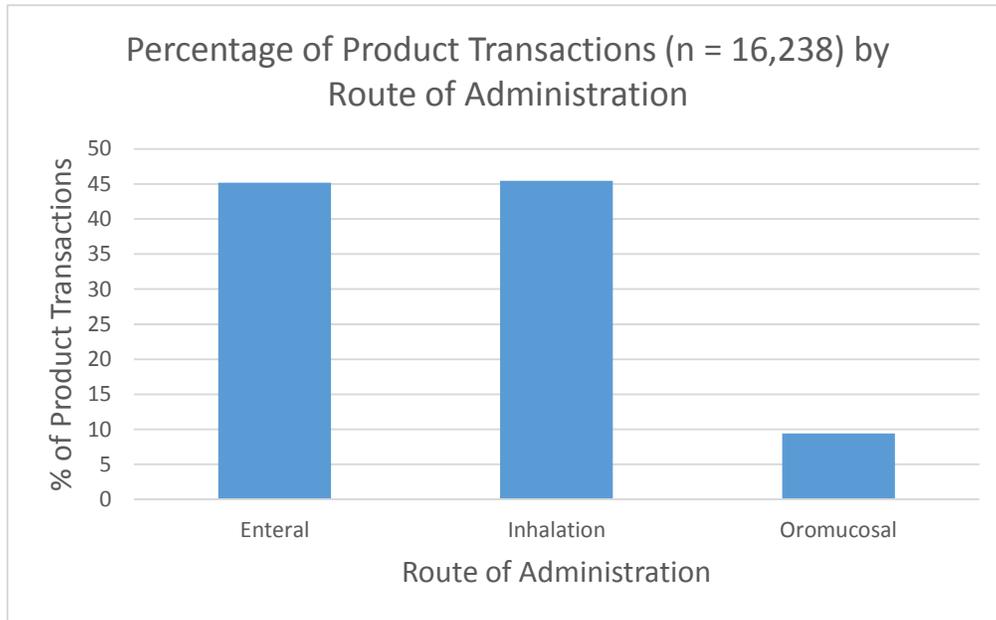

Box 5.1. Definitions to classify medical cannabis products by THC:CBD ratios.

Product Classifications Based on THC to CBD content:

- **Very High THC to CBD** = 100:1 or higher
- **High THC to CBD** = >4:1 up to 99:1
- **Balanced** = 1:1 up to 4:1
- **High CBD to THC** = \geq 1:1 up to 99:1
- **Very High CBD to THC** = 100:1 or higher

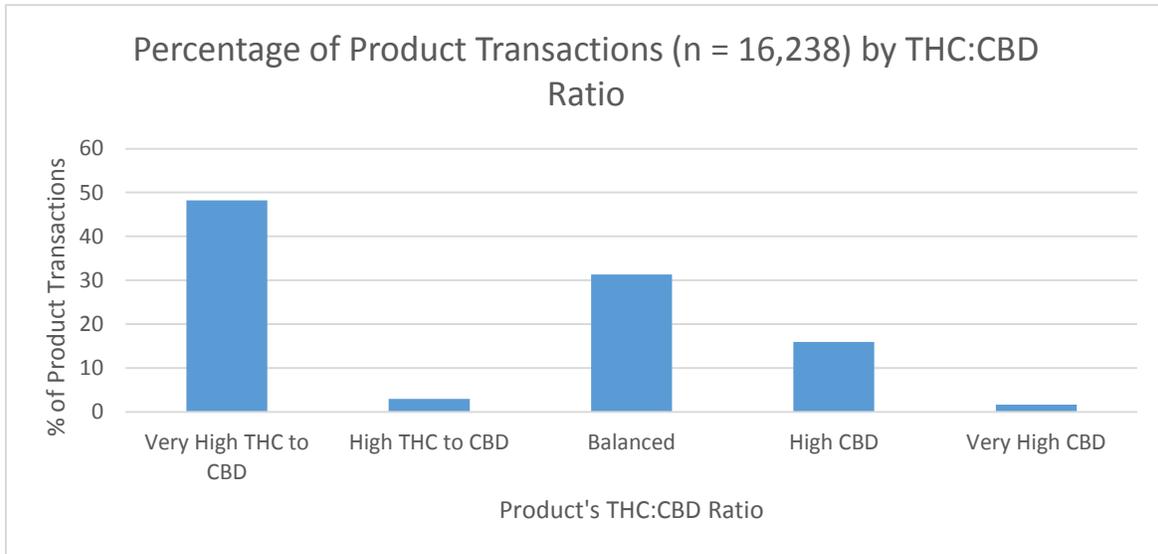

Products purchased for enteral administration (swallowed – includes capsules and oral solutions) and inhalation (vaporized oil) represented the majority of the products purchased (90.6% of all product transactions) with significantly fewer products purchased for oromucosal absorption (oil absorbed through cheek; 9.4% of all product transactions). In fact, products for enteral administration and inhalation were roughly equally purchased by patients, respectively representing 45.2% (n = 7333) and 45.4% (n = 7376) of all products dispensed. See Figure 5.1.

Figure 5.1. Purchasing transactions categorized by the product’s intended route of administration (out of 16,238 products dispensed).

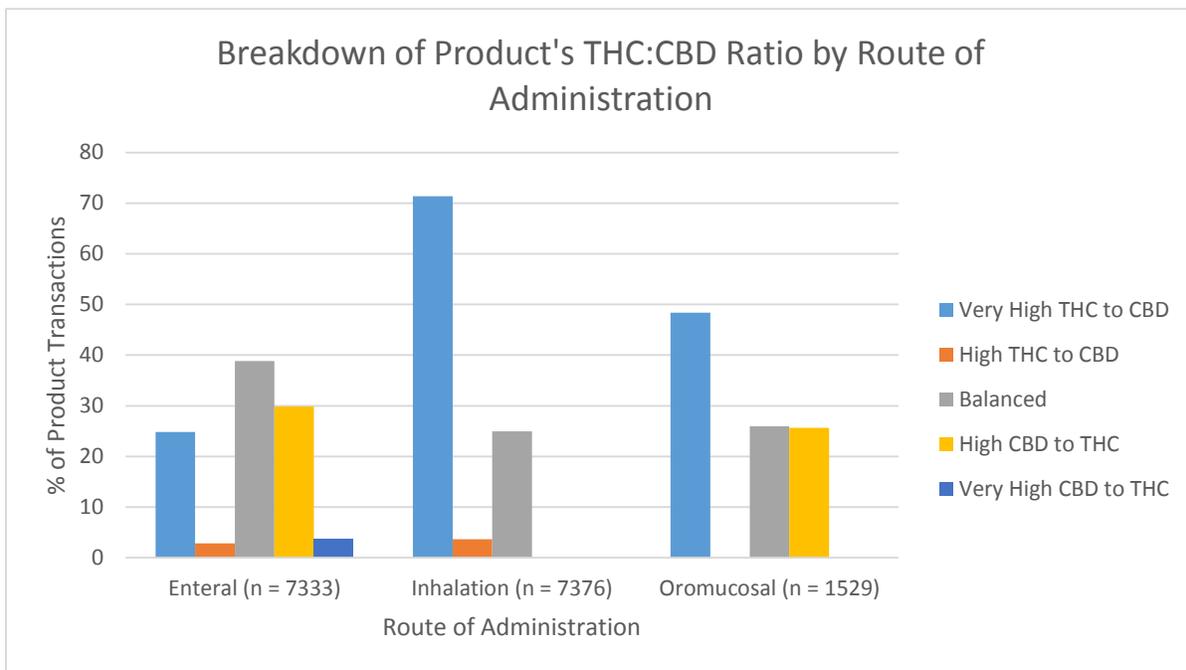

When products were classified by the ratio of THC to CBD present in the product, the following patterns emerged. Firstly, 48.2% of all product transactions were for products with very high THC amounts compared to CBD (hundreds to one). Balanced products (roughly equal amounts of THC to CBD) represented the next biggest group of products purchased, representing 31.3% of products dispensed. This was followed by high CBD to THC products which represented 15.9% of all product transactions. See Figure 5.2.

Figure 5.2. Product transactions represented by the THC to CBD ratio available in the product.

Product transactions were also examined by the products' THC:CBD ratios as a function of their routes of administration (see Figure 5.3). Of all product transactions intended for enteral administration, close to 39% of them were for products with relatively balanced THC:CBD ratios followed by products with high CBD:THC (29.9%) and very high THC:CBD products (24.8%). Product transactions for inhalation predominately had very high THC to CBD (71.4%). Lastly, close to half (48.4%) of all oromucosal product transactions were for very high THC:CBD products, with roughly a quarter each constituting balanced and high CBD to THC products (respectively 26.0% and 25.6%).

Figure 5.3. A percentage breakdown of product transactions by the THC:CBD product ratio types as a function of route of administration.

Most Frequently Purchased Product(s)

Examining purchasing history across all patients is very complex. For example, patients may experiment with different products as they explore what works best for them, and some may establish a pattern of using more than one product. Additionally, those using more than one product do not always purchase all of those products at each purchasing transaction. As a first approach to assessing routine use of products, we report here the product(s) most frequently purchased by each patient. Table 5.1 shows the product(s) that were identified as the most frequently purchased by patients (indicated by “X”), as well as the percentage of patients it represents from the 1529 patients included in this analysis. Additionally, the table displays the average daily THC and CBD dose across patients for the product(s) purchased most frequently based on THC/CBD content information (provided by the medical cannabis manufacturers) as well as pharmacist-entered information regarding the length of time the product supply should last. Omitted from display in Table 5.1 are cases where two or less people had the same combination of most frequently purchased product(s)—this was done for ease of interpretation, as some of those cases seemed to be indicative of a wider range of experimentation across multiple products and/or indicative of patients with a shorter purchasing history.

Table 5.1 shows that roughly 72% of all patients most frequently purchased a single product that falls under 1) a specific THC:CBD ratio and 2) is intended for a particular route of administration (note the rows that have a single “X” in Table 5.1). Roughly a quarter of all patients most frequently purchased a very high THC to CBD product intended for vaporization followed by relatively similar numbers of patients most frequently purchasing a single, balanced-enteral product or a single, high CBD:THC-enteral product (respectively 12.6% and 13.7%). For patients most frequently purchasing two or more products an equal number of times, the most common combination was for an enteral-balanced product and an inhaled-very high THC:CBD product, accounting for 3% of all patients.

While the subsequent portions of this section will be devoted to stratifying routine product use by qualifying condition, the following statement should be made: the method for determining routine product use in this report (most frequently purchased) is relatively simple and, therefore, poses limitations for understanding the complexities in medication usage. Future endeavors will include a further discussion and potential refinement in methodology to better capture medical cannabis use in program participants

Table 5.1. Product(s) most frequently purchased by each patient (out of 1529 patients), along with average daily THC/CBD dose (mg).

Severe and Persistent Muscle Spasm Patients

Of the 1529 patients represented in this analysis, 44.3% (677) of them were certified as having Severe and Persistent Muscle Spasms, including those Characteristic of Multiple Sclerosis. Table 5.2 shows the product(s) that were identified as the most frequently purchased by muscle spasm patients (indicated by “X”), as well as the percentage of patients it represents from the 677 patients included in this analysis.

The most frequently purchased product for the majority of patients (70.2%) was a single product with a specific THC:CBD ratio and route of administration. The most common product purchased was a very high THC:CBD-inhaled product (32.3% of all patients) followed by a balanced-enteral and balanced-inhaled product (16.7% and 7.2%, respectively). For patients who purchased multiple products most frequently an equal number of times, the most common combination purchased was for a very high THC:CBD-inhaled product and a balanced-enteral product, accounting for 4.3% of all patients.

Table 5.2. Product(s) most frequently purchased by each muscle spasm patient (out of 677 patients), along with average daily THC/CBD dose (mg).

		X	X		X		X			X		X			0.1 (1)	161.6 mg / 848.6 mg

Cancer Patients

Of the 1529 patients represented in this analysis, 26.6% (406) of them were certified for Cancer. Table 5.3 shows the product(s) that were identified as the most frequently purchased by cancer patients (indicated by “X”), as well as the percentage of patients it represents from the 406 patients included in this analysis.

The majority of patients (61.6%) most frequently purchased a single product with a specific THC:CBD ratio and route of administration. Most commonly purchased products were a very high THC:CBD-inhaled product (23.9% of all patients) followed by a balanced-enteral and very high THC:CBD-oral mucosal product (10.3% and 9.6%, respectively). For patients who purchased multiple products most frequently an equal number of times, the most common combination purchased was for a very high THC:CBD product – one for enteral administration and one for inhalation (accounted for 5.4% of all patients).

Seizure Patients

Of the 1529 patients represented in this analysis, 19.8% (303) of them were certified for Seizures, including those Characteristic of Epilepsy. Table 5.4 shows the product(s) that were identified as the most frequently purchased by seizure patients (indicated by “X”), as well as the percentage of patients it represents from the 303 patients included in this analysis.

89.1% of all patients most frequently purchased a single product with a specific THC:CBD ratio and route of administration. Most commonly used products were a high CBD:THC-enteral product (59.7% of all patients) followed by a very high THC:CBD-inhaled product and high CBD:THC-oral mucosal product (7.9% and 5.0%, respectively).

Table 5.4. Product(s) most frequently purchased by each seizure patient (out of 303), along with average daily THC/CBD dose (mg).

Crohn's Disease Patients

Of the 1529 patients represented in this analysis, 6.7% (103) of them were certified for Crohn's Disease. Table 5.5 shows the product(s) that were identified as the most frequently purchased by Crohn's patients (indicated by "X"), as well as the percentage of patients it represents from the 103 patients included in this analysis.

71.8% of all patients most frequently purchased a single product with a specific THC:CBD ratio and route of administration. Most commonly used products were a very high THC:CBD-inhaled product (28.2% of all patients) followed by a balanced-enteral and balanced-inhaled product (16.5% and 8.7%, respectively). For patients who purchased multiple products most frequently an equal number of times, the most common combination identified was for a balanced-enteral product and a very high THC:CBD-inhaled product, accounting for 4.9% of all patients.

Table 5.5. Product(s) most frequently purchased by each Crohn’s Disease patient (out of 103 patients), along with average daily THC/CBD dose (mg).

Terminal Illness Patients

Of the 1529 patients represented in this analysis, 5.4% (82) of them were certified for Terminal Illness. Table 5.6 shows the product(s) that were identified as the most frequently purchased by terminal illness patients (indicated by “X”), as well as the percentage of patients it represents from the 82 patients included in this analysis.

68.3% of all patients most frequently purchased a single product with a specific THC:CBD ratio and route of administration. Most commonly used products were a very high THC:CBD-inhaled product (26.8% of all patients) followed by a balanced-enteral and balanced-orumucosal product (both respectively accounting for 8.5% of all patients). For patients who purchased multiple products most frequently an equal number of times, the most common combination identified was for a very high THC:CBD product – one for enteral administration and the other for oromucosal absorption (accounted for 3.7% of all patients).

Table 5.6. Product(s) most frequently purchased by each terminal illness patient (out of 82 patients), along with average daily THC/CBD dose (mg).

HIV/AIDS Patients

Of the 1529 patients represented in this analysis, 3.2% (49) of them were certified for Human Immunodeficiency Virus and/or Acquired Immune Deficiency Syndrome (HIV/AIDS). Table 5.7 shows the product(s) that were identified as the most frequently purchased by HIV/AIDS patients (indicated by “X”), as well as the percentage of patients it represents from the 49 patients included in this analysis.

75.5% of all patients most frequently purchased a single product with a specific THC:CBD ratio and route of administration. Most commonly used products were a very high THC:CBD-inhaled product (51.0% of all patients) followed by a balanced-enteral product (12.2% of patients). For patients who purchased multiple products most frequently an equal number of times, the most common combination identified was for two inhaled products – one of a very high THC:CBD ratio and the other a balanced THC:CBD ratio (accounted for 10.2% of all patients).

Table 5.7. Product(s) most frequently purchased by each HIV/AIDS patient (out of 49 patients), along with average daily THC/CBD dose (mg).

										X		4.8 (1)	28.4 mg / 28.4 mg

Medical Cannabis Use Patterns: Conclusions

To establish medication use patterns in program participants, a total of 16,238 product transactions were analyzed from 1529 patients in the 1st program year cohort. When product transactions were examined by each product's intended route of administration and THC:CBD content, the following patterns emerged. Firstly, roughly 90% of all products were purchased for enteral administration (through mouth via capsules or oral solutions) and inhalation (vaporized oil). Secondly, approximately 50% of all product transactions were for products very high in THC relative to CBD followed by balanced THC:CBD products (~30%) and high CBD:THC products (~15%). Very high THC:CBD products were most commonly purchased for inhalation or oromucosal absorption, while balanced and high CBD:THC products were most commonly used for enteral administration.

For this report, the most frequently purchased product(s) were identified for each patient as one method for understanding routine purchasing patterns. 72.5% of all patients most frequently purchased one type of product, with the most frequently purchased single product being a very high THC:CBD-inhaled product followed by a high CBD:THC-enteral and balanced-enteral product. For specific differences in the most frequently purchased products among qualifying conditions, the reader is encouraged to refer back to those specific sections.

6. Benefits

Summary

Information on patient benefits comes from the Patient Self-Evaluation (PSE) completed by patients prior to each medical cannabis purchase and from patient and health care practitioner surveys. Results of analysis of PSE and survey data indicate perceptions of a high degree of benefit for most patients.

Patients responded to a survey question asking them how much benefit they believe they received from using medical cannabis on a scale from 1 (no benefit) to 7 (great deal of benefit). Across all patients 64% indicated a benefit rating of 6 or 7 and this degree of benefit was indicated by at least half of the patients with each medical condition (see Table 6.1). A small but important proportion of patients indicated little or no benefit: 9% gave a rating of 1, 2, or 3. When patients were asked what the most important benefit was for them, two-thirds indicated a reduction in symptoms directly related to their qualifying medical condition and most of the remainder indicated more general quality of life benefits.

An important part of this report is the verbatim comments written by patients, and the reader is encouraged to review these comments in *Appendix A: Patient-Reported Benefits from Surveys*. Examples of these comments include:

- “Almost all muscle spasm and pain associated with spasms are gone. I used to have constant nerve triggered pain that is minimal now. Results were almost immediate. I am sleeping way better now also.”
- “[NAME] has passed away. I am her daughter and was her care giver. She was open to trying medical cannabis and we got the liquid form. It was a saving grace. She was in a lot of pain and when prescribed medications did NOT work – we started this and it kept her calm and relaxed. I am very thankful that we were able to have this option available. It helped to make her last months more bearable and truly it would have been miserable without it.”
- “I am getting enough sleep for the first time since about 2011. My absence seizures have gone from 3-4 a day to almost 0. It also has lessened the severity of grand mal seizures. The recovery time after has gone from around 12 hours to around 4.”
- “At first it helped a lot but my seizures have returned.”
- “Spasms – only a little better.”

Table 6.1. Patient-perceived benefit (n=792).

	No Response	1	2 or 3	4 or 5	6 or 7
All Patients	4%	4%	5%	23%	64%
Muscle Spasms	2%	3%	3%	22%	69%
Cancer	5%	5%	6%	21%	64%
Seizures	5%	5%	9%	29%	51%
Crohn's Disease	0%	2%	5%	22%	71%
Terminal Illness	11%	3%	3%	13%	71%
HIV/AIDS	4%	0%	8%	8%	79%
Tourette Syndrome	6%	0%	0%	25%	69%
Glaucoma	23%	8%	0%	0%	69%
ALS	9%	9%	0%	18%	64%

Patient responses about degree of benefit experienced: 1=no benefit; 7=great deal of benefit.

Health care practitioners were somewhat more conservative in assessment of benefit to their patients. Across all the benefit ratings by health care practitioners, 38% indicated a rating of 6 or 7 and 23% indicated little or no benefit (rating of 1, 2, or 3). Similarity in benefit assessment between health care practitioners and patients appears to vary by medical condition, with highest discrepancy among seizure patients. Descriptive comments suggest at least part of the difference is driven by perspective of what constitutes benefit. The patients cite quality of life benefits more often than the health care practitioners, who appear to focus more on objective measures such as seizure counts.

The symptom scores provided in the Patient Self-Evaluation data have the advantage of completeness, since they are required prior to each medical cannabis purchase. In this report a reduction of $\geq 30\%$ was applied to most symptoms to indicate clinically meaningful symptom reduction. In the text of the report, we present results for the more conservative of the two methods used to calculate $\geq 30\%$ symptom reduction. However, *Appendix D: Symptom Results*

from the Patient Self-Evaluation shows results for both methods (details can be found in this chapter). Results show patterns similar to those in the survey benefits rating, but usually somewhat smaller in size. For example, among patients with muscle spasms, weekly muscle spasm frequency was reduced $\geq 30\%$ within the first four months of medical cannabis use in 48% of patients (see Table 6.2). Importantly, in the four months after first achieving this degree of spasm reduction, more than half the patients retained this degree of improvement. That is, of all patients with muscle spasms, 48% achieved $\geq 30\%$ reduction in spasm frequency and 28% both achieved that degree of improvement and retained it over the next four months. Full results for symptom improvement analyses and for persistence of improvements are in *Appendix D: Symptom Results from the Patient Self-Evaluation*. Results for selected symptoms are presented in Table 6.2. For most symptoms, between half and two-thirds of patients who achieve clinically meaningful improvement retained that degree of improvement over the next four months.

Examples of proportion of patients achieving and retaining $\geq 30\%$ symptom reduction include:

- Among seizure patients, 68% reported $\geq 30\%$ reduction in seizure frequency and 49% both achieved that level of reduction and retained it, on average, for at least four months
- Among patients with Tourette syndrome, 61% reported $\geq 30\%$ reduction in tic frequency and 46% both achieved that level of reduction and retained it, on average, for at least four months
- Among patients with Crohn's disease, 51% reported $\geq 30\%$ reduction in number of liquid stools per day and 29% both achieved that level of reduction and retained it, on average, for at least four months
- Among patients with severe, persistent muscle spasms, 48% reported $\geq 30\%$ reduction in spasm frequency and 28% both achieved that level of reduction and retained it, on average, for at least four months
- Among cancer patients with at least moderate levels of nausea when they started using medical cannabis, 38% reported $\geq 30\%$ reduction of nausea and 23% both achieved that level of reduction and retained it, on average, for at least four months
- Among cancer patients with at least moderate levels of pain when they started using medical cannabis, 29% reported $\geq 30\%$ reduction of pain and 12% both achieved that level of reduction and retained it, on average, for at least four months

Moderate to severe levels of non-disease-specific symptoms such as fatigue, anxiety, and sleep difficulties were common across all the medical conditions. And the reductions in these symptoms was often quite large. These findings support the understanding that some of the benefit perceived by patients is expressed as improved quality of life.

The type(s) of medical cannabis used at the time patients achieved clinically meaningful improvement was analyzed for each symptom assessed within each category of medical condition. Full results of those analyses are in *Appendix D: Symptom Results from the Patient Self-Evaluation* and summaries are presented in this chapter. In most cases, a few combinations

of product types were purchased more frequently than others when analyzing data by patient condition

Table 6.2 Symptom improvement for selected symptoms. Note: for spasticity, pain, appetite, nausea, and vomiting the analysis was conducted on patients with moderate to severe symptoms at baseline.

	% of Patients who Achieved Threshold Symptom Improvement (≥30% Improvement Unless Otherwise Noted)	% of All Patients that Both Achieved Threshold Symptom Improvement and Retained that Degree of Improvement for at Least 4 Months
MUSCLE SPASMS		
Weekly spasm frequency (n = 629)	48%	28%
Spasticity (n = 618)	36%	17%
Pain (n = 640)	34%	17%
CANCER		
Pain (n = 356)	29%	12%

Weekly tic frequency (n = 28)	61%	46%
GLAUCOMA (see text)		
ALS		
Weekly spasm frequency (n = 18)	33%	22%
Spasticity (n = 15)	20%	20%
Pain (n = 17)	47%	12%

Benefits Reported on Surveys

In addition to collecting data on severity of symptoms related to each patient's qualifying condition or conditions before each medical cannabis purchase, the Office of Medical Cannabis sought to gain a qualitative understanding of patient-reported benefits and harms of program participation. Utilizing expertise within the Minnesota Department of Health, the Office of Medical Cannabis developed a Patient Experience survey, which captures information on benefits and harms of program participation. A parallel survey was developed for each patient's certifying health care practitioner, which captures similar information from the clinician's perspective. The surveys include scaled response and open-response questions; health care practitioners were also asked to provide any clinical observations they noted about the patient's experience with medical cannabis. Healthcare providers familiar with the program provided feedback as part of the development process.

Survey Methodology and Data Preparation

The surveys are provided through an online platform with a hard copy alternative. The Patient Experience survey is sent three months after the patient's first medical cannabis purchase, six months after the first purchase and every six months thereafter. Healthcare practitioner surveys are sent six months after the patient's first purchase and every six months thereafter. Surveys are accessible through the patient or healthcare practitioner's registry page and through introductory emails containing unique links. To maximize survey submission rates, the survey can be submitted with incomplete responses to any of the questions. Each of the surveys is available online to the recipient for 45 days. Patient recipients receive reminder emails after one week; after two weeks with no response, paper copies of surveys are mailed to the recipient. For patients without online access the full process is accomplished by mail.

Initially, patient and healthcare practitioners (HCPs) were sent one survey three months after the patient's first purchase, without recurrence. This schedule was revised to include recurring surveys roughly every six months to provide patients and their HCPs an opportunity to report ongoing progress or changes to the patient's condition; however the HCP survey sent three months after the first purchase was eliminated based on feedback that three months may not allow enough time for the provider to see their patient following initial certification. These changes were implemented in April 2016; as a result, HCP survey data collected three months after the first purchase is only available for the first six months of the program (this includes patients who enrolled and made a first purchase between July 1, 2015 and December 31, 2015). All survey data presented in this chapter are from the patient and health care practitioner surveys sent three months after the patient's first medical cannabis purchase.

Patients and their certifying HCPs were asked to report the "most important benefit" and "most important negative effect" related to medical cannabis treatment. Survey responses from patients and health care practitioners on perceived benefits and perceived negative effects

were reported in free-text format; each response was individually reviewed and classified into a category of benefit or negative effects. Reported benefits typically included either direct improvement of symptoms related to the patient’s qualifying condition or more general improvements in health or quality of life, referred to in this report as global health benefits. Additionally, many responses included more than one type of benefit; in these cases, the first reported benefit was presumed to be the most important benefit. In this report, we examine both overall perceptions of benefit, as well as type of reported benefit.

Patient Experience Survey Results

Patient Experience Survey Response Rate

Of 1491 patients who were approved and made their first medical cannabis purchase in the first year of the program (July 1, 2015- June 30, 2016), 792 patients (53%) submitted a survey three months after making the first purchase. As of December 31, 2016, 90 patients (5%) were known to be deceased since enrolling in the program. These patients were included in this report, as in some cases caregivers or relatives and HCPs completed surveys, reflecting on the patient’s experience for the period of time the patient did use medical cannabis.

Table 6.3. Patient survey response rates by age group.

	Total	Patient Responses
0-4	62	17 (53%)
5-17	129	76 (59%)
18-24	89	51 (57%)
25-35	234	132 (56%)
36-49	355	192 (54%)
50-64	462	258 (56%)
65+	160	66 (41%)
Total	1491	792 (53%)

Table 6.4. Patient total counts and patient response rates by qualifying medical condition.

	Total	Patient Responses
Muscle Spasms	653	373 (57%)
Cancer	386	157 (41%)
Seizures	287	182 (63%)
Crohn's Disease	99	55 (56%)
Terminal Illness	79	38 (48%)
HIV/AIDS	46	24 (52%)
Tourette Syndrome	28	16 (57%)
Glaucoma	21	13 (62%)
ALS	21	11 (52%)

Table 6.5. Patient survey response rates by race and ethnicity.

	Total	Patient Responses
American Indian	37	14 (38%)
Asian	24	8 (33%)
Black	86	35 (41%)
Hawaiian	3	0 (0%)
White	1249	712 (57%)
Other	24	9 (38%)
Hispanic	35	14 (40%)

Patient response rates varied across age group, qualifying condition and race and ethnicity (Tables 6.3-6.5). Elderly patients (ages 65 and over) had the lowest response rate (41%); patients certified for cancer and terminal illness also had low response rates relative to other certified condition groups (41% and 48%, respectively). In general, racial and ethnic minorities were under-represented in survey responses.

Patient Perceptions of Benefits from Medical Cannabis

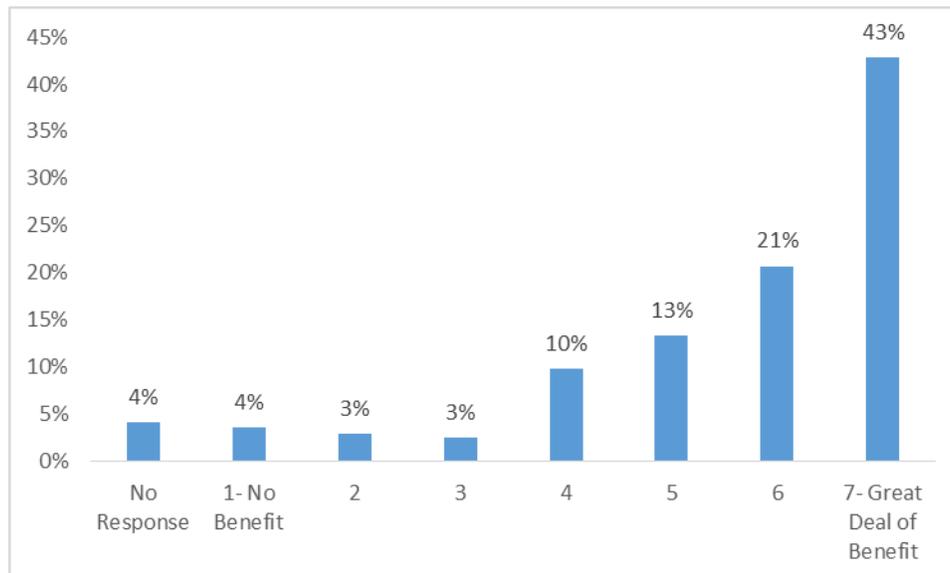

The Patient Experience and HCP surveys both ask respondents to report how much benefit they believe the patient received from using medical cannabis, on a scale from 1 (no benefit) to 7 (a great deal of benefit). Figures 6.1-6.10 show the distribution of benefit scores on this scale, as reported by patients, for all patients and by patients with each qualifying condition.

The percentages in Figures 6.1-6.10 are based on the total number of patient responses in each condition group and not the number of complete benefit scores for each group (33 patients submitted surveys without completing the benefit score question, but were included in the denominators).

ALL QUALIFYING CONDITIONS

Figure 6.1 below shows all patient responses about degree of benefit experienced. Among patient respondents, 43% report the highest degree of benefit from medical cannabis: “a great deal of benefit” or a score of 7 on a scale from 1-7.

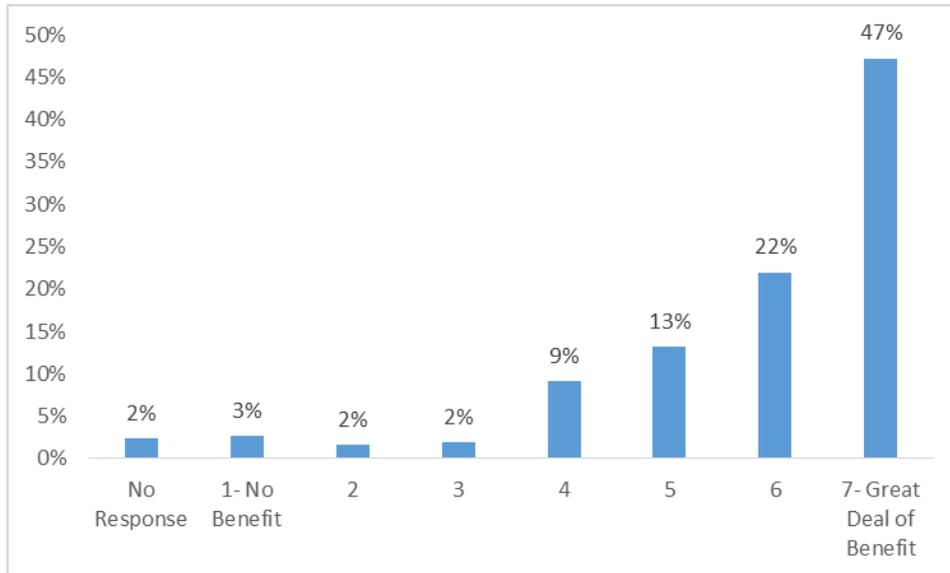

Figure 6.1. Patient-Perceived Benefit: All Conditions (N=792).

SEVERE AND PERSISTENT MUSCLE SPASMS

Figure 6.2 shows responses from patients certified for severe and persistent muscle spasms regarding degree of benefit experienced. Among respondents, 47% report a score of 7 on a scale from 1-7.

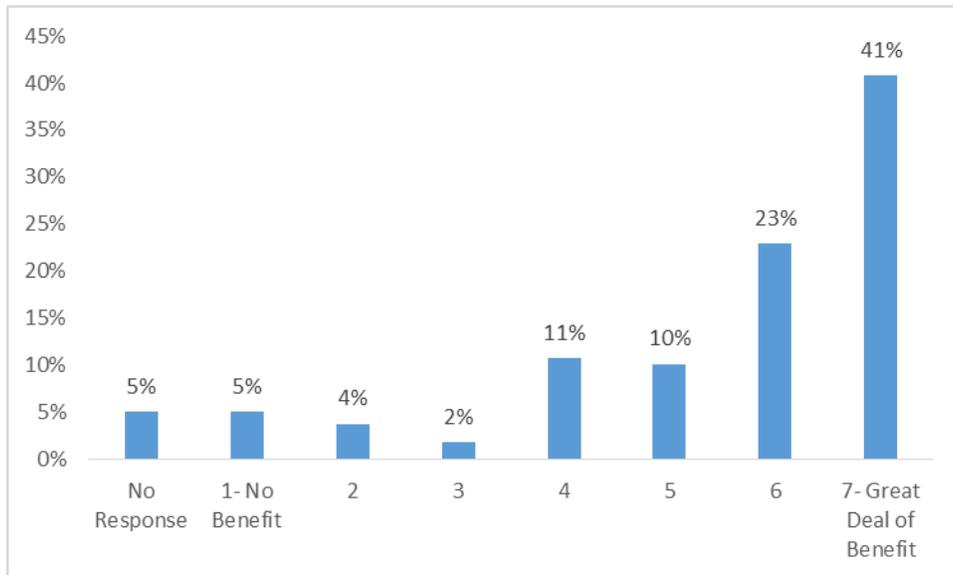

Figure 6.2. Patient-Perceived Benefit: Muscle Spasms (N=373)

CANCER

Figure 6.3 shows responses from patients certified for cancer regarding degree of benefit experienced. Among respondents, 41% report a score of 7 on a scale from 1-7.

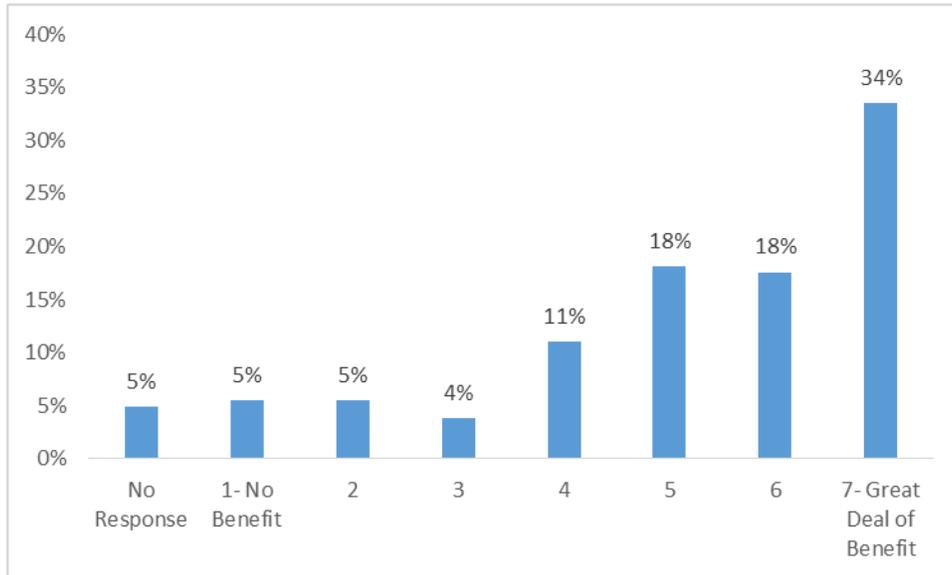

Figure 6.3. Patient-Perceived Benefit: Cancer (N=157)

SEIZURES

Figure 6.4 shows responses from patients certified for seizure disorders regarding degree of benefit experienced. Among respondents, 34% report a score of 7 on a scale from 1-7.

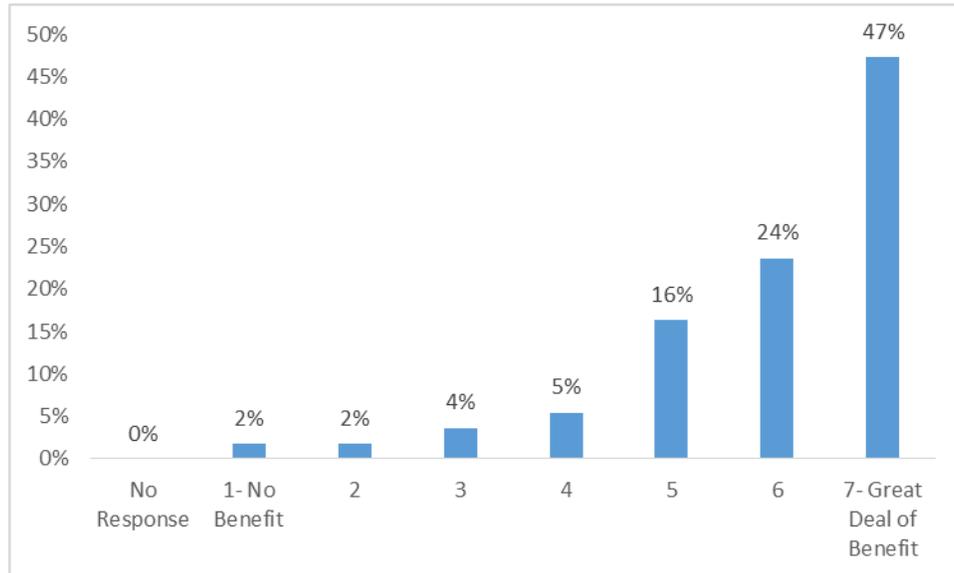

Figure 6.4. Patient-Perceived Benefit: Seizures (N=182)

CROHN'S DISEASE

Figure 6.5 shows responses from patients certified for Crohn's disease regarding degree of benefit experienced. Among respondents, 47% report a score of 7 on a scale from 1-7.

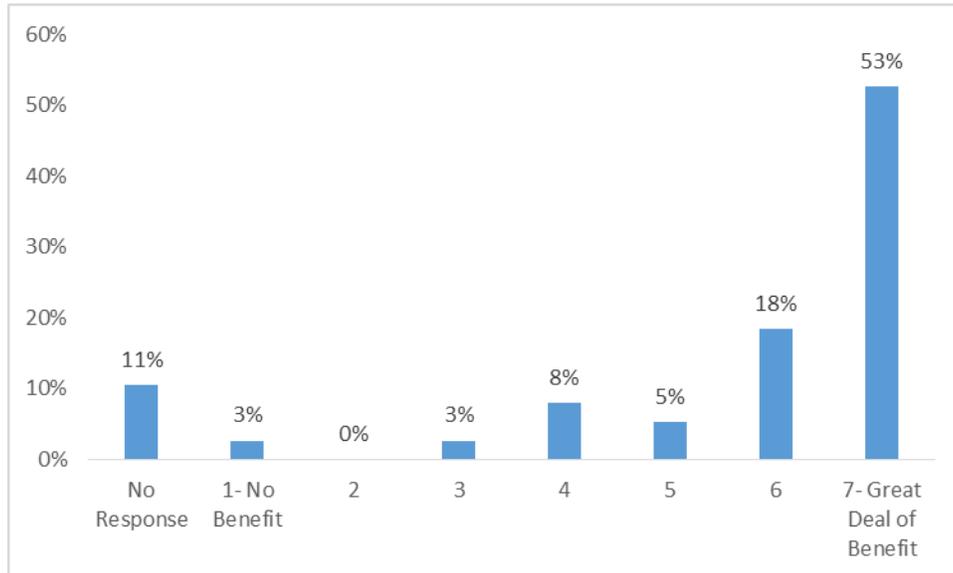

Figure 6.5. Patient-Perceived Benefit: Crohn's Disease (N=55)

TERMINAL ILLNESS

Figure 6.6 shows responses from patients certified for terminal illness regarding degree of benefit experienced. Among respondents, 53% report a score of 7 on a scale from 1-7.

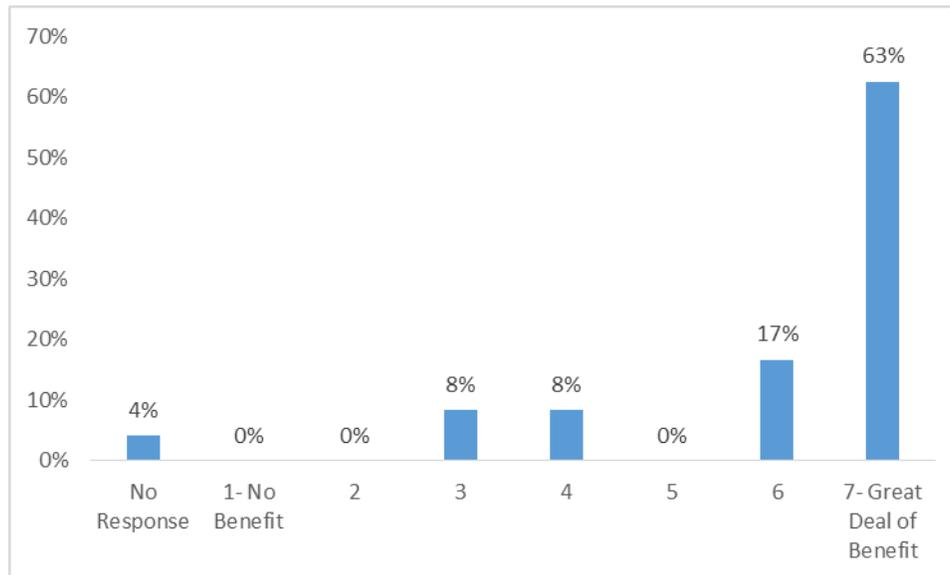

Figure 6.6. Patient-Perceived Benefit: Terminal Illness (N=38)

HIV/AIDS

Figure 6.7 shows responses from patients certified for HIV/AIDS regarding degree of benefit experienced. Among respondents, 63% report a score of 7 on a scale from 1-7.

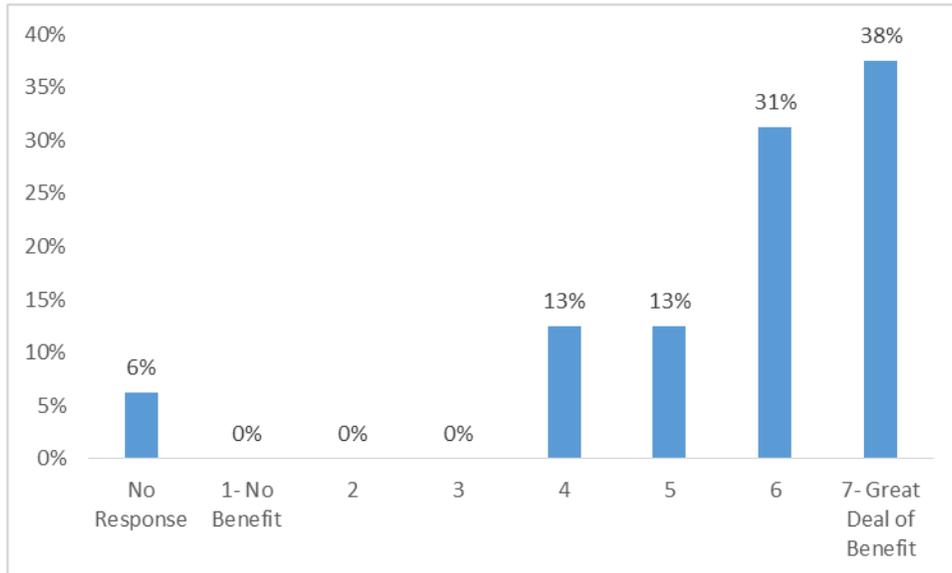

Figure 6.7. Patient-Perceived Benefit: HIV/AIDS (N=24)

TOURETTE SYNDROME

Figure 6.8 shows responses from patients certified for Tourette syndrome regarding degree of benefit experienced. Among respondents, 38% report a score of 7 on a scale from 1-7.

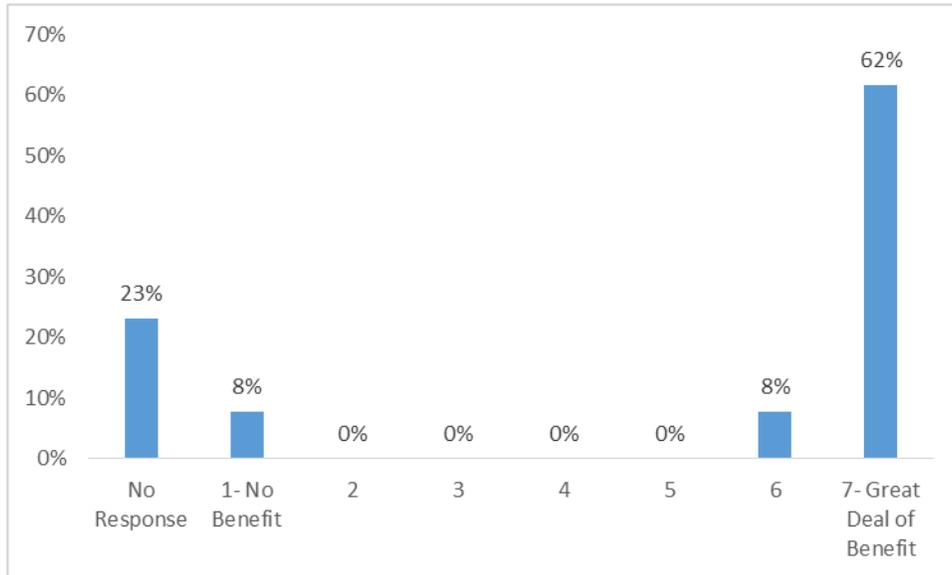

Figure 6.8. Patient-Perceived Benefit: Tourette Syndrome (N=16)

GLAUCOMA

Figure 6.9 shows responses from patients certified for glaucoma regarding degree of benefit experienced. Among respondents, 62% report a score of 7 on a scale from 1-7.

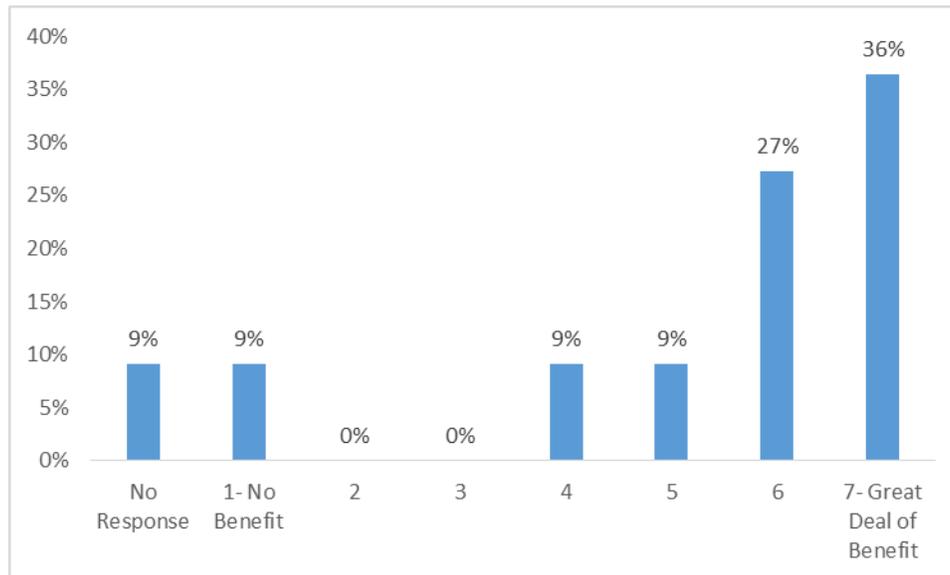

Figure 6.9. Patient-Perceived Benefit: Glaucoma (N=13)

ALS

Figure 6.10 shows responses from patients certified for ALS regarding degree of benefit experienced. Among respondents, 36% report a score of 7 on a scale from 1-7.

Figure 6.10. Patient-Perceived Benefit: ALS (N=11)

Patient Perceptions of Types of Benefits from Medical Cannabis Treatment

In both the Patient Experience and HCP surveys, patients and their certifying HCPs had an opportunity to describe the most significant benefit to the patient that was associated with medical cannabis treatment. Each response was reviewed and classified as symptom improvement (based on qualifying condition), or global health benefit, which included all health benefits not specifically related to the relief of symptoms directly associated with the patient's qualifying medical condition(s). Note that not all completed surveys had a response for this question; 86% of the Patient Experience surveys did and 66% of the HCP surveys did. Among the 681 completed Patient Experience survey responses that indicated a most significant benefit, 64% classified the benefit as symptom improvement and 25% classified it as a global health benefit; the remaining comments regarding benefit were improvement of symptoms other than those related to the qualifying condition or global health benefits. Tabulation of those responses is reported below, but the reader is also encouraged to read the verbatim responses in *Appendix A: Patient-Reported Benefits from Surveys*. Reading the words written by the patient gives a more nuanced understanding of the benefits and provides a reminder that each of the respondents is an individual person. The following is a selection of the comments, chosen to reflect the full range of benefits perceived:

- “Almost all muscle spasms and pain associated with spasms are gone. I used to have constant nerve triggered pain that is minimal now. Results were almost immediate. I am sleeping way better now also.”
- “A large reduction in symptoms, allowing me to participate in my daily life without a large number of limits my symptoms would place on me – stools decreased from over 8 a day to about 2 with much less blood and mucous in stools. Pain has reduced to a tolerable amount”
- “[NAME] has passed away. I am her daughter and was her care giver. She was open to trying medical cannabis and we got the liquid form. It was a saving grace. She was in a lot of pain and when prescribed medications did NOT work – we started this and it kept her calm and relaxed. I am very thankful that we were able to have this option available. It helped to make her last months more bearable and truly it would have been miserable without it.”
- “Has eased my muscle spasms and cramping. Has helped my visual issues. Has helped me to maintain healthy weight. Have been able to sleep much better and have cut other pain prescriptions way back. Seems to take pain away enough that I have been more active and am able to function on household tasks to a somewhat normal level. My brain seems to be working better as well ie. concentration/focusing and remembering.”
- “I am getting enough sleep for the first time since about 2011. My absence seizures have gone from 3-4 a day to almost 0. It also has lessened the severity of grand mal seizures. The recovery time after has gone from around 12 hours to around 4.”
- “Within 1 week of use, my tics disappeared and have stayed gone even with occasional use. This has never happened previously in my life, so it is very effective.”
- “At first it helped a lot but my seizures have returned.”
- “Spasms – only a little better.”

Symptom Improvement from Medical Cannabis Treatment

Table 6.6 summarizes the reported “most important benefits” which could be considered improvement of a symptom related to the patient’s qualifying condition from reports of patients, categorized by the benefit score reported by the patient. For patients with severe muscle spasms, reports of spasm reduction or pain reduction were considered symptom improvement. For patients with cancer (regardless of whether their condition was associated with severe/chronic pain, nausea or severe vomiting, cachexia or severe wasting, or a combination), pain reduction, nausea and/or vomiting reduction, and weight gain and/or appetite improvement were considered symptom improvement. For patients with seizures, reports of fewer seizures, less severe seizures, or both, were considered symptom improvement. For patients with Crohn’s disease, pain reduction, weight gain and/or appetite improvement, and reduction in related symptoms including stool frequency were considered symptom improvement. For patients with terminal illnesses (regardless of whether their condition was associated with severe/chronic pain, nausea or severe vomiting, cachexia or

severe wasting, or a combination), reduction in pain, nausea and/or vomiting and weight gain and/or appetite improvement were considered symptom improvement. For patients certified for HIV/AIDS, reduction in pain, nausea and/or vomiting, and weight gain and/or appetite improvement were considered symptom improvement. In patients with Tourette syndrome, reduced tics or specific mention of reduced Tourette symptoms were considered symptom improvement. In patients certified for glaucoma, reduction in intraocular pressure or reference to treatment of glaucoma “symptoms” was considered symptom improvement. Finally, for patients with ALS, reduction in pain or spasms were considered symptom improvement.

Among patients with severe and persistent muscle spasms, 26% reported pain reduction and another 25% reported spasm reduction as the most important benefit. Among seizure patients, 51% reported seizure reduction (either in frequency or severity). Among cancer patients, 26% reported pain reduction as the primary benefit; 25% reported weight gain, appetite improvement, or reduced nausea or vomiting. Among Crohn’s disease respondents, 25% reported reduced pain, 16% reported reduced severity or frequency of gastrointestinal symptoms and 4% reported weight gain or appetite improvement as the primary benefit. Among patients with terminal illness, 21% reported reduced nausea or vomiting, 18% reported pain reduction and 8% reported weight gain or appetite improvement as the most important benefit. Thirty-one percent of glaucoma patient respondents reported reduction of glaucoma-related symptoms. Among ALS patients, 27% reported pain reduction and 9% reported spasm reduction as the most important benefit. Among HIV/AIDS patients, 25% reported reduced pain, 17% reported reduced nausea and/or vomiting and 12% reported weight gain or appetite improvement as the most important benefit. Finally, among patients with Tourette syndrome, 63% reported a reduction in tics or other symptoms of Tourette syndrome.

Table 6.6. Distribution of Symptom Improvement by Condition: Patient Surveys

	1 (No Benefit)	2	3	4	5	6	7 (Great Deal of Benefit)	Total

Patient Perceptions of Global Health Benefits from Medical Cannabis

Many patients responded to the question regarding “most important benefit” by describing benefits not specifically related to the symptoms of their qualifying conditions. These responses were reviewed and classified into categories of “global health benefits”- broader benefits which impact the patient’s overall health. Global health benefits reported by patients included improvement in quality of life, improvement in sleep (whether or not explicitly tied to reduction in symptoms related to qualifying condition), improved mobility and/or ability to function or perform regular tasks, reduced anxiety or increased calmness, improved alertness and/or cognitive functioning, and reduced usage of other medications (often reported as reduction in dosage and/or side effects related to use of other medications). Clearly, global health benefits may be due to improvements in symptoms specifically related to the qualifying condition, so the dividing line between these categories is a bit blurry.

Table 6.7 shows the number of responses by type of global health benefit, along with the associated benefit score reported by the patient. Overall, 6% of patient respondents reported

improved sleep as the most important benefit from medical cannabis; 4% reported improved quality of life, 4% reported reduced usage of other medication, 3% reported reduced anxiety, and 2% reported improved alertness or cognitive function.

Table 6.7. Distribution of Global Health Benefits Condition: Patient Surveys

	1 (No Benefit)	2	3	4	5	6	7 (Great Deal of Benefit)	Total

Health Care Practitioner Survey Results

HCP Survey Response Rate

As a result of changing the survey schedule during the first program year, the healthcare providers of 774 patients who were enrolled and made a first medical cannabis purchase in the first six months of the program (July 1 – December 31, 2015) received a survey three months after the patient’s first purchase; the remaining 717 could therefore not be included in the reporting below. The subset of Patient Experience survey responses that corresponds to this group of HCP responses is included below for comparison. Of 774 patients in this group, 437 patients (57%) submitted a survey three months after making the first purchase. Of the 262 health care practitioners (HCP) who certified these patients, 114 (43.5%) completed surveys for 251 (32%) patients.

Table 6.8. Healthcare Practitioner and Patient Experience survey response rates by age group.

	Total	HCP Responses	Patient Responses
0-4	15	7 (47%)	9 (60%)
5-17	90	36 (40%)	49 (54%)
18-24	48	18 (38%)	28 (58%)
25-35	110	32 (29%)	59 (54%)
36-49	194	66 (34%)	114 (59%)
50-64	225	65 (29%)	131 (58%)
65+	92	27 (29%)	47 (51%)
Total	774	251 (32%)	437 (58%)

Table 6.9. Patient total counts and HCP/patient response rates by qualifying medical condition.

	Total	HCP Responses	Patient Responses
Muscle Spasms	305	98 (32%)	182 (60%)
Cancer	192	51 (27%)	84 (44%)
Seizures	189	64 (34%)	120 (63%)
Crohn's Disease	58	25 (43%)	34 (59%)
Terminal Illness	43	12 (28%)	21 (49%)
HIV/AIDS	26	12 (46%)	15 (58%)
Tourette Syndrome	11	4 (36%)	6 (55%)
Glaucoma	11	3 (27%)	5 (45%)
ALS	15	5 (33%)	7 (47%)

Table 6.10. Patient total counts and HCP/patient response rates by race and ethnicity.

	Total	HCP Responses	Patient Responses
American Indian	16	6 (38%)	7 (44%)
Asian	17	8 (47%)	7 (41%)
Black	41	14 (35%)	15 (37%)
Hawaiian	1	0 (0%)	0 (0%)
White	665	218 (33%)	395 (59%)
Other	14	5 (36%)	6 (43%)
Hispanic	18	4 (22%)	6 (33%)

Response rates for the Patient Experience and HCP surveys varied widely across age group, qualifying condition and race and ethnicity (Tables 6.8-6.10). Patient response rate was lowest among the oldest age group (65+; 51%) and HCP response rate was generally lower for older age groups. Among HCP responses, certifiers of patients with HIV/AIDS and Crohn’s disease had the highest response rates (46% and 43%, respectively). Among patient responses, patients certified for severe and persistent muscle spasms, seizures and Crohn’s disease had the highest response rates (60%, 63%, and 59%, respectively). Finally, racial and ethnic minorities were generally under-represented among patient responses.

Healthcare Practitioner Perceptions of Benefit

The Patient Experience and HCP surveys both ask respondents to report how much benefit they believe the patient received from using medical cannabis, on a scale from 1 (no benefit) to 7 (a great deal of benefit). Figures 6.11-6.20 show the distribution of benefit scores on this scale, as reported by HCPs, for all patients and by patients with each qualifying condition.

A note on how proportions were calculated: the total number of HCP responses is reflected in Figures 6.11-6.20; this includes 45 HCP responses with either no response or a “0” option selected for the benefit scale, which indicates that the HCP did not have enough information about the patient to answer the question of benefit.)

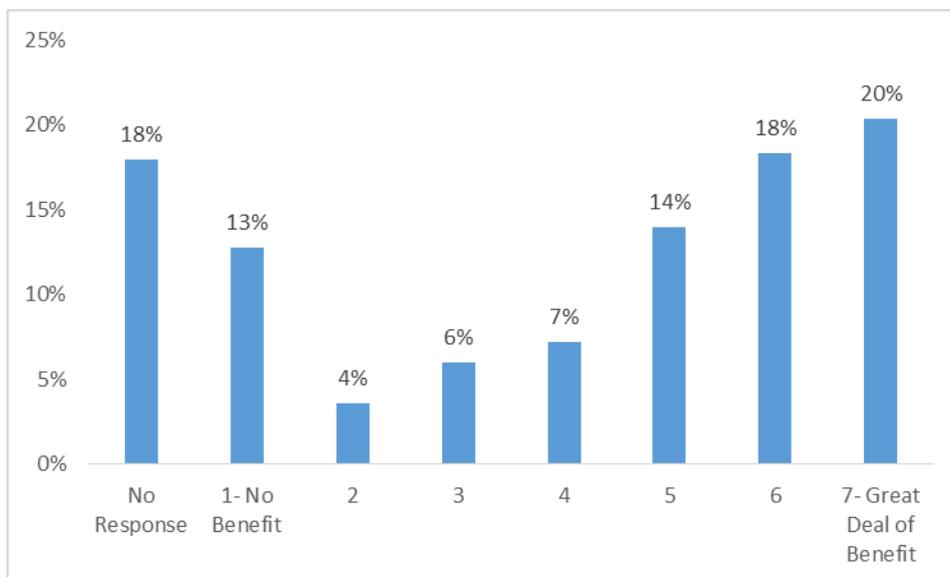

Note that results from patient surveys (Figures 6.1-6.10) and health care practitioner surveys (Figures 6.11-6.20) do not pertain to identical groups of patients. That is, some patients have

only a patient survey completed, some have only a HCP survey completed, some have neither completed, and some (n=126) have a completed survey from both the patient and their certifying HCP. For this reason, comparison of results from patient and HCP surveys must be approached with caution, except for the last group, where there is a completed survey from both the patient and the HCP. Further on in this section (Table 6.13 and Figures 6.21-6.28) comparisons for that last group are presented. In general, responses from HCPs report a lower degree of benefit than the patient responses.

ALL QUALIFYING CONDITIONS

Figure 6.11 shows all HCP responses about degree of benefit experienced. Benefit ratings were provided on 206 of the 251 submitted surveys. Among the 251 surveys, 32 (13%) reported no benefit and 51 (20%) reported the highest degree of benefit (score of 7); 150 (60%) reported a benefit score ≥ 4 on the seven-point scale.

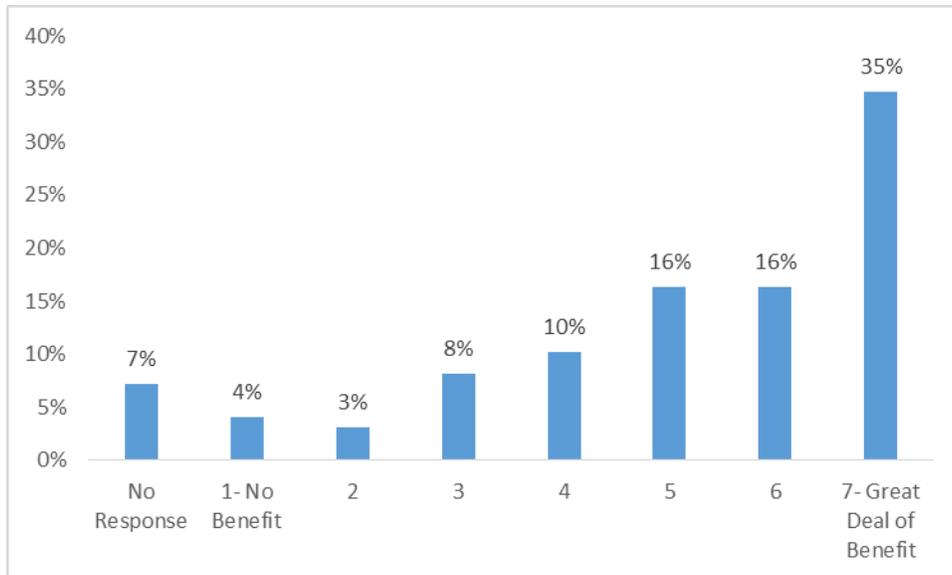

Figure 6.11. HCP-Perceived Benefit: All Conditions (N=251)

SEVERE AND PERSISTENT MUSCLE SPASMS

Figure 6.12 shows HCP benefit score responses for patients certified for severe and persistent muscle spasms. Benefit ratings were provided on 91 of the submitted surveys. Among the 91 responses, 4 reported no benefit and 34 reported the highest degree of benefit (score of 7); 76 (84%) reported a benefit score ≥ 4 on the seven-point scale.

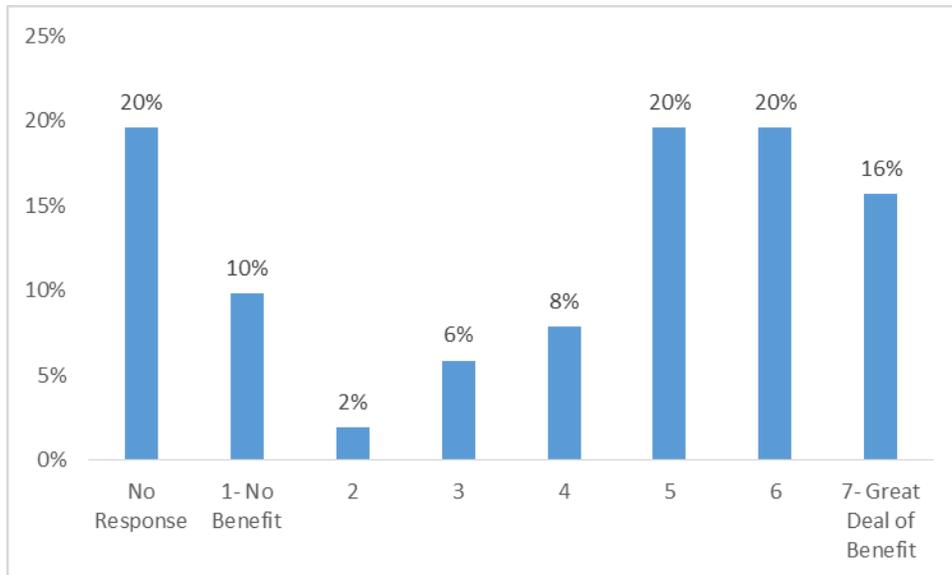

Figure 6.12. HCP-Perceived Benefit: Severe and Persistent Muscle Spasms (N=98)

CANCER

Figure 6.13 shows HCP benefit score responses for patients certified for cancer. Benefit ratings were provided on 41 of the submitted surveys. Among the 41 responses, 5 reported no benefit and 8 reported the highest degree of benefit (score of 7); 32 (78%) reported a benefit score ≥ 4 on the seven-point scale.

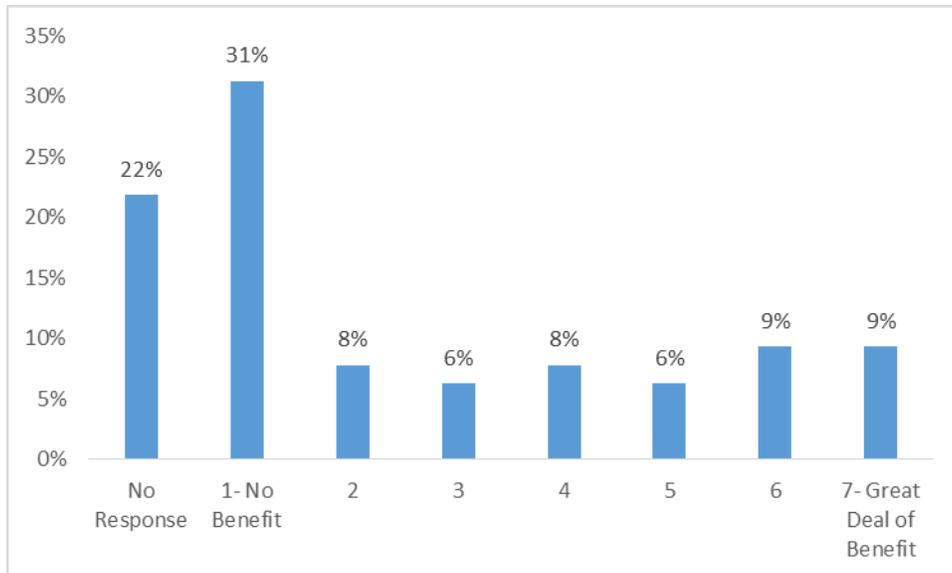

Figure 6.13. HCP-Perceived Benefit: Cancer (N=51)

SEIZURES

Figure 6.14 shows HCP benefit score responses for patients certified for seizures. Benefit ratings were provided on 50 of submitted surveys. Among the 50 responses, 20 reported no benefit and 6 reported the highest degree of benefit (score of 7); 21 (42%) reported a benefit score ≥ 4 on the seven-point scale.

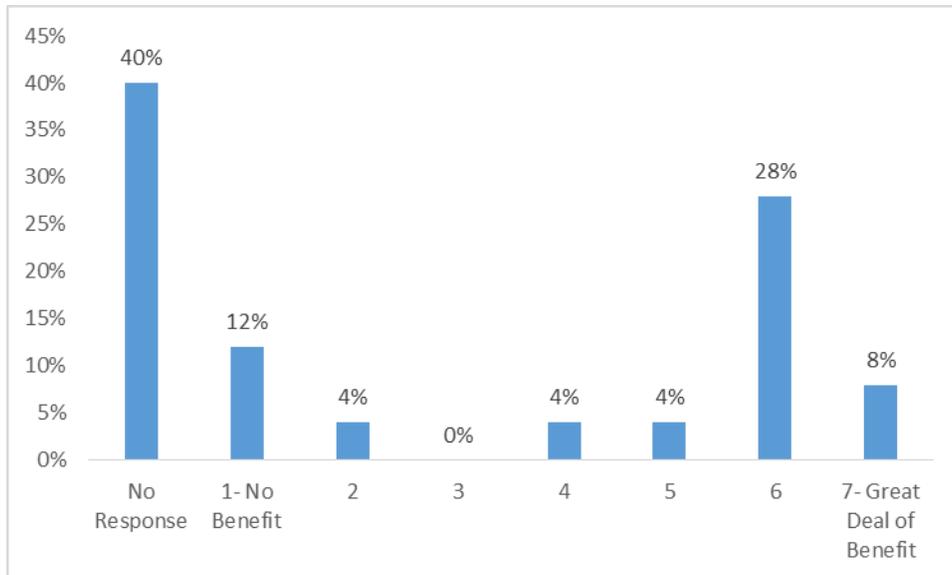

Figure 6.14. HCP-Perceived Benefit: Seizures (N=64)

CROHN'S DISEASE

Figure 6.15 shows HCP benefit score responses for patients certified for Crohn's disease. Benefit ratings were provided on 15 of the completed surveys. Among the 15 responses, 3 reported no benefit and 2 reported the highest degree of benefit (score of 7); 11 (73%) reported a benefit score ≥ 4 on the seven-point scale.

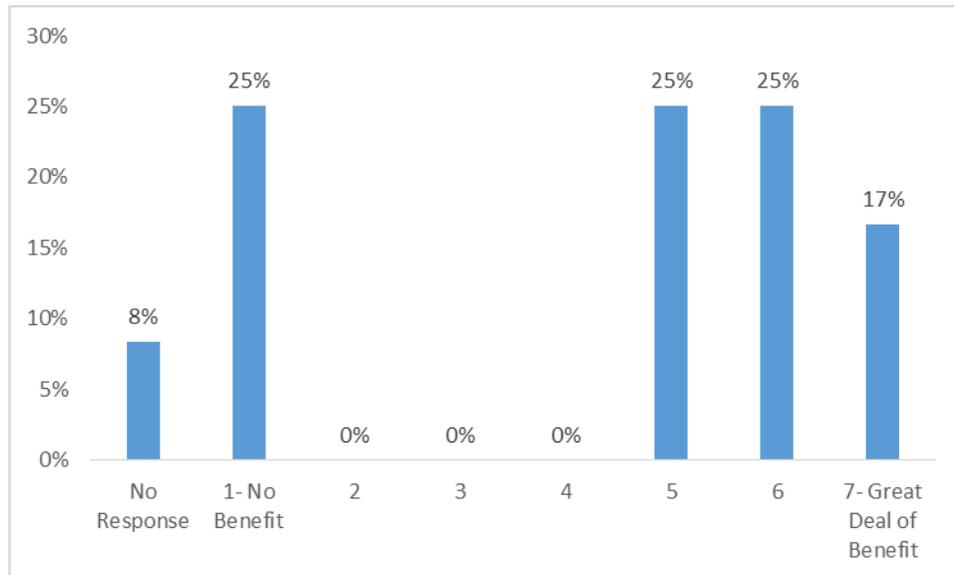

Figure 6.15. HCP-Perceived Benefit: Crohn's Disease (N=25)

TERMINAL ILLNESS

Figure 6.16 shows HCP benefit score responses for patients certified for terminal illness. Benefit ratings were provided on 11 of the completed surveys. Among the 11 responses, 3 reported no benefit and 2 reported the highest degree of benefit (score of 7); 8 (73%) reported a benefit score ≥ 4 on the seven-point scale.

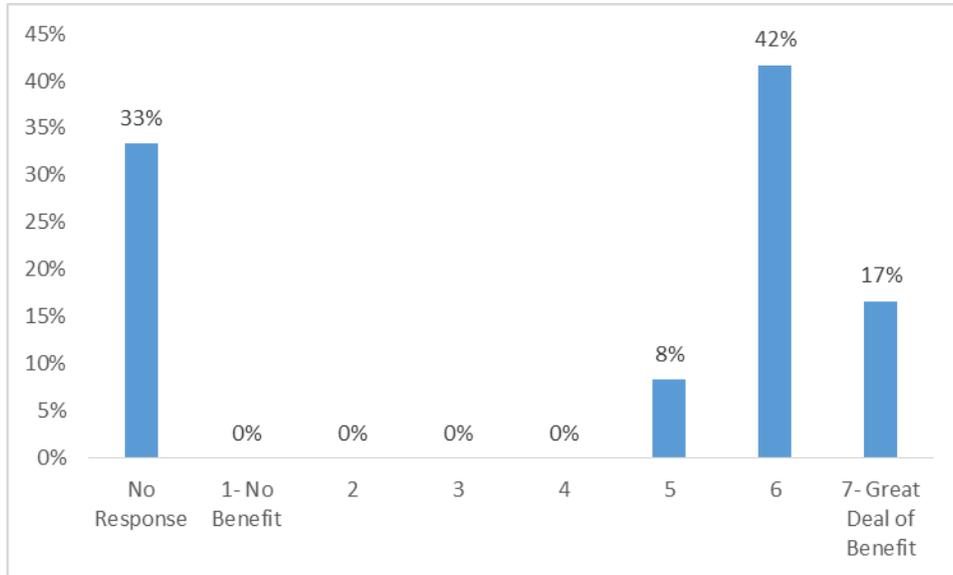

Figure 6.16. HCP-Perceived Benefit: Terminal Illness (N=12)

HIV/AIDS

Figure 6.17 shows HCP benefit score responses for patients certified for HIV/AIDS. Benefit ratings were provided on 8 of the 12 completed surveys. Among the 8 responses, none reported no benefit and two reported the highest degree of benefit (score of 7); all eight reported a benefit score ≥ 4 on the seven-point scale.

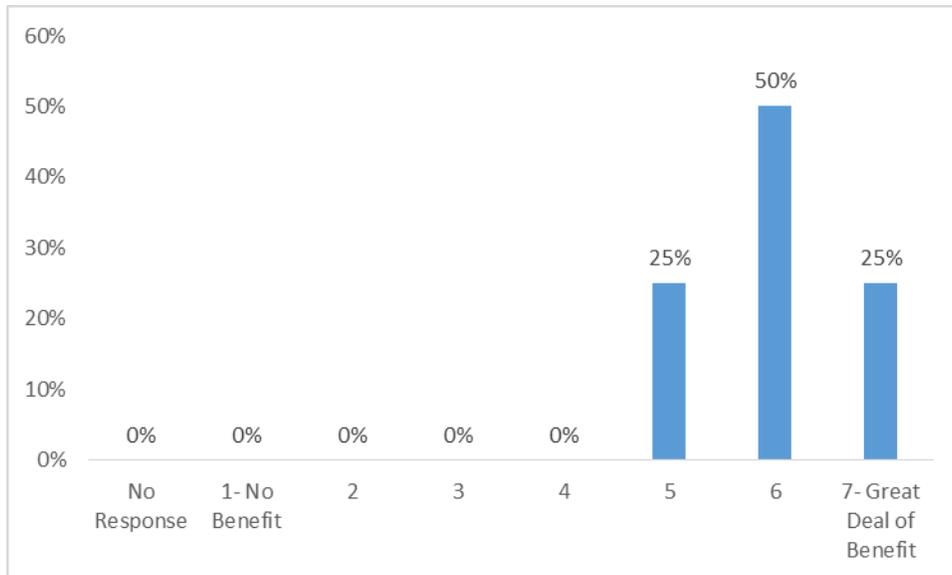

Figure 6.17. HCP-Perceived Benefit: HIV/AIDS (N=12)

TOURETTE SYNDROME

Figure 6.18 shows HCP benefit score responses for patients certified for Tourette syndrome. Benefit ratings were provided on all four of the completed surveys. Among the 4 responses, none reported no benefit and one reported the highest degree of benefit (score of 7); all four reported a benefit score ≥ 4 on the seven-point scale.

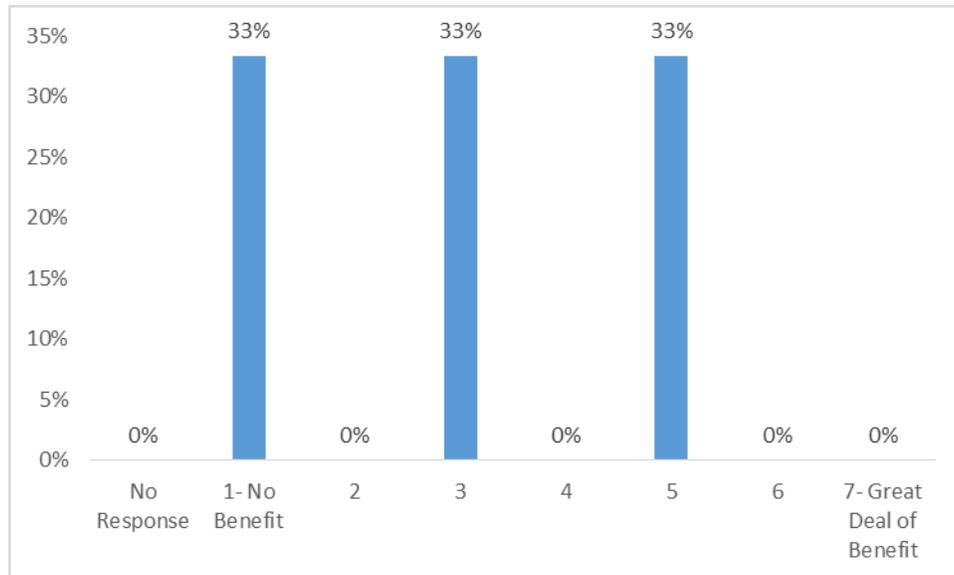

Figure 6.18. HCP-Perceived Benefit: Tourette Syndrome (N=4)

GLAUCOMA

Figure 6.19 shows HCP benefit score responses for patients certified for glaucoma. Benefit ratings were provided on all three of the completed surveys. Among the 3 responses, one reported no benefit and none reported the highest degree of benefit (score of 7); only one reported a benefit score ≥ 4 on the seven-point scale.

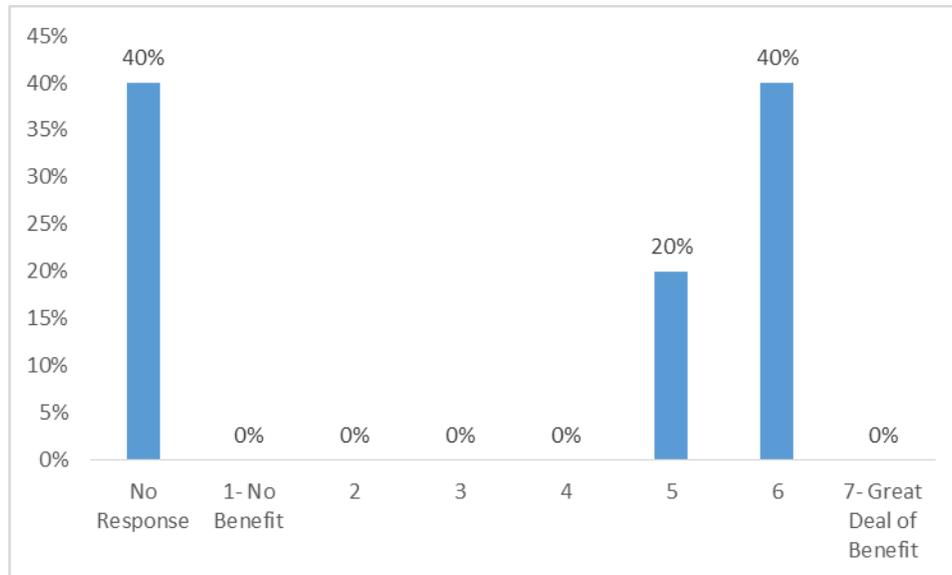

Figure 6.19. HCP-Perceived Benefit: Glaucoma (N=3)

ALS

Figure 6.20 shows HCP benefit score responses for patients certified for ALS. Benefit ratings were provided on 3 of the 5 completed surveys. Among the 3 responses, none reported no benefit and none reported the highest degree of benefit (score of 7); all three reported a benefit score ≥ 4 on the seven-point scale.

Figure 6.20. HCP-Perceived Benefit: ALS (N=5)

HCP Perceptions of Symptom Improvement from Medical Cannabis Treatment

Similar to the format in the Patient Experience survey, the HCP surveys asks certifying HCPs to describe the most significant benefit to the patient that is associated with medical cannabis treatment. Each response was reviewed and classified into broad categories of symptom improvement or global health benefits, as described in an earlier section. A full report of all benefit comments from HCPs can be found in *Appendix B: Healthcare Practitioner-Reported Benefits from Surveys*. Table 6 summarizes the reported “most important benefits” which could be considered improvement of a symptom related to the patient’s qualifying condition from reports of both patients and HCPs, again using a subset of patient responses from the same time window as HCP responses (surveys for patients making a first purchase between July 2015 and December 2015).

Table 6.11 Distribution of Symptom Improvement by Condition

Symptom Improvement by Score		1	2	3	4	5	6	7	Total
		(No Benefit)						(Great Deal of Benefit)

<i>Reduced Nausea/Vomiting</i>	Patient (n=15)	-	-	-	-	-	-	3 (20%)	3 (20%)
	HCP (n= 12)	-	-	-	-	-	2 (17%)	-	2 (17%)
<i>Weight Gain/Appetite Improvement</i>	Patient (n=15)	-	-	-	-	-	-	2 (13%)	2 (13%)
	HCP (n= 12)	-	-	-	-	-	-	-	-
Tourette Syndrome									
<i>Reduced Tics/Tourette Symptoms</i>	Patient (n=6)	-	-	-	-	1 (17%)	-	3 (50%)	4 (67%)
	HCP (n= 5)	-	-	-	-	-	2 (40%)	1 (20%)	3 (60%)

Symptom Improvement by Score		1 (No Benefit)	2	3	4	5	6	7 (Great Deal of Benefit)	Total
Glaucoma									
<i>Reduced Glaucoma Symptoms</i>	Patient (n=5)	-	-	-	-	-	-	2 (40%)	2 (40%)
	HCP (n= 3)	-	-	1 (33%)	-	-	-	-	1 (33%)
ALS									
<i>Spasm Reduction</i>	Patient (n=7)	-	-	-	-	-	1 (14%)	-	1 (14%)
	HCP (n= 5)	-	-	-	-	1 (20%)	1 (20%)	-	2 (40%)
<i>Pain Reduction</i>	Patient (n=7)	-	-	-	-	-	1 (14%)	2 (29%)	3 (43%)
	HCP (n= 5)	-	-	-	-	-	1 (20%)	-	1 (20%)

Patients represented in Patient Experience survey responses and in HCP responses were different; thus a direct comparison cannot be made between the proportions of patients and HCPs reporting any given benefit. However, it is worth noting that relatively high levels of symptom improvement benefit (most scores are above 4) are seen in both patient and HCP survey results. Among patient respondents certified for muscle spasms, 22% report spasm reduction at a high degree of benefit (scores of 6 or 7) and 18% of HCP responses for patients with muscle spasms report spasm reduction at a high degree of benefit. Among responses of patients certified for seizures, 40% reported reduction in seizure number or severity at a high degree of benefit; among HCP responses for patients with seizures, 14% reported seizure reduction (severity or frequency) at a high degree of benefit. Among patient responders certified for cancer, 15% reported pain reduction at a high degree of benefit; 13% reported reduced nausea or vomiting at a high degree of benefit and 12% reported weight gain or appetite improvement at a high degree of benefit. Among HCP responses for patients certified for cancer, 8% reported pain reduction at a high degree of benefit, 14% reported reduced nausea or vomiting and 2% reported weight gain or appetite improvement at a high degree of benefit.

HCP Perceptions of Global Health Benefits from Medical Cannabis Treatment

Table 6.12 summarizes responses to the Patient Experience and HCP surveys about the most significant benefit to the patient that were not classified as improvement of symptoms related to the qualifying medical condition.

As with Table 6.11, the proportion of patients reporting a type of global health benefit cannot be directly compared to the proportion of HCPs reporting a type of global health benefit to the patient because each group of responders is different. However, in general a higher proportion of the patient responses report a global health benefit as the primary benefit from medical cannabis than HCP responses and generally global health benefits are reported at a relatively high degree of perceived benefit (scores of 4 or greater).

Overall, 1% of HCP respondents and 6% of patient respondents reported improved sleep as the most important benefit from medical cannabis; 3% of HCP respondents and 4% of patients reported improved quality of life; 2% of HCP reports and 3% of patient reports cited reduced usage of other medications or related side effects as the most important benefit.

A full report of all benefit comments from HCPs can be found in *Appendix B: Healthcare Practitioner-Reported Benefits from Surveys*.

Additional Clinical Observations

Healthcare practitioners were asked to provide any additional clinical observations or insights on the impact of medical cannabis treatment on the patient’s condition, and were specifically prompted to report any observations on drug interactions. A third of the 114 observations describe a decrease in the patients’ other medications- mainly opioids and benzodiazepines. The survey healthcare practitioners will complete for patients certified for intractable pain will ask specifically about this issue. There were a few comments about drug interactions with anti-epileptic drugs, including in some cases the anticipated ability to decrease dose of Clobazam. A full report of these observations can be found in *Appendix C: Healthcare Practitioner-Reported Clinical Observations from Surveys*.

Patient Versus HCP Perceptions of Benefit from Medical Cannabis

Among survey respondents, there were 126 patients who submitted a survey for whom their certifying health care practitioner also completed a survey. Comparison of benefit scores reported by the patient to benefit scores reported by the healthcare practitioner are shown in Table 6.13, grouping scores of 1 or 2 in a category representing no or little benefit; scores of 3, 4, or 5 were grouped into a category representing mild or moderate benefit and scores of 6 or 7 were placed in a category representing strong benefit. Among these 126 patients and their HCPs, 81 (64%) of patient-HCP pairs were in general agreement regarding degree of benefits experienced: 46% reported strong benefit from medical cannabis; 15% reported mild or moderate benefit and 3% reported no or little benefit (Table 6.13). When interpreting the meaning of these comparisons, it must be kept in mind that the 126 patients for whom both Patient Experience and HCP survey results are available are not necessarily representative of all patients who enrolled in the program during its first year of operation.

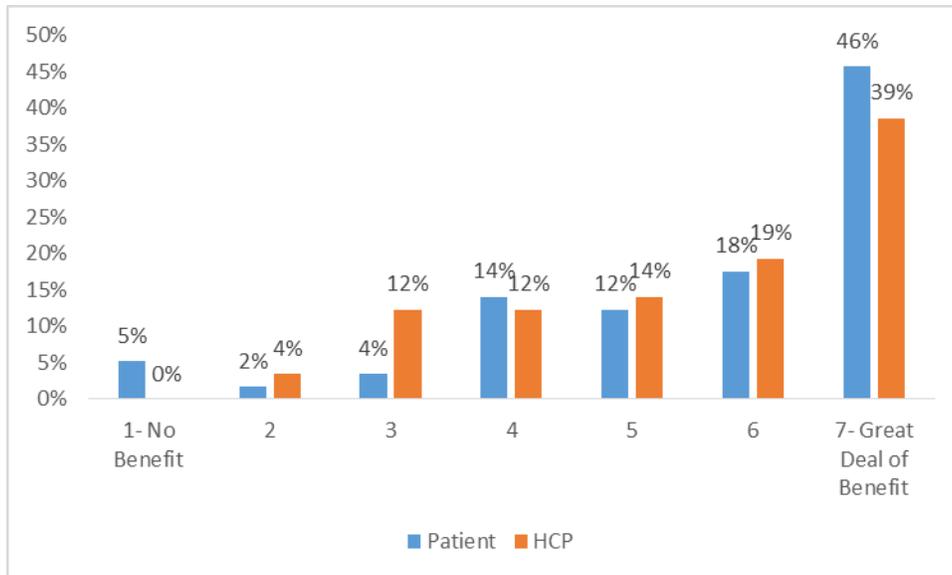

Table 6.13. Distribution of patient-reported benefits and HCP-reported benefits for patients with both patient and HCP surveys completed (n=126).

	HCP-Perceived Benefit		
Patient-Perceived Benefit	No/Little Benefit (1-2)	Mild/Moderate Benefit (3-5)	Strong Benefit (6-7)
No/Little Benefit (1-2)	4 (3%)	1 (1%)	2 (2%)
Mild/Moderate Benefit (3-5)	7 (6%)	19 (15%)	10 (8%)
Strong Benefit (6-7)	2 (2%)	23 (18%)	58 (46%)

Severe and Persistent Muscle Spasms

Figure 6.21 shows benefit scores reported by patients and their certifying HCPs for muscle spasms patients for whom both scores were available (n=57). Comparison of proportions of patients and HCPs reporting each benefit score shows fairly good agreement: 46% of patients and 39% of HCPs report scores of 6 or 7; 5% of patients and 0% HCPs report no benefit.

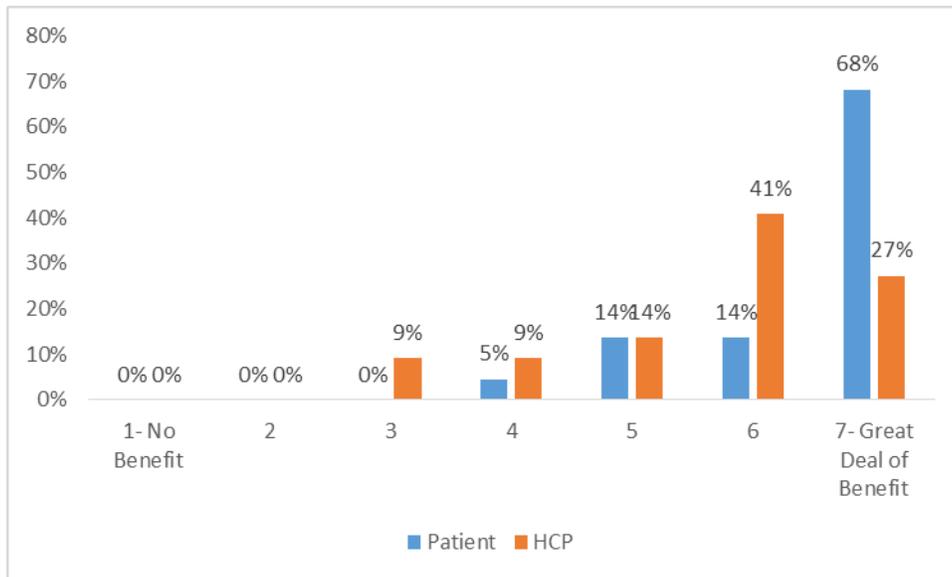

Figure 6.21. Muscle Spasms (N=57): Perceived Benefit

Cancer

Figure 6.22 shows benefit scores reported by patients and their certifying HCPs for cancer patients for whom both scores were available (n=22). Comparison of proportions of patients and HCPs reporting each benefit score shows differences in effect size but general agreement that patients experienced some benefit. Among this group, 68% of patients and 27% of HCPs report scores of 6 or 7; 0% patients and 0% HCPs report scores of 1 or 2.

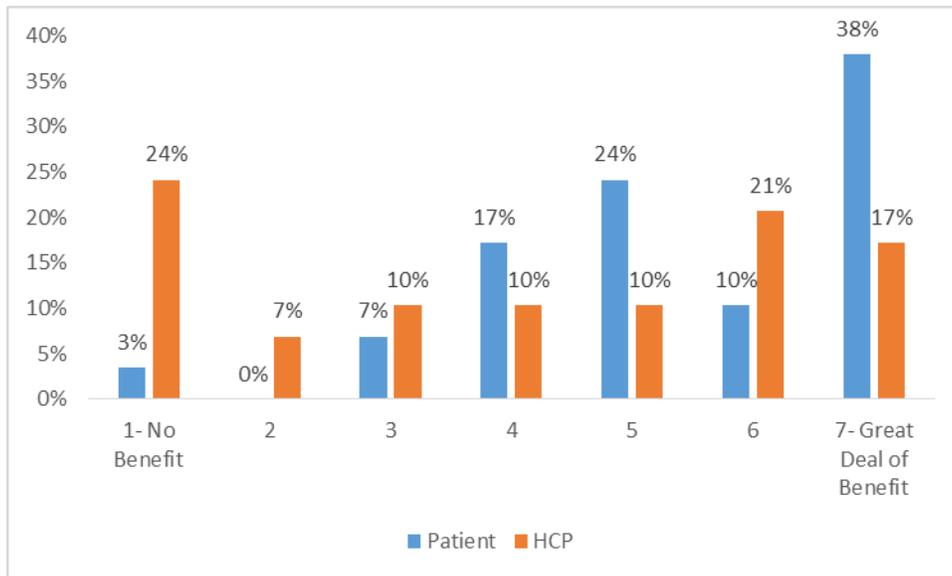

Figure 6.22. Cancer (N=22): Perceived Benefit

Seizures

Figure 6.23 shows benefit scores reported by patients and their certifying HCPs for seizure patients for whom both scores were available (n=29). Comparison of proportions of patients and HCPs reporting each benefit score shows that generally patients report higher degrees of benefit than HCPs: 38% of patients versus 17% of HCPs report scores of 6 or 7; 3% of patients versus 24% HCPs report no benefit.

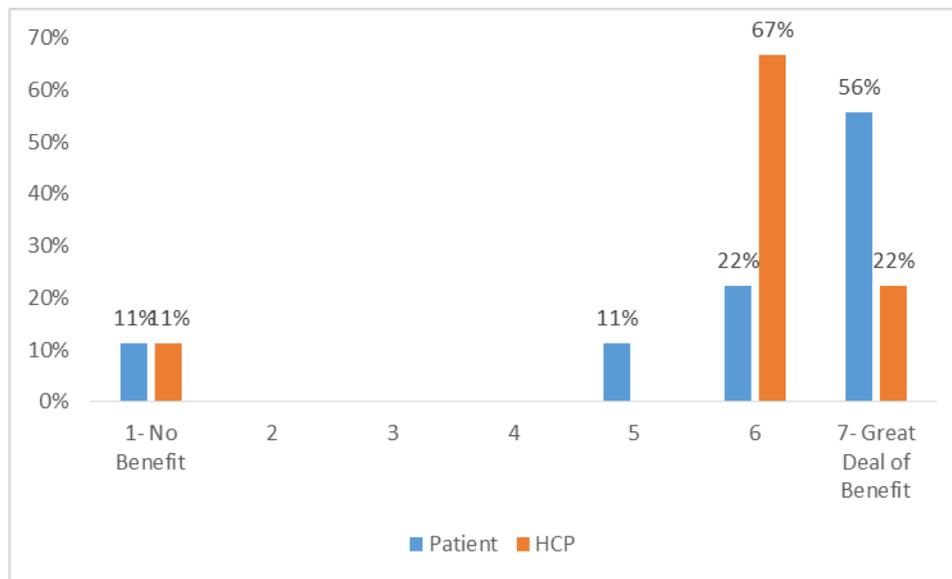

Figure 6.23. Seizures (N=29): Perceived Benefit

Crohn's Disease

Figure 6.24 shows benefit scores reported by patients and their certifying HCPs for Crohn's disease patients for whom both scores were available (n=9). Comparison of proportions of patients and HCPs reporting each benefit score shows general agreement about degree of benefit experienced: 89% of patients and 78% of HCPs report scores of 6 or 7; 11% of both patients and HCPs report scores of 1.

Figure 6.24. Crohn's Disease (N=9): Perceived Benefit

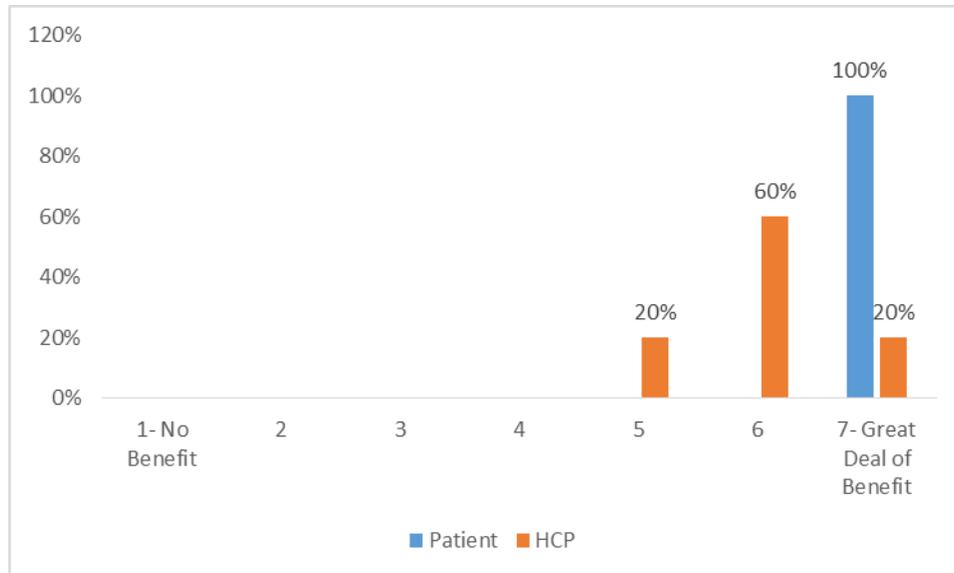

Terminal Illness

No patients with terminal illness had both an HCP-submitted survey and patient-submitted survey.

HIV/AIDS

Figure 6.25 shows benefit scores reported by patients and their certifying HCPs for HIV/AIDS patients for whom both scores were available (n=5). Comparison of proportions of patients and HCPs reporting each benefit score shows general agreement about degree of benefit experienced: 100% of patients and 80% of HCPs report scores of 6 or 7.

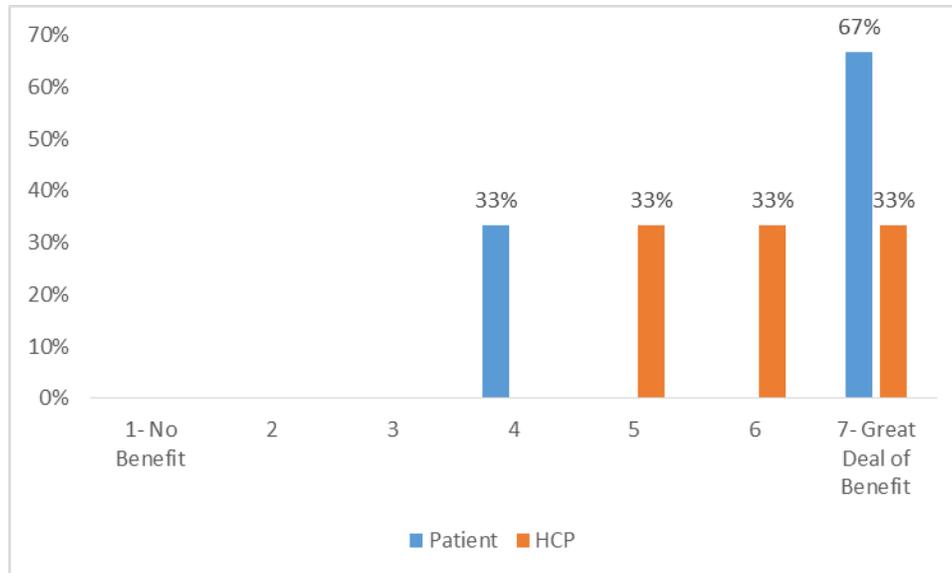

Figure 6.25. HIV/AIDS (N=5): Perceived Benefit

Tourette Syndrome

Figure 6.26 shows benefit scores reported by patients and their certifying HCPs for Tourette syndrome patients for whom both scores were available (n=3). Comparison of proportions of patients and HCPs reporting each benefit score shows general agreement about degree of benefit experienced: 67% of patients and 67% of HCPs report scores of 6 or 7.

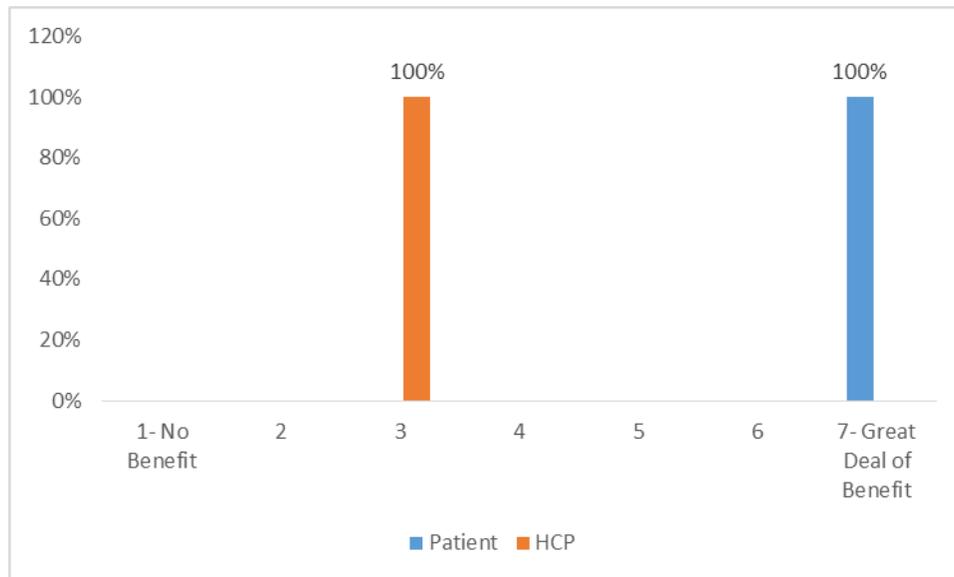

Figure 6.26. Tourette Syndrome (N=3): Perceived Benefit

Glaucoma

Figure 6.27 shows the benefit scores reported for one glaucoma patient who completed a survey (reported benefit score of 7) and whose HCP also completed a survey (reported benefit score of 3).

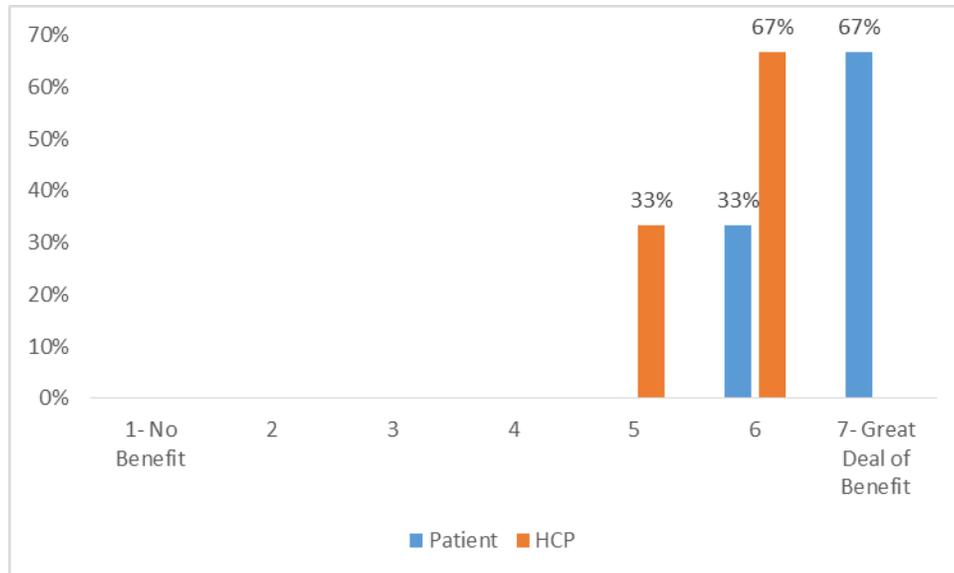

Figure 6.27. Glaucoma (N=1): Perceived Benefit

ALS

Figure 6.28 shows benefit scores reported by patients and their certifying HCPs for ALS patients for whom both scores were available (n=3). Comparison of proportions of patients and HCPs reporting each benefit score shows general agreement about degree of benefit experienced: 100% of patients and 67% of HCPs report scores of 6 or 7.

Figure 6.28. ALS (N=3): Perceived Benefit

Benefits Reported on Surveys: Conclusions

Of 1491 patients making a purchase in the first program year, 53% completed a survey three months after the first purchase. Among respondents, 43% reported experiencing the highest degree of benefit from medical cannabis and 87% reported at least a moderate degree of benefit (score of 4 or greater on a 1 to 7 scale). Patients reported the types of benefits experienced, which were predominantly (64%) various types of symptom improvement; many patients (25%) also reported global health benefits as the most important benefits from medical cannabis.

For patients making a purchase in the first six months of the program (n=774), 32% of HCP surveys were submitted. Overall, HCP reports of benefit were more conservative than those of patients, but 20% reported that the patient experienced the highest degree of benefit from medical cannabis and 60% reported at least a moderate degree of benefit. Among patients purchasing in the first six program months, 126 patients had both patient and HCP surveys completed and comparison of benefit scores indicated general agreement between the two scores for most patients.

Benefits Reported on the Patient Self-Evaluation

The Patient Self-Evaluation (PSE) contains questions that allow the Office of Medical Cannabis (OMC) to look for improvements in symptoms over time. Patients are required to complete a PSE prior to each medical cannabis purchase (including before their first medical cannabis purchase). This allows for capture of the patients’ symptoms at baseline – prior to taking any medical cannabis, as well as prior to each subsequent medical cannabis purchase. Hence, symptom change over time can be analyzed during the patients’ participation in the program.

All patients received a standard set of 8 symptom measures on the PSE. In addition, some patients received additional symptom questions depending on their qualifying medical condition(s). These two sets of symptom measures will be subsequently discussed below. Data from the PSE were extracted from patients who enrolled during the first program year (enrolled between July 1, 2015 and June 30, 2016; 1660 patients enrolled during this time period).

Standard 8 Symptom Measures

The standard 8 symptom measures that all patients received are answered on a 0-10 numerical rating scale (NRS), with 0 indicating absence of the symptom to 10 indicating that the symptom is as bad as the patient can imagine (see Box 6.1). Therefore, higher scores on these measures indicate poorer management of these symptoms. Patients are asked to rate symptom severity over the past 24 hours.

Box 6.1. Listing of the Standard 8 symptom measures that all patients answer, including the responses options available to patients.

<u>Standard 8 Symptom Measures:</u>											
Anxiety									Fatigue		
Lack of Appetite									Nausea		
Depression									Pain		
Disturbed Sleep									Vomiting		
<u>Response Options (0 – 10 NRS):</u>											
	0	1	2	3	4	5	6	7	8	9	10
Symptom not present											Symptom as bad as one can image

To understand whether patients derived any symptom benefits during their participation in the program, the following three questions were explored for each Standard 8 symptom measure:

QUESTION 1

Of those patients who experienced moderate to severe symptoms at baseline (score of 4 or higher at baseline), what percentage of them experienced at least a 30% improvement in symptoms within four months of their first medical cannabis purchase? The threshold of $\geq 30\%$ reduction on a 0-10 point scale was chosen because this threshold has been documented in clinical trials to represent clinically meaningful change – especially for pain reduction and spasticity reduction. Examples of $\geq 30\%$ change include moving from a score of 10 to a score of 7, from 9 to 6, from 8 to 5, from 7 to 4, etc.

QUESTION 2

If a patient achieved at least a 30% improvement on symptoms within 4 months of their first medical cannabis purchase (determined in Question 1), what percentage of them will, on average, still maintain that level of improvement in the four months following that initial 30% symptom improvement? [Four-month follow-up period]

QUESTION 3

What medical cannabis products were purchased just *prior* to the patient’s initial report of symptom improvement (first time patient indicated $\geq 30\%$ improvement on the PSE)? What was the average daily intake of delta-9-tetrahydrocannabinol (THC) and cannabidiol (CBD) for these product types?

To address Question 1 the following procedure was adopted for each standard 8 measure: all patients who scored 4 or higher at baseline were identified as those experiencing moderate to severe symptoms, and all standard 8 responses that were submitted within 4 months of their first medical cannabis purchase were retained. From this dataset, each patient’s standard 8 responses were compared to their baseline response over time. The first instance a patient achieved at least a 30% symptom improvement was recorded, effectively demonstrating when – during the first 4 months following their first medical cannabis purchase – the patient achieved symptom improvement, if at all.

Calculating the percentage of patients who achieved $\geq 30\%$ symptom improvement within 4 months of their first medical cannabis purchase (Question 1) was done in two ways. In one method, the number of patients who achieved $\geq 30\%$ symptom improvement within 4 months was divided by the total number of patients that ever made a first purchase (patients with baseline PSE data). In the other method, the number of patients achieving $\geq 30\%$ symptom improvement within 4 months was divided by patients who had submitted additional PSE data (beyond their baseline response) within 4 months of their first purchase. The denominator in

the former method includes all patients who made a first purchase (all patients with a baseline PSE submission), while the latter method effectively restricts the denominator to those patients who submitted additional PSE symptom data following their baseline submission and within 4 months of their first purchase. Therefore, the former method allows for a more conservative estimation of symptom benefit. In the text of this report, we present results using the former, more conservative estimate of benefit. Those who made no additional purchases after their first purchase may have discontinued use because of lack of effectiveness, though they may have discontinued use for other reasons as well (i.e., medical cannabis cost, side effects, etc.).

Since Question 1 examines symptom improvement within 4 months of their first medical cannabis purchase, patients who had not been enrolled in the program for at least 4 months since their first medical cannabis purchase were not included in the analysis. When PSE data were extracted in late December 2016, 1512 patients from the first year cohort (91.1% of the 1st year cohort) had been enrolled for at least 4 months since their first medical cannabis purchase—results on the standard 8 symptom measures are reported on this cohort subset.

Question 2 was addressed by observing all symptom responses in the four months *following* the time point when the patient first achieved $\geq 30\%$ symptom improvement. For each patient, all symptom responses identified during those follow-up four months were averaged together. Patients who, on average, still maintained at least a 30% symptom improvement from baseline were identified as those showing persistence in their symptom benefits.

For Question 3, products that were purchased just *prior* to each patient's initial $\geq 30\%$ symptom improvement were identified and categorized by their THC/CBD ratio and intended route of administration (ROA). See Box 6.2 for definitions of these categories.

Box 6.2. Categories to describe medical cannabis products purchased by patients.

Medical Cannabis Products Categorized by THC:CBD Content Ratio:

- **Very High THC to CBD** = 100:1 or higher
- **High THC to CBD** = >4:1 up to 99:1
- **Balanced** = 1:1 up to 4:1
- **High CBD to THC** = \geq 1:1 up to 99:1
- **Very High CBD to THC** = 100:1 or higher

Product Routes of Administration (ROA):

- **Enteral:** for absorption through the gastrointestinal tract (includes capsules and oral solutions to swallow).
- **Inhalation:** for absorption through the lungs (includes products for vaporization)
- **Oromucosal:** for absorption through the oral mucosa (includes sublingual sprays and tinctures to hold in the mouth)

Overall Results on Standard 8 Symptom Measures

Data on the Standard 8 symptom measures were first analyzed across all patients regardless of their qualifying condition(s) and are displayed in Table 6.14 (n = 1512). The third and fourth column respectively display the number and percentage of patients (out of 1512 patients) experiencing moderate to severe symptoms at baseline (baseline response \geq 4) on a given Standard 8 measure. With the exception of vomiting, the responses from patients indicated a high degree of burden on all symptom measures at baseline (~60-90% patients indicated moderate to severe symptoms).

The fifth column in Table 6.14 shows the percentage and number of patients (out of those reporting at moderate to severe levels at baseline) who had achieved at least a 30% symptom improvement at any time within 4 months of their first medical cannabis purchase. Anywhere from 36% to 60% of patients reported achieving at least a 30% improvement in symptoms within 4 months of their first medical cannabis purchase. Improvements in pain and fatigue were the least likely to reach \geq 30% improvement in patients (respectively at 36.3% and 40.2%), with the greatest proportion of patients reaching \geq 30% improvement in nausea (55.6%), depression (56.8%), and vomiting (60.2%).

The number of patients who had symptom data in the 4-month period *following* their initial \geq 30% symptom improvement are listed in the sixth column in Table 6.14. All symptom responses during this time period were averaged together within each patient. The seventh column shows the percentage and number of patients who had achieved \geq 30% symptom improvement that had – on average – maintained at least that level of improvement in the 4-

month follow-up period. Roughly a half to two-thirds of the patients who achieved at least 30% symptom improvement had maintained it in the following 4 months. Lastly, the right-most column shows the percentage of all patients who both achieved and maintained at least a 30% symptom improvement in the 4-month follow-up period. For the majority of all symptoms, roughly a third of all patients experiencing moderate to severe symptoms will both achieve and maintain at least a 30% improvement in symptoms for at least 4 months.

For a more detailed look on overall results from the eight standard symptom measures, please refer to *Appendix D: Symptom Results from the Patient Self-Evaluation*. This Appendix shows the following for each Standard 8 measure: 1) a figure showing the distribution of patient responses at baseline, 2) a figure showing the cumulative percentage of patients achieving at least 30% symptom improvement at 2 weeks, 1 month, 2 months, 3 months, and 4 months (the denominator is different between the orange and blue bars; orange bars include all moderate to severe scoring patients at baseline while blue bars restrict analyses to only those patients who submitted data by the time point indicated on the x-axis), and 3) a figure showing the frequency distribution of patients by the average symptom change (%) each patient experienced in the 4-month follow-up period since they initially achieved $\geq 30\%$ symptom reduction.

Table 6.14. Overall standard 8 symptom results.

Condition	Standard 8 Symptom Measure	# of Patients Reporting at Moderate to Severe Levels at Baseline	% of Patients Reporting at Moderate to Severe Levels at Baseline	% of Patients Achieving $\geq 30\%$ Symptom Improvement within 4 months of First Purchase out of all Moderate to Severe Baseline Scorers (n)	# of Patients with Data in 4-mo Period Following Initial $\geq 30\%$ Symptom Improvement	% of Patients Who Achieved $\geq 30\%$ Symptom Improvement that Maintained it for at Least 4 months (n)	% of Patients that Both Achieved $\geq 30\%$ Symptom Improvement and Retained that Degree of Improvement for at Least 4 months
All Patients - Collapsed Across Conditions (n = 1512)	Anxiety	1185	78.4	53.8 (638)	460	53.1 (339)	28.6
	Appetite Lack	963	63.7	53.7 (517)	383	57.1 (295)	30.6
	Depression	1000	66.1	56.8 (568)	419	56.7 (322)	32.2
	Disturbed Sleep	1323	87.5	50.3 (665)	519	52.0 (346)	26.2
	Fatigue	1381	91.3	40.2 (555)	415	48.6 (270)	19.6
	Nausea	864	57.1	55.6 (480)	362	59.2 (284)	32.9
	Pain	1312	86.8	36.3 (476)	329	45.0 (214)	16.3
	Vomiting	480	31.7	60.2 (289)	213	57.8 (167)	34.8

Results on Standard 8 Symptom Measures Stratified by Qualifying Condition

Data on the Standard 8 symptom measures were also analyzed separately by qualifying condition. Results are presented in Table 6.15 below. The first column indicates the qualifying condition and the total number of patients who had been enrolled in the program for at least 4 months since their first medical cannabis purchase. For some conditions, results are further broken down by condition subcategories (i.e., breakdown cancer patients based on whether their certifying condition was accompanied by pain, nausea/vomiting, etc.); condition subcategories are preceded by a star (*). The third and fourth columns in Table 6.15 indicate the number and percentage of patients who experienced moderate to severe symptoms (score ≥ 4) at baseline for each symptom.

The fifth column in Table 6.15 indicates the percentage and number of patients (out of those reporting at moderate to severe levels at baseline) that had achieved at least a 30% symptom improvement at any time within 4 months of their first medical cannabis purchase. The number of patients who had symptom data in the 4-month period *following* their initial $\geq 30\%$ symptom improvement are listed in the sixth column in Table 6.15. All symptom responses submitted during this time period were averaged together within each patient. The seventh column shows the percentage and number of patients that had achieved at least a 30% symptom improvement that had subsequently maintained it, on average, for at least 4 months. Lastly, the right-most column shows the percentage of all patients that had both achieved and maintained at least a 30% symptom improvement for at least 4 months.

Results generally show a high degree of burden for these eight symptoms at baseline. The instances where symptom severity is noticeably lower tend to be as expected; for example, nausea and vomiting in patients with Tourette syndrome and in patients with glaucoma. Among baseline responses to the eight symptom measures, those with the highest proportion rated as moderate to severe (score ≥ 4) include fatigue, disturbed sleep, pain, and anxiety. For each of the medical conditions, a substantial proportion of patients achieved $\geq 30\%$ reduction in most of the eight symptoms. Improvement was generally a bit higher in patients with seizures and with Tourette Syndrome and a bit lower in patients with cancer. Overall, a smaller proportion of patients achieved $\geq 30\%$ reduction of pain and fatigue and a higher proportion of patients achieved $\geq 30\%$ improvement in appetite and reduction in vomiting. For each medical condition, roughly half to three-quarters of the patients who experienced a $\geq 30\%$ reduction in a particular symptom within the first four months maintained that level of improvement over the following four months.

Table 6.15. Standard 8 symptom results stratified by qualifying condition.

Condition	Standard 8 Symptom Measure	# of Patients Reporting at Moderate to Severe Levels at Baseline	% of Patients Reporting at Moderate to Severe Levels at Baseline	% of Patients Achieving ≥30 Symptom Improvement within 4 months of First Purchase (n)	# of Patients with Data in 4-mo Period Following Initial ≥30% Symptom Improvement	% of Patients Who Achieved ≥30% Symptom Improvement that Maintained it for at Least 4 months (n)	% of Patients that Both Achieved ≥30% Symptom Improvement and Retained that Degree of Improvement for at Least 4 months

Appendix D: Symptom Results from the Patient Self-Evaluation shows the following for each Standard 8 measure stratified by qualifying medical condition: 1) a figure showing the distribution of patient responses at baseline, 2) a figure showing the cumulative percentage of patients achieving at least 30% symptom improvement at 2 weeks, 1 month, 2 months, 3 months, and 4 months (the denominator is different between the orange and blue bars; orange bars include all moderate to severe scoring patients at baseline while blue bars restrict analyses to only those patients who submitted data by the time point indicated on the x-axis), 3) a figure showing the frequency distribution of patients by the average symptom change (%) each patient experienced in the 4-month follow-up period since they initially achieved $\geq 30\%$ symptom reduction, and 4) a table of medical cannabis products patients purchased just prior to achieving $\geq 30\%$ symptom improvement for the first time, along with the average daily THC and CBD dose taken by patients.

Medical cannabis products that were purchased just prior to the initial 30% symptom improvement are discussed only briefly in this section (Question 3), and the reader is encouraged to see *Appendix D: Symptom Results from the Patient Self-Evaluation* for the full table of results. Here, only a few results regarding medical cannabis purchases are discussed as examples—some in relation to improvements on a particular Standard 8 measure, and others in relation to a particular condition-specific symptom measure.

Table 6.16 below shows the most common medical cannabis products that were purchased by cancer patients just prior to achieving the initial 30% reduction in nausea symptoms. The second column from the right indicates the number of patients who purchased specific products just prior to that initial symptom reduction (products purchased indicated by “X”s). The table also shows the average daily amount of THC and CBD (mg) patients consumed (right-most column), which was derived from manufacturer-supplied product information and pharmacist-entered calculations of how long the purchased supply would last. Very High THC:CBD vaporization products were purchased most frequently (n = 20), followed by a combination of Very High THC:CBD enteral products and Very High THC:CBD vaporization products (n = 12). See *Appendix D: Symptom Results from the Patient Self-Evaluation* for full results.

Table 6.16. Top 5 medical cannabis product(s) purchased by cancer patients just prior to achieving the initial 30% reduction in the Standard 8 nausea measure.

Very High THC to CBD	Enteral				Inhalation				Oromucosal				% of Patients out of 109 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)		
	High THC to CBD	Balanced	High CBD to THC	Very High CBD to THC	High THC to CBD	High THC to CBD	Balanced	High CBD to THC	Very High CBD to THC	High THC to CBD	High THC to CBD	Balanced			High CBD to THC	Very High CBD to THC
					X										18.3 (20)	55.9 mg/0.4 mg
X					X										11.0 (12)	71.6 mg/0.5 mg
										X					8.3 (9)	86.3 mg/0.4 mg
		X													6.4 (7)	135.5 mg/83.2 mg
X		X			X			X							4.6 (5)	61.4 mg/15.6 mg

Table 6.17 below shows the most common medical cannabis products that were purchased by terminal illness patients just prior to achieving the initial 30% reduction in nausea symptoms. The most frequently purchased products were a combination of both Very High THC:CBD products for oral administration and vaporization (n = 3), followed by Balanced THC:CBD products for inhalation only (n = 3). See *Appendix D: Symptom Results from the Patient Self-Evaluation* for full results.

Table 6.17. Top 7 medical cannabis product(s) purchased by terminal illness patients just prior to achieving the initial 30% reduction in the Standard 8 nausea measure.

Enteral			Inhalation			Oromucosal			% of Patients out of 26 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)
Very High THC to CBD	High THC to CBD	Balanced	Very High CBD to THC	High CBD to THC	Balanced	Very High THC to CBD	High THC to CBD	Balanced		
X						X			11.5 (3)	67.1 mg/0.5 mg

X		X				X			7.7 (2)	45.5 mg/37.5 mg
		X			X				7.7 (2)	110.1 mg/5.9 mg
		X						X	7.7 (2)	78.6 mg/61.1 mg
		X							7.7 (2)	49.0 mg/46.0 mg
			X						7.7 (2)	4.4 mg/206.7 mg

Table 6.18 below shows the most common medical cannabis products purchased by HIV/AIDS patients just prior to their initial 30% reduction in pain symptoms. Balanced THC:CBD products were purchased most frequently (n = 6), followed by Very High THC:CBD products for inhalation (n = 3). See *Appendix D: Symptom Results from the Patient Self-Evaluation* for full results.

Table 6.18. Top 4 medical cannabis product(s) purchased by HIV/AIDS patients just prior to achieving the initial 30% reduction in the Standard 8 pain measure.

Enteral			Inhalation			Oromucosal			% of Patients out of 18 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)
Very High THC to CBD	High THC to CBD	Balanced	Very High CBD to THC	High CBD to THC	Balanced	Very High THC to CBD	High THC to CBD	Balanced		
		X							33.3 (6)	23.1 mg/22.1 mg
			X						16.7 (3)	65.2 mg/0.3 mg
X		X							11.1 (2)	5.0 mg/0.0 mg
			X		X				11.1 (2)	51.7 mg/18.2 mg

Condition-Specific Symptom Measures

In addition to the Standard 8 measures, some patients received additional symptom questions on the PSE to more adequately address condition-specific symptoms. These include, among others, questions on seizure frequency for seizure patients, questions on spasm frequency for muscle spasm and ALS patients, and Crohn’s activity in Crohn’s patients. While patients received the same response options on the Standard 8 measures (respond from 1-10 on a

numerical rating scale), response options for condition-specific measures varied and will be described in this section. All condition-specific measures were investigated within the same framework as the Standard 8 measures: 1) what percentage of patients achieved symptom improvement within the four months since their first medical cannabis purchase compared to their baseline responses, 2) what percentage of those achieving symptom improvement showed general persistence in the 4-month follow-up period, and 3) what medical cannabis products were purchased just prior to the patient reporting initial symptom improvements. A summary of results are similarly presented in a table like those presented for the Standard 8 measures (see Table 6.19 below).

The first column in Table 6.19 lists each condition that received additional symptom questions beyond the Standard 8. The second column briefly indicates the nature of these additional condition-specific symptom measures, with the number of patients included in the analysis at baseline indicated in the third column (baseline, meaning patients who provided data and met criteria on these measures at the beginning of the program – prior to purchasing any medical cannabis). The fourth column indicates the percentage and number of patients achieving a specified threshold of symptom improvement within four months of purchasing their first medical cannabis (denominator is patients included in the analysis at baseline). The threshold to determine symptom improvement for these analyses are subsequently described below, found in the descriptive section for each condition. The number of patients who had symptom data in the 4-month period following their initial symptom improvement are listed in the fifth column in Table 6.19. All symptom responses during this time period were averaged together within each patient. The sixth column indicates the percentage and number of patients who had achieved symptom improvement that subsequently still maintained that improvement for at least 4 months. Lastly, the right-most column shows the percentage of all patients who both achieved and maintained symptom improvements for at least 4 months. A more detailed discussion of these condition-specific results will follow Table 6.19.

Table 6.19. Condition-Specific Measures.

Condition	Condition-Specific Symptom Measure	# of Patients Included in Analysis	% of Patients Achieving Threshold Symptom Improvement within 4 months of First Purchase (n)	# of Patients with Data in 4-mo Period Following Initial Threshold Symptom Improvement	% of Patients Who Achieved Threshold Symptom Improvement that Maintained it for at Least 4 months (n)	% of Patients that Both Achieved Threshold Symptom Improvement and Retained that Degree of Improvement for at Least 4 months
Muscle Spasms	Weekly Spasms Frequency	629	48.0 (302)	225	57.6 (174)	27.6
	0-10 Spasticity Scale	618	36.4 (225)	197	47.1 (106)	17.2
Cancer: Nausea/Vomiting	Chemo-Induced Nausea	147	37.4 (55)	29	34.5 (19)	12.9
	Chemo-Induced Vomiting	77	41.6 (32)	20	56.3 (18)	23.4
Cancer: Cachexia/Wasting	Weight	147	13.6 (20)	15	45.0 (9)	6.1
Seizures	Weekly Seizure Frequency	262	68.3 (179)	150	70.9 (127)	48.5
Crohn's Disease	# Liquid Stools	41	51.2 (21)	17	57.1 (12)	29.3
	Abdominal Pain	73	53.4 (39)	29	35.9 (14)	19.2
	General Well-Being	15	46.7 (7)	5	28.6 (2)	13.3
	Measures Combined	102	51.0 (52)	41	42.3 (22)	21.6
	Weight	102	20.6 (21)	18	57.1 (12)	11.8
Terminal Illness: Cachexia/Wasting	Weight	29	20.7 (6)	5	50.0 (3)	10.3
HIV/AIDS	Weight	48	14.6 (7)	3	42.9 (3)	6.3
Tourette Syndrome	Weekly Tic Frequency	28	60.7 (17)	15	76.5 (13)	46.4
ALS	Weekly Spasms Frequency	18	33.3 (6)	4	66.7 (4)	22.2
	0-10 Spasticity Scale	15	20.0 (3)	3	100.0 (3)	20.0

Severe and Persistent Muscle Spasms

Patients with muscle spasms were given two questions to assess the severity of their muscle spasms. First, patients were given the option to respond to the number of muscle spasms they experienced the day before or the number of muscle spasms they experienced within the last week. These allowed for the calculation of weekly spasm frequency. Secondly, patients were asked to rate the severity of their muscle spasms on a 0-10 numerical rating scale (NRS), with 0 indicating absence of spasms to 10 indicating spasticity being as bad as the patient could imagine. For the analysis in Table 6.19 above, responses to the 0-10 spasticity measure were restricted to patients experiencing moderate to severe spasticity at baseline (score of 4 or higher), while all patients responding to the weekly spasms frequency question were included in the analysis. In the analysis of both measures, symptom improvement was defined as achieving at least a 30% reduction in symptoms (30% decrease in weekly spasm frequency; 30% decrease on the 0-10 NRS spasticity measure) compared to baseline.

Weekly spasm frequency was reduced by $\geq 30\%$ in nearly half (48.0%) of the muscle spasm patients. Among patients who achieved $\geq 30\%$ reduction, 58% (27.6% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Severity of muscle spasticity was reduced by $\geq 30\%$ for 36.4% of the patients with moderate to severe muscle spasticity at baseline. Among patients who achieved $\geq 30\%$ reduction, 47% (17.2% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Table 6.20 below shows the top 5 medical cannabis product types that were purchased by muscle spasm patients just prior to achieving $\geq 30\%$ weekly spasm reduction for the first time, including the number of patients who purchased those specific product types (second column from right). It also shows the average daily amount of THC and CBD (mg) patients consumed (right-most column), which was derived from manufacturer-derived product information and pharmacist-entered calculations of how long the purchased supply would last. Full purchasing details are in *Appendix D: Symptom Results from the Patient Self-Evaluation*. The most frequently purchased product types preceding the initial symptom improvement were a combination of Balanced THC:CBD products for oral administration and Balanced THC:CBD products for vaporization (n = 34), followed by Very High THC:CBD products for vaporization (n = 30).

Table 6.20. Top 5 medical cannabis product types purchased by muscle spasm patients just prior to achieving $\geq 30\%$ reduction in weekly spasms. Last column shows the average daily THC/CBD dose that was used by patients purchasing those product types (second column from right).

Enteral					Inhalation					Oromucosal					% of Patients out of 301 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)
Very High THC to CBD	High THC to CBD	Balanced	High CBD to THC	Very High CBD to THC	Very High THC to CBD	High THC to CBD	Balanced	High CBD to THC	Very High CBD to THC	Very High THC to CBD	High THC to CBD	Balanced	High CBD to THC	Very High CBD to THC		
		X					X								11.3 (34)	55.3 mg/35.1 mg
					X										10.0 (30)	77.8 mg/0.5 mg
		X			X										9.6 (29)	79.6 mg/30.0 mg
		X													8.3 (25)	23.6 mg/22.4 mg
					X		X								7.0 (21)	99.8 mg/17.5 mg

Cancer: Nausea and Vomiting

Patients certified for cancer accompanied by severe and persistent nausea or vomiting were asked to assess the severity of chemotherapy-induced nausea and vomiting on a 0-10 numerical rating scale. Patients who experienced chemotherapy-induced nausea and vomiting at moderate to severe levels at baseline (score of 4 or higher) were included in the analysis in Table 6.19, with symptom improvement being defined as achieving at least a 30% improvement in symptoms (30% decrease on the 0-10 nausea/vomiting NRS) compared to baseline.

Severity of chemotherapy-induced nausea was reduced by $\geq 30\%$ for 37.4% of the patients with moderate to severe chemotherapy-induced nausea at baseline. Among the patients who achieved $\geq 30\%$ reduction, 35% (12.9% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Severity of chemotherapy-induced vomiting was reduced by $\geq 30\%$ for 41.6% of the patients with moderate to severe chemotherapy-induced vomiting at baseline. Among the patients who achieved $\geq 30\%$ reduction, 56% (23.4% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Cancer: Cachexia and Severe Wasting

Body weights were analyzed for patients certified for cancer accompanied by cachexia and/or severe wasting. Symptom improvement was defined as achieving at least a 3% increase in body weight compared to baseline weight.

An increase of at least 3% in body weight was reported by 13.6% of patients. Among the patients who achieved $\geq 3\%$ increase in body weight, 45% (6.1% of patients included in analysis at baseline) retained that increase over the next four months.

Seizures

Patients with seizures were given two questions to assess the severity of their seizures. First, patients were given the option to respond to the number of seizures they experienced the day before or the number of seizures they experienced within the last week. These allowed for the calculation of weekly spasm frequency. Table 6.19 shows results from the weekly seizure frequency measure, with symptom improvement defined as achieving at least a 30% improvement in symptoms (30% decrease in weekly seizure frequency) compared to baseline.

Weekly seizure frequency was reduced by $\geq 30\%$ in 68.3% of the seizure patients. Among patients who achieved $\geq 30\%$ reduction, 71% (48.5% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Table 6.21 below shows the top 5 medical cannabis product types that were purchased by seizure patients just prior to achieving $\geq 30\%$ symptom improvement for the first time, including the number of patients who purchased those specific product types (second column from right). It also shows the average daily amount of THC and CBD (mg) patients consumed (right-most column), which was derived from manufacturer-derived product information and pharmacist-entered calculations of how long the purchased supply would last. Full purchasing details are in *Appendix D: Symptom Results from the Patient Self-Evaluation*. The most frequently purchased product types preceding the initial symptom improvement were skewed towards relatively high CBD:THC products, with preference for oral administration of these products.

Table 6.21. Top 5 medical cannabis product types purchased by seizure patients just prior to achieving ≥30% reduction in weekly seizures. Last column shows the average daily THC/CBD dose that was used by patients purchasing those product types (second column from right).

Enteral				Inhalation				Oromucosal				% of Patients out of 178 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)
Very High THC to CBD	Balanced	High CBD to THC	Very High CBD to THC	Very High THC to CBD	Balanced	High CBD to THC	Very High CBD to THC	Very High THC to CBD	Balanced	High CBD to THC	Very High CBD to THC		
		X										48.3 (86)	7.6 mg/159.5 mg
										X		16.9 (30)	13.2 mg/407.4 mg
	X				X							4.5 (8)	56.0 mg/37.4 mg
		X	X									3.4 (6)	4.9 mg/282.5 mg
	X											2.8 (5)	19.3 mg/15.9 mg

Crohn's Disease

Three questions from the Harvey-Bradshaw Index (HBI), which measures Crohn's disease activity, were included on the PSE for Crohn's disease patients. These three questions addressed the following: 1) the number of liquid or soft stools experienced yesterday, 2) general well-being yesterday (response options: "Very well", "Slightly below par", "Poor", "Very poor", "Terrible"), and 3) abdominal pain yesterday (response options: "None", "Mild", "Moderate", "Severe"). Responses to these three questions were summed into a combined score for each patient (combined according to HBI scoring guidelines) as well as analyzed separately in Table 6.19. The three questions were selected from the HBI because they were patient-reported measures (versus clinician assessments). The HBI has been validated, but since only three questions from the HBI were used, the clinical significance of these aggregate and individual scores is unclear. Lastly, body weight data submitted through the PSE were analyzed and included in Table 6.19.

Patients who indicated they experienced five or more liquid/soft stools at baseline were included in the analysis, with symptom improvement defined as achieving at least a 30% reduction in liquid/soft stools. Patients who indicated their general well-being was "Very Poor" or "Terrible" at baseline were included in the well-being analysis, with symptom improvement defined as feeling "Slightly Below Par" or "Very Well". Patients who indicated they experienced "Moderate" or "Severe" abdominal pains were included in the abdominal pain analysis, with symptom improvement defined as experiencing "Mild" to "No" abdominal pain. For the combined Crohn's activity measure (combined score on the three HBI measures), symptom improvement was defined as those achieving at least a 30% symptom improvement (30% decrease in the combined score compared to baseline). Lastly, body weight improvement was defined as a 3% increase in body weight.

Number of liquid/soft stools per day decreased by $\geq 30\%$ for 51.2% of patients with at least five liquid/soft stools per day at baseline. Among patients who achieved $\geq 30\%$ reduction, 57% (29.3% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Severity of abdominal pain improved for 53.4% of patients with moderate or severe abdominal pain at baseline. Among patients who reported an improvement in abdominal pain, 36% (19.2% of patients included in analysis at baseline) retained that improvement over the next four months.

General well-being improved for 46.7% of patients who described their baseline well-being as "Very Poor" or "Terrible" at baseline. Among patients who reported an improvement in general well-being, 29% (13.3% of patients included in analysis at baseline) retained that improvement over the next four months.

On the combined Crohn's activity measure (number of liquid/soft stools, abdominal pain, general well-being), 51.0% of Crohn's Disease patients achieved $\geq 30\%$ improvement. Among

patients who achieved $\geq 30\%$ reduction, 42% (21.6% of patients included in analysis at baseline) retained that level of improvement over the next four months.

An increase of at least 3% in body weight was reported by 20.6% of patients. Among the patients who achieved $\geq 3\%$ increase in body weight, 57% (11.8% of patients included in analysis at baseline) retained that increase over the next four months.

Terminal Illness

Body weight measures on the PSE were analyzed in patients certified for terminal illness: accompanied by cachexia or severe wasting. Symptom improvement was defined as a 3% increase in body weight from their baseline body weight.

An increase of at least 3% in body weight was reported by 20.7% of patients. Among the patients who achieved $\geq 3\%$ increase in body weight, 50% (10.3% of patients included in analysis at baseline) retained that increase over the next four months.

HIV/AIDS

Body weight measures on the PSE were analyzed in HIV/AIDS patients. Similar to all body weight measures of improvement discussed previously, symptom improvement was defined as a 3% increase in body weight compared to their baseline body weight.

An increase of at least 3% in body weight was reported by 14.6% of patients. Among the patients who achieved $\geq 3\%$ increase in body weight, 43% (6.3% of patients included in analysis at baseline) retained that increase over the next four months.

Tourette Syndrome

Patients with Tourette Syndrome were given two questions to assess the severity of their tics. First, patients were given the option to respond to the number of tics they experienced the day before or the number of tics they experienced within the last week. These allowed for the calculation of weekly tic frequency. For Table 6.19, weekly tic frequency was analyzed in all patients, with symptom improvement defined as a 30% improvement in symptoms (30% decrease in weekly tics compared to baseline).

Weekly tic frequency was reduced by $\geq 30\%$ in 60.7% of the Tourette Syndrome patients. Among patients who achieved $\geq 30\%$ reduction, 76% (46.4% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Table 6.22 below shows the top 4 medical cannabis product types that were purchased by Tourette patients just prior to achieving $\geq 30\%$ symptom improvement for the first time, including the number of patients who purchased those specific product types (second column from right). It also shows the average daily amount of THC and CBD (mg) patients consumed (right-most column), which was derived from manufacturer-derived product information and pharmacist-entered calculations of how long the purchased supply would last. Full purchasing details are in *Appendix D: Symptom Results from the Patient Self-Evaluation*. The most frequently purchased product types preceding the initial symptom improvement were Very High THC:CBD oromucosal products (4 patients) and a combination of Balanced THC:CBD oral products and Very High THC:CBD oral products (2 patients)

Table 6.22. Top 4 medical cannabis product types purchased by Tourette patients just prior to achieving $\geq 30\%$ reduction in weekly tics. Last column shows the average daily THC/CBD dose that was used by patients purchasing those product types (second column from right).

Enteral			Inhalation			Oromucosal			% of Patients out of 17 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)
Very High THC to CBD	Balanced	High CBD to THC	Very High THC to CBD	Balanced	High CBD to THC	Very High THC to CBD	Balanced	High CBD to THC		
						X			23.5 (4)	147.3 mg/0.7 mg
X	X								11.8 (2)	24.0 mg/15.0 mg
	X								11.8 (2)	11.5 mg/8.5 mg
			X						11.8 (2)	64.6 mg/0.2 mg

Glaucoma

Intraocular pressure results were collected on the PSE from Glaucoma patients and are presented in Table 6.23 for each of the 21 patients included in this analysis. At the first PSE (prior to first medical cannabis purchase) patients were asked to provide the date and results of the most recent intraocular pressure test. On subsequent PSEs patients were asked to provide the date and results of any intraocular pressure test done since submission of the last PSE.

Results for seven of the 21 patients (33%) suggest a decrease in intraocular pressure after initiation of medical cannabis: patients #4, 8, 9, 14, 16, 17, and 19. One of those seven did not show a decrease at 5 months, but did show a decrease at 9 months. Four of them had measurement results after the date of the result that indicated a decrease: patients #4, 16, 17, and 19. Of those four, three have results indicating persistence of reduction over several months. The fourth (#19) had a reduction in month 2 but returned toward pre-medical cannabis levels at month 4. More detailed study, including accessing medical record data, would be needed to confirm measurement results and to assess whether observed improvements could have been due to changes in glaucoma therapy other than medical cannabis use.

Table 6.23. Intraocular pressure test results (left eye/right eye) from glaucoma patients (n = 21). Test results are noted by the month they occurred prior to or after the patients' first medical cannabis purchase ("First Visit").

Patient	Before 1st Medical Cannabis Purchase							First Visit	After 1st Medical Cannabis Purchase										
	12-mo	11-mo	5-mo	4-mo	3-mo	2-mo	1-mo		1-mo	2-mo	3-mo	4-mo	5-mo	6-mo	7-mo	9-mo	10-mo	11-mo	13-mo

ALS

Patients with ALS were given two questions to assess the severity of their muscle spasms. First, patients were given the option to respond to the number of spasms they experienced the day before or the number of spasms they experienced within the last week. These allowed for the calculation of weekly spasm frequency. Table 6.19 presents results on weekly spasm frequency and spasm severity (0-10 NRS). For the spasticity scale measure, patients who experienced moderate to severe spasms at baseline (scored 4 or higher) were included in the analysis, with symptom improvement defined as achieving at least a 30% symptom improvement (30% decrease on the 0-10 NRS compared to baseline).

Weekly spasm frequency was reduced by $\geq 30\%$ in 33.3% of the ALS patients. Among patients who achieved $\geq 30\%$ reduction, 67% (22.2% of patients included in analysis at baseline) retained that level of improvement over the next four months.

Severity of muscle spasticity was reduced by $\geq 30\%$ for 20.0% of the ALS patients with moderate to severe muscle spasticity at baseline. Among the three patients who achieved $\geq 30\%$ reduction, all three retained that level of improvement over the next four months (20.0% of patients included in analysis at baseline).

Table 6.24 below shows the top 5 medical cannabis product types that were purchased by ALS patients just prior to achieving $\geq 30\%$ weekly spasm reduction for the first time, including the number of patients who purchased those specific product types (second column from right). It also shows the average daily amount of THC and CBD (mg) patients consumed (right-most column), which was derived from manufacturer-derived product information and pharmacist-entered calculations of how long the purchased supply would last. Full purchasing details are in *Appendix D: Symptom Results from the Patient Self-Evaluation*. The most frequently purchased product types preceding the initial symptom improvement were skewed towards balanced THC:CBD products and relatively high THC:CBD products.

Table 6.24. Top 5 medical cannabis product types purchased by ALS patients just prior to achieving $\geq 30\%$ reduction in weekly spasms. Last column shows the average daily THC/CBD dose that was used by patients purchasing those product types (second column from right).

Enteral			Inhalation			% of Patients out of 6 (n)	Avg Daily THC Use (mg) / Avg Daily CBD Use (mg)
Very High THC to CBD	High THC to CBD	Balanced	Very High THC to CBD	High THC to CBD	Balanced		
		X				33.3 (2)	12.8 mg/5.1 mg
X			X			16.7 (1)	59.8 mg/0.3 mg
	X	X	X		X	16.7 (1)	67.0 mg/6.0 mg
	X	X				16.7 (1)	37.5 mg/8.1 mg
			X			16.7 (1)	42.2 mg/0.3 mg

Benefits Reported on the Patient Self-Evaluation: Conclusions

Similar to survey results, the PSE also demonstrated improvements on symptoms in medical cannabis patients. Patients enrolling in the program initially report a high degree of symptom burden with anywhere from roughly 40-60% of patients reporting symptom improvements within the 4 month period following their first medical cannabis purchase. If patients experienced improvements in symptoms, roughly half to three-quarters of them maintained those levels of improvement in the 4-month period following their initial report of improvement.

There are some limitations on the PSE to consider when interpreting results. Firstly, there is no symptom data on patients who decide over time not to purchase medical cannabis any longer (or for extended periods of time). As discussed earlier, patients must complete a PSE prior to each medical cannabis purchase. If a patient stops purchasing medical cannabis, there will be a parallel pause in symptom data to understand whether there may have been a lack of symptom improvements to halt purchases. This is the reason for presenting many analyses on symptom improvements in the context of the initial baseline patient pool – regardless of whether they provided any subsequent symptom data or not. This allows for more of a conservative estimate of symptom benefit over time. A second limitation on the PSE has to do with the patient’s approach and conscientiousness in completing the PSE—all symptom measures are self-reported which involves cognitive resources and motivation for the patient to complete the surveys as accurately as possible.

7. Adverse Side Effects

Summary

This chapter provides insight into the frequency and severity of adverse (negative) side effects through three sources of information: the Patient Self-Evaluation completed by the patient prior to each medical cannabis purchase, patient and health care practitioner surveys, and adverse event reports to the two medical cannabis manufacturers.

The three information sources tell a similar story. Around 20-25% of enrolled patients report negative physical or mental side effects of some kind, with the majority – around 60% - reporting only one and 90% reporting 3 or fewer unique side effects. The vast majority of adverse side effects, around 90%, are mild to moderate in severity. An assessment of the 30 patients reporting severe side effects, meaning “interrupts usual daily activities,” found no apparent pattern in patient age, medical condition, or type of medical cannabis product used. Results reported in this chapter are generally similar to those reported in published clinical trials of cannabis and cannabinoids, though with a somewhat lower frequency of occurrence reported in the program. Fortunately, up to the present no serious adverse events (life threatening or requiring hospitalization) have been reported.

Some limitations of the data should be mentioned. For example, when the patient completes a Patient Self-Evaluation and has it reviewed in consultation with pharmacist staff, the completeness and accuracy of reported side effects (on the Patient Self-Evaluation) ultimately depend on the attention and good communication of the patient. Perhaps a more significant risk for under-reporting through Patient Self-Evaluation data is the situation when a patient has an intolerable side effect and decides to make no more purchases of medical cannabis. If the patient doesn't go to a cannabis patient center for another purchase, the patient doesn't fill out another Patient Self-Evaluation, so the side effect is not documented through this mechanism. From anecdotal report and survey responses, we know this does occur. However, inquiries made of patients who have discontinued medical cannabis purchasing suggests this does not happen often. Finally, a weakness of the survey data is that many responders did not complete the question on most significant negative effect and a substantial proportion who did indicated cost or access issues, rather than physical or mental side effects. Though physical or mental side effects were probably minor or not present if the respondent indicated cost or access issues as the most significant negative effect, we don't know that for sure. We are unable to characterize most significant negative effect for those who did not submit a response.

Though the limitations mentioned in the paragraph above no doubt undercount the frequency of physical and mental side effects to some degree, their impact does not seem likely to

significantly change the main conclusions of the analyses reported in this section: at this point, the safety profile of the medical cannabis products available through the Minnesota program seems quite favorable.

Adverse Side Effects Reported on the Patient Self-Evaluation

Patients have the opportunity to report adverse side effects they attribute to medical cannabis on the Patient Self-Evaluation (PSE). Patients must complete a PSE prior to each medical cannabis purchasing transaction. Therefore, the administration of the PSE is timed so that patients can reflect on their experience with the medication they purchased previously and report those experiences on the following patient self-evaluation. A pharmacist at one of the eight medical cannabis dispensaries can then review PSE-reported information, which includes an opportunity to discuss side effects with the patient prior to approving that patient for another medical cannabis purchase. When reporting side effects on the PSE, patients are able to choose side effects from a pre-made list of options or write in side effects that do not fit one of the listed options. In addition, patients also indicate the severity with which each side effect is experienced (see Box 7.1).

Box 7.1. Definitions on severity provided to patients for adverse side effect reporting.

Adverse side effects were examined within the 1st program year cohort (n = 1660). Patients who had made at least their first medical cannabis purchase were identified, and from these patients, all PSEs that were

Adverse Side Effect Severity: Definitions

Mild: Symptoms do not interfere with daily activities

Moderate: Symptoms may interfere with daily activities

Severe: Symptoms interrupt usual daily activities

submitted within the four months following their first medical cannabis purchase were included in a dataset. This led to a total of 1502 patients (90.5% of the cohort) being represented. For the following analyses, each side effect was counted once for a given patient if it was reported multiple times. If a side effect was reported multiple times, the observation that was categorized at the highest severity level was included in the analyses for this report. In cases where a patient opted to write in their side effects (rather than choosing from the pre-made list of options), their responses were assessed carefully for adjudication for coding purposes. Therefore – while not affecting a substantial number of side effect responses – it should be noted that one limitation for accurate coding is the patient’s ability to adequately articulate their experiences.

Of the 1502 patients, 18.1% (n = 272) reported any adverse side effects within the four month period following their first medical cannabis purchase. Of those 272 patients reporting any adverse side effects, the majority reported only one (n = 164, 60.3%), with approximately 90% of them reporting three or fewer different, adverse side effects (Figure 7.1).

Figure 7.1. Distribution of patient counts by number of different, adverse side effects reported (out of 272 patients).

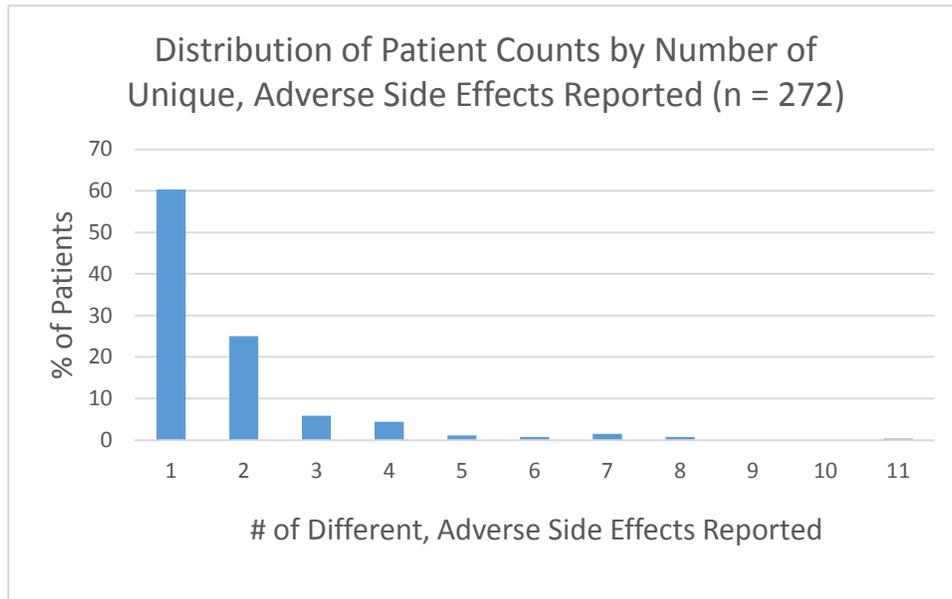

Figure 7.2 shows the percentage of patients reporting specific adverse side effects (Table 7.1 below lists adverse side effects that were reported by less than 2% of all patients). Of all side effects reported, dry mouth and drowsiness/somnolence/sedation were the most commonly reported side effects among patients. Overall, the frequency distribution of unique side effects mirrors typical clinical trial data on side effects from cannabis/cannabinoid use (see [“A Review of Medical Cannabis Studies relating to Chemical Compositions and Dosages for Qualifying Medical Conditions”](#) on the [Office of Medical Cannabis](#) website).

Figure 7.2. The most commonly reported adverse side effects represented by the percentage of patients reporting them (out of 272 patients).

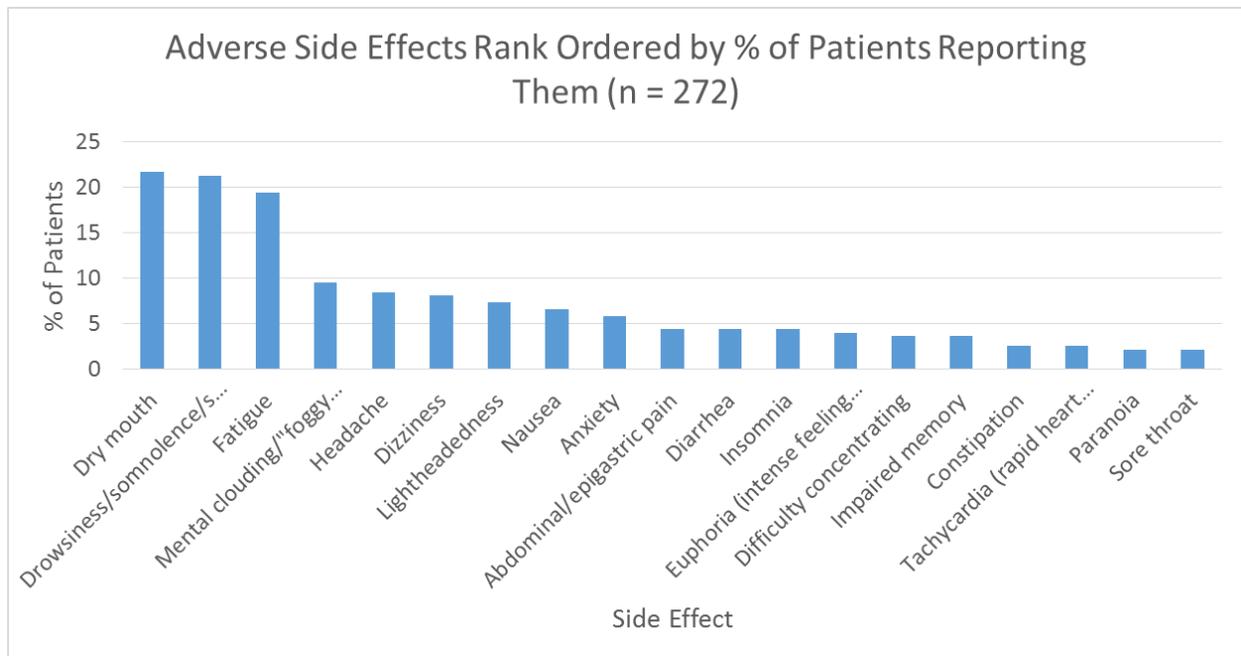

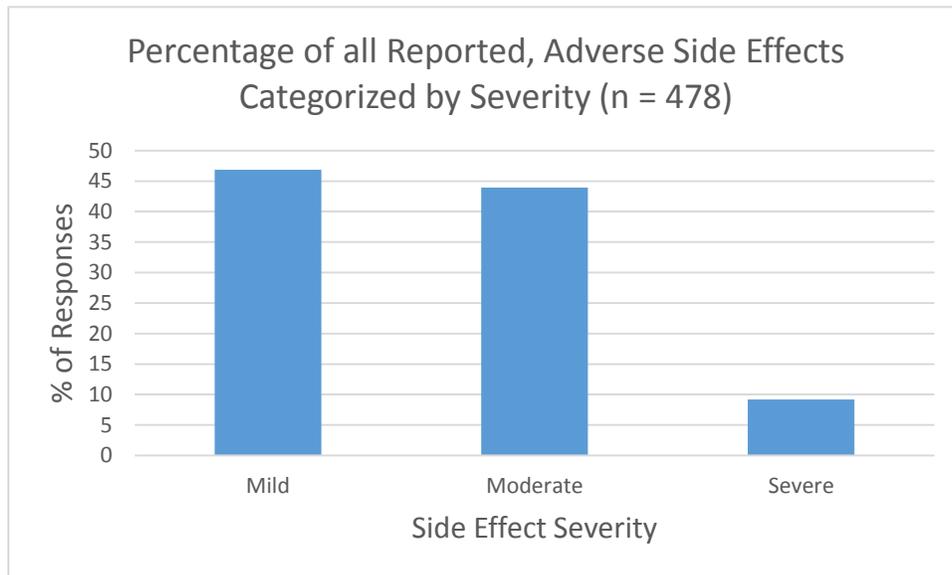

Table 7.1. Adverse side effects that were reported by less than 2% of patients (out of 272 patients).

Side Effect	% of Patients (n)
Asthenia (muscle weakness)	1.8% (5)
Chest pain	1.8% (5)
Confusion	1.8% (5)
Disorientation	1.5% (4)
Eye redness	1.5% (4)
Lethargy	1.5% (4)
Blurred Vision	1.1% (3)
Decreased muscle coordination/balance	1.1% (3)
Increased agitation	1.1% (3)
Numbness	1.1% (3)
Panic attack	1.1% (3)
Personality/mood change	1.1% (3)
Tinnitus (ringing perception in the ears)	1.1% (3)
"Stoned" feeling	0.7% (2)
Body stiffness	0.7% (2)
Coughing/lung irritation	0.7% (2)
Decreased appetite	0.7% (2)
Dry eyes	0.7% (2)
Feeling cold	0.7% (2)
Increased seizures	0.7% (2)
Tremors	0.7% (2)
"Wired" feeling	0.4% (1)
Bloating	0.4% (1)
Burping	0.4% (1)

Side Effect	% of Patients (n)
Change in quality of seizures	0.4% (1)
Chest colds	0.4% (1)
Cognitive change	0.4% (1)
Cramping with bowel movement	0.4% (1)
Dysphoria (intense feeling of unease or unpleasantness)	0.4% (1)
Exacerbation of lymphedema	0.4% (1)
Eye muscle twitching	0.4% (1)
Hives	0.4% (1)
Hyperactive bowel sounds	0.4% (1)
Hypomania	0.4% (1)
Increase in mucus secretions	0.4% (1)
Increased aggression	0.4% (1)
Increased urine output	0.4% (1)
Increased yelling	0.4% (1)
Mouth irritation/burning	0.4% (1)
Rash on face	0.4% (1)
Repressed immune system	0.4% (1)
Sleep disturbance	0.4% (1)
Sneezing	0.4% (1)
Thrush	0.4% (1)
Urinary retention	0.4% (1)
Vomiting	0.4% (1)
Worsening acne	0.4% (1)

The 272 patients reporting any adverse side effects submitted a combined total of 478 side effect responses within 4 months of their first medical cannabis purchase. When aggregating all side effect responses across patients, only 9.2% (44) of all responses were reported as severe (see Figure 7.3).

Figure 7.3. Percentage of all reported, adverse side effect responses categorized by severity.

Severe Adverse Side Effects

All adverse side effect responses that were categorized as severe are further broken down by the percent of patients categorizing them as such—please see Table 7.2 below.

Table 7.2. Table shows the number of patients reporting the listed side effects along with the percentage of those respondents who indicated that the side effect was severe.

Side Effect	# of Patients Reporting	% of Patients Reporting as Severe (n)
Dry mouth	59	6.8% (4)
Drowsiness/somnolence/sedation	58	5.2% (3)
Fatigue	53	3.8% (2)
Mental clouding/"foggy brain"	26	7.7% (2)
Headache	23	4.3% (1)
Dizziness	22	9.1% (2)
Lightheadedness	20	0% (0)
Nausea	18	11.1% (2)
Anxiety	16	12.5% (2)
Abdominal/epigastric pain	12	8.3% (1)
Diarrhea	12	16.7% (2)
Insomnia	12	8.3% (1)
Euphoria (intense feeling of well-being or pleasure)	11	9.1% (1)
Difficulty concentrating	10	20% (2)
Impaired memory	10	10% (1)
Constipation	7	14.3% (1)
Tachycardia (rapid heart rate)	7	28.6% (2)
Paranoia	6	16.7% (1)
Sore throat	6	0% (0)
Asthenia (muscle weakness)	5	60% (3)
Chest pain	5	20% (1)
Confusion	5	0% (0)
Disorientation	4	0% (0)
Eye redness	4	0% (0)
Lethargy	4	50% (2)
Blurred Vision	3	0% (0)
Decreased muscle coordination/balance	3	33.3% (1)
Increased agitation	3	0% (0)
Numbness	3	33.3% (1)
Panic attack	3	33.3% (1)
Personality/mood change	3	0% (0)
Tinnitus (ringing perception in the ears)	3	0% (0)
"Stoned" feeling	2	50% (1)
Body stiffness	2	0% (0)

Table 7.2 Continued. Table shows the number of patients reporting the listed side effects along with the percentage of those respondents who indicated that the side effect was severe.

Side Effect	# of Patients Reporting	% of Patients Reporting as Severe (n)
Coughing/lung irritation	2	0% (0)
Decreased appetite	2	0% (0)
Dry eyes	2	0% (0)
Feeling cold	2	0% (0)

Mouth irritation/burning	1	0% (0)
Rash on face	1	0% (0)
Repressed immune system	1	0% (0)
Sleep disturbance	1	0% (0)
Sneezing	1	0% (0)
Thrush	1	0% (0)
Urinary retention	1	0% (0)
Vomiting	1	0% (0)
Worsening acne	1	0% (0)

The 44 severe side effect responses (9.2% of total side effect responses) were attributed to 30 patients (11.0% of patients reporting any side effects). Patients experiencing severe side effects represent a wide range of ages, including children and elderly patients; 14 patients were male and 16 patients were female. Their age, gender, and certifying conditions generally matched the whole first year cohort. Half of patients reporting severe side effects were taking a form of balanced THC:CBD product (n=15); 10 patients were using a high CBD product, 9 patients were using a very high THC product and 4 patients were using a high THC product. Seven of 30 patients (23%) were using a combination of products with varying THC:CBD ratios (the most common combination was very high THC products and 1:1 THC:CBD products); 9 patients used a combination of products with different routes of administration (the most common combination was enteral and inhaled). Refer to Table 7.3 for details on the patients reporting severe side effects, along with the product types that were purchased just prior to experiencing the severe side effect.

PSE-Reported Adverse Side Effects: Conclusions

Less than a quarter of patients from the cohort (~18%) reported adverse side effects within the first 4 months since purchasing their first medical cannabis products. Roughly 90% of those that do report any side effects report 3 or fewer unique side effects during that time period. Results also suggest that relatively few patients experience severe, adverse side effects, with less than 10% of all responses (attributed to 30 patients) being categorized as severe.

Table 7.3. Patients reporting “severe” side effects: patient age, gender, and condition, product types purchased at most recent visit, and type of side effect reported.

Adverse Side Effects Reported on Surveys

Patient-Reported Negative Effects of Medical Cannabis

For overall patient response rate to the survey three months after first purchase and comparison of responders and non-responders see the section with survey results in the Benefits chapter above.

The Patient Experience survey asks respondents to report the degree, or severity, of any negative effects they believe the patient received from using medical cannabis, on a scale from 1 (no negative effects) to 7 (a great deal of negative effects). The survey then asked the respondent to describe, in their own words, the most significant negative effect. Table 7.4 shows the distribution of negative effects by severity score within three broad categories: physical side effects (including dry mouth, fatigue, headache, dizziness, blurred vision); mental side effects (including mental clouding, paranoia, sedation or symptoms related to “high”); and issues related to accessing the medications (distance to distribution center, inconvenient operating hours for distribution centers, etc.). Based on anticipated reports on the high cost of medication, patients were asked to report on the affordability of the medication separately. However, 53 (7%) patients included cost in their estimation of the most significant negative effects related to medical cannabis; these reports are excluded from Table 7.4 but included in *Appendix E: Patient-Reported Negative Effects from Surveys*. Finally, please see the chapter titled, “Affordability and Suggestions for Improvement” for patient perceptions of medication affordability.

Of 792 completed patient surveys, 744 responses (94%) included a negative effects score and 441 (56%) included a response regarding most important negative effect, including comments stating “no negative effect.” Of 744 negative effect scale responses, 452 (61%) reported a score of 1, or “no negative effect.” This includes 13 patients who, though they entered a score of 1, entered a narrative description of physical or mental side effects. A total of 195 responses (25% of all patient responses) reported physical or mental negative effects. These reports generally mirrored side effects reported in clinical trials of medical cannabis (see “[A Review of Medical Cannabis Studies relating to Chemical Compositions and Dosages for Qualifying Medical Conditions](#)” on the [Office of Medical Cannabis](#) website). Reports of the most severe negative effects were as follows: scores of 7 (great deal of negative effects) were associated with reports of allergic reaction (n=1), pain (n=1), severe diarrhea (n=1), change in mood/behavior (n=1) and decreased awareness of surroundings (n=1). Scores of 6 were associated with reported physical side effects of dizziness or related symptoms (n=3), severe diarrhea (n=1), stomach pain (n=1), burning sensation with sublingual product (n=1), sleeping problems (n=1) and worsening seizures (n=2), and mental side effects of crying and irritability (n=1). Scores of 5 which reported physical negative effects included drug interactions, increased seizure activity, allergic reaction, lightheadedness, fatigue, headaches, visual impairment, dry mouth, a report that the

product “made me sick” and pain related to vaping (n=1 each). Scores of 5 which reported mental negative effects included reports of paranoia (n=2), inability to concentrate (n=1), and increased anxiety (n=1).

Apart from physical or mental negative effects, some patients reported issues related to program access, including distance to the nearest cannabis patient center (n=13). Other negative effects (not included in Table 7.4) were reported including issues related to the program design (n=9), negative attitudes of others toward the patient’s use of medical cannabis (n=17) and fear of legal or employment-related consequences related to program participation (n=5). Finally, 16 reports of negative effects were related to lack of efficacy of the medicine in treating the patient’s condition. A full listing of patient-reported negative effect comments is available in *Appendix E: Patient-Reported Negative Effects from Surveys*.

Table 7.4. Summary of most significant negative effects experienced by the patient, per patient reports.

	1: No Negative Effects	2	3	4	5	6	7: Great Deal of Negative Effects	Total
Physical Side Effects	10 (1%)	57 (7%)	15 (2%)	26 (3%)	10 (1%)	9 (1%)	3 (0%)	130 (16%)
Mental Side Effects	3 (0%)	18 (2%)	14 (2%)	19 (2%)	4 (1%)	1 (0%)	2 (0%)	61 (8%)
Access-Related Issues	4 (1%)	3 (1%)	1 (0%)	2 (0%)	1 (0%)	1 (0%)	1 (0%)	13 (2%)

Note: Results are broken down by negative effect scale scores. Percentages are calculated based on the total number of patient survey responses received (n=792).

HCP-Reported Negative Effects from Medical Cannabis

Like the Patient Experience survey, the HCP survey asks respondents to report the degree, or severity, of any negative effects they believe the patient received from using medical cannabis, on a scale from 1 (no negative effects) to 7 (a great deal of negative effects). Table 7.5 shows the distribution of negative effects by severity score within three broad categories: physical side effects (including dry mouth, fatigue, headache, dizziness, blurred vision); mental side effects (including mental clouding, paranoia, sedation or symptoms related to “high”); and issues related to accessing the medications (long distance to distribution center, inconvenient operating hours for distribution centers, etc.).

Of 251 total HCP survey responses, 200 responses (80%) included a negative effects score and 107 responses (43%) included a description of any negative effect(s). Of 200 negative effect scale responses, 128 (64%) reported a score of 1, or “no negative effect.” This includes 6 HCP

reports which entered a narrative description of physical or mental side effects. There were 33 HCP reports (13% of all HCP survey responses) of physical or mental negative effects resulting from medical cannabis treatment. As seen in the patient survey results, these generally mirrored side effects described in clinical trials (see [“A Review of Medical Cannabis Studies relating to Chemical Compositions and Dosages for Qualifying Medical Conditions”](#) on the [Office of Medical Cannabis](#) website). Healthcare providers describing negative effects with high scores reported the following: a score of 7 was associated with a report of “abdominal discomfort”; dizziness (n=1) and sedation (n=1) were reported with scores of 6; finally, constipation, lethargy and worsened seizure activity (n=1) and a report of “too strong per patient” (n=1) were associated with a score of 5. Four HCP responses reported access-related issues as a negative effect. Additionally, 25 HCP reports (10% of all HCP survey responses) described cost as a negative effect related to medical cannabis (these reports are not included in Table 7.5).

A full listing of all negative effect comments from HCPs can be found in *Appendix F: Healthcare Practitioner-Reported Negative Effects from Surveys*.

Table 7.5. Summary of most significant negative effects experienced by the patient, per HCP reports.

Negative Effects By Score (1-7 Scale)	1 (No Negative Effects)	2	3	4	5	6	7 (Great Deal of Negative Effects)	Total
<i>Physical Side Effects</i>	4 (2%)	5 (2%)	6 (2%)	2 (1%)	1 (0%)	1 (0%)	1 (0%)	20 (8%)
<i>Mental Side Effects</i>	2 (1%)	6 (2%)	3 (1%)	1 (0%)	-	1 (0%)	-	13 (5%)
<i>Access Issues</i>	1 (0%)	2 (1%)	1 (0%)	-	-	-	-	4 (2%)

Note: Results are broken down by negative effect scale scores. Percentages in each cell are based on the total number of HCP survey responses (n=251).

Adverse Side Effects Reported on Surveys: Conclusions

Based on data from surveys completed by patients and their certifying healthcare practitioners three months after the patient’s first medical cannabis purchase, 25% of patient respondents report physical or mental side effects related to medical cannabis use. A minority of healthcare provider responders (13%) report physical or mental side effects. Both groups describe negative effects related to medical cannabis use including the cost of products and issues related to

accessing medicine. Most patients and HCPs reporting physical or mental side effects report low degrees of severity (negative effect scale scores of 1-3).

Adverse Event Reporting to Manufacturers

There is potential for enrolled patients, their family and caregivers, and health care practitioners to be concerned about an adverse event potentially caused by medical cannabis and to want to register their concern quickly. Both manufacturers have processes in place to receive these messages by telephone and by email. They collect and document information related to the incident and report it to the Office of Medical Cannabis. In nature and severity these reports have been similar to the adverse events reported in Patient Self-Evaluations and surveys.

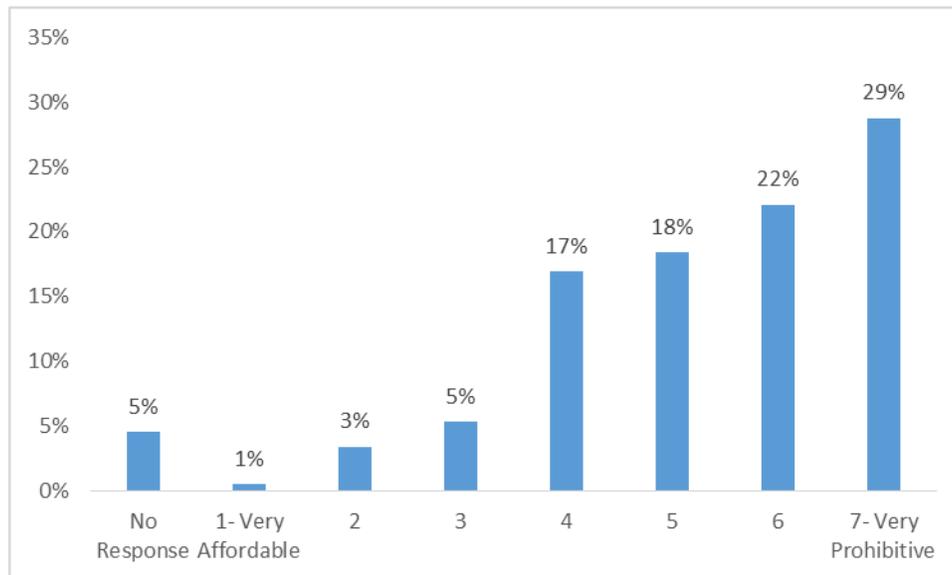

Patients, their registered caregivers, and certifying health care practitioners have a duty as program participants to report serious adverse events. Called “serious adverse incidents” in the program’s rules (4770.4002), these are essentially occurrences that lead to hospitalization or are life-threatening events. As of the date of this report, no reported adverse events have met the definition of “serious adverse incident.”

8. Affordability and Suggestions for Improving the Program

Patient Perceptions of Affordability

Unlike traditional pharmaceuticals whose costs are often covered through insurance reimbursement, medical cannabis must be purchased solely out of pocket. The Patient Experience survey asked patients to rate the cost of the medication on a scale from 1, or very affordable, to 7, or very prohibitive. Responses to this question are displayed in Figure 8.1. Of 792 respondents, 683 (86%) reported that they found medical cannabis to be at least somewhat unaffordable (score of 4 or greater).

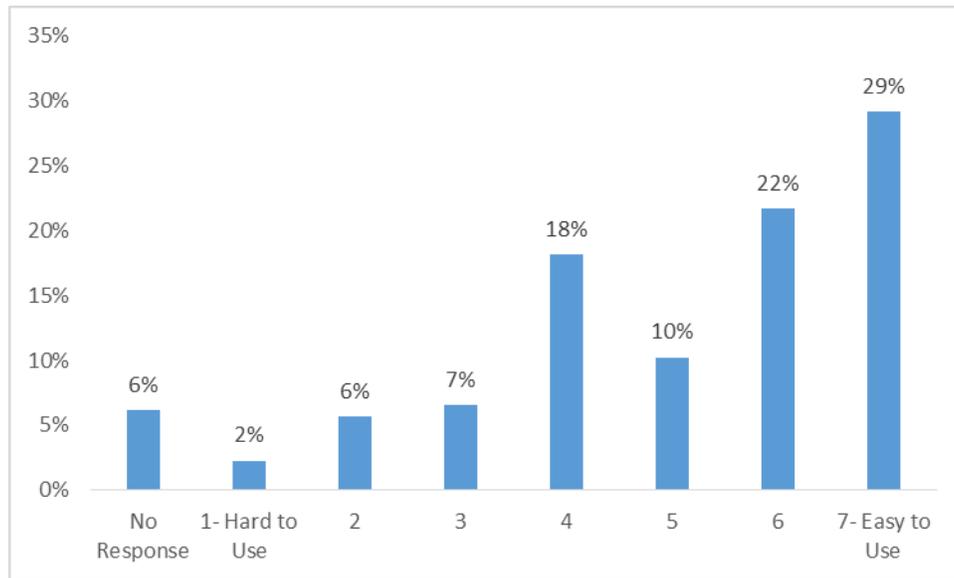

Figure 8.1. Patient Perceptions of Product Affordability

Patient Perceptions of Online Registry

Patients were asked how easy or difficult the online registry system, through which the Minnesota Medical Cannabis program is administered, is to use. Patients were asked to rate usability on a scale from 1, or very difficult to use, to 7, or very easy or intuitive to use. Responses were generally positive (Figure 2), with 51% of patients reporting high scores of usability (6 or 7).

Figure 8.2. Online Registry Ease of Use

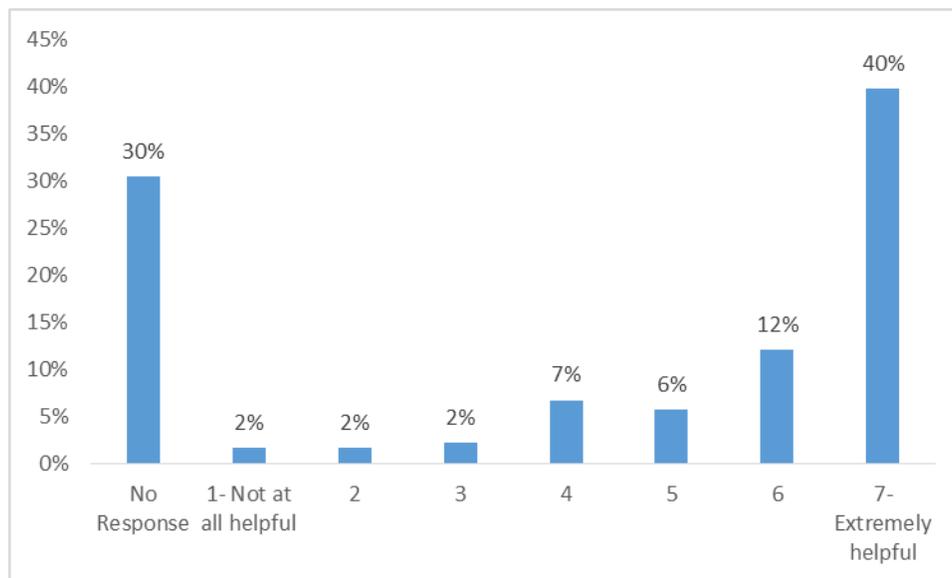

Patient reports on the ease of use of the Medical Cannabis Registry online system (1=very difficult to use; 4=neither difficult nor easy to use; 7=very easy/intuitive to use). Note: percentages are based on total number of patient responses; 49 patients did not complete this question and are not represented in the figure.

Patient Perceptions of Office of Medical Cannabis Call Center

Patients were asked to rate the helpfulness of the Office of Medical Cannabis Call Center (also known at the Support Center), which provides support for patients, caregivers and providers in navigating the registration and enrollment process as well as assisting with other program-related inquiries. The Patient Experience survey asked patients to rate the helpfulness of the call center on a scale from 1, or not very helpful, to 7, or very helpful. Over half of all patient responses reported high scores of helpfulness (6 or 7).

Figure 8.3. Call Center Helpfulness

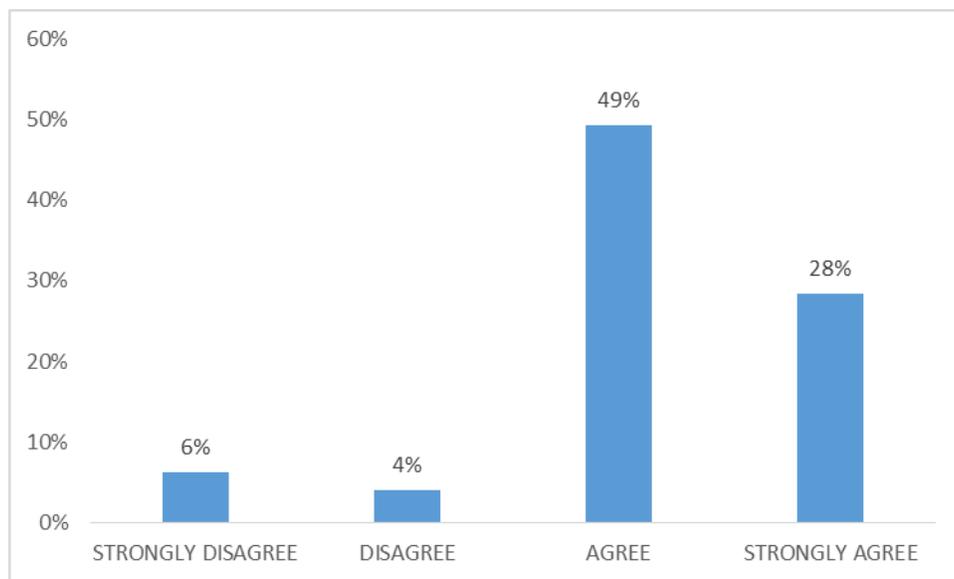

Patient reports on the helpfulness of the Office of Medical Cannabis Patient Support Center (1=not very helpful; 4=somewhat helpful; 7=very helpful). Note: percentages are based on total number of patient responses; 241 patients did not complete this question (several indicated no experience with the call center) and are not represented in the figure.

Patient Perceptions of Office of Medical Cannabis Website

Patients were asked to state their level of agreement with the statement: “The Office of Medical Cannabis website provides me with the information I need to understand and participate in the program.” Among all patient respondents, 49% agreed and 28% strongly agreed that the website met their needs for information; however 10% expressed that they did not feel the website met their needs for program participation (Figure 8.4) and 12% did not respond to the survey question.

Figure 8.4. “The website provides the information I need to understand and participate in the program”

Patient Suggestions

Patients were asked to provide feedback on the program; all responses submitted from the first year cohort are tabulated in *Appendix G: Patient Suggestions for Improving the Program from Surveys*. Many patients used this space to elaborate on the program’s impact on their lives; others suggested changes to the program’s administration or reported concerns related to product cost or access to cannabis patient centers.

Suggestions and Information Requests from Healthcare Practitioners

Healthcare practitioners were asked to provide suggestions for improving the program, and were also asked if any additional information from the program would be useful to them. The full tabulation of comments is available in *Appendix H: Healthcare Practitioner Suggestions for Improving the Program and Requests for Additional Information from Surveys*. Many comments reported in these sections of the survey mirrored those reported as clinical observations; there were 39 additional comments relating to affordability of the products. Other common responses included requests for information on medical cannabis dosing and specific information on what products their patient was purchasing. Other responses included requests for more patient education regarding products, information on drug interactions, and data on efficacy in specific patient populations.

REVIEW

Open Access

Sleep abnormalities associated with alcohol, cannabis, cocaine, and opiate use: a comprehensive review

Gustavo A. Angarita, Nazli Emadi, Sarah Hodges and Peter T. Morgan*

Abstract

Sleep abnormalities are associated with acute and chronic use of addictive substances. Although sleep complaints associated with use and abstinence from addictive substances are widely recognized, familiarity with the underlying sleep abnormalities is often lacking, despite evidence that these sleep abnormalities may be recalcitrant and impede good outcomes. Substantial research has now characterized the abnormalities associated with acute and chronic use of alcohol, cannabis, cocaine, and opiates. This review summarizes this research and discusses the clinical implications of sleep abnormalities in the treatment of substance use disorders.

Keywords: Sleep, Insomnia, Alcohol, Cannabis, Cocaine, Opiates

Background

Sleep problems are commonly associated with drug and alcohol use. Nearly 70 % of patients admitted for detoxification report sleep problems prior to admission, and 80 % of those who report sleep problems relate them to their substance use [169]. The association between substance use and sleep problems appears to be bidirectional [105, 110], with sleep problems increasing risk for developing substance use disorders [31, 89, 210], and acute and chronic substance use leading to acute and chronic problems with sleep [44, 47, 89, 97, 104, 138, 156, 168]. Evidence also indicates that long-term abstinence from chronic substance use can reverse some sleep problems [13, 37]. This paper aims to explore and clarify the strong yet not entirely understood connection between abnormalities in sleep and substance use. By improving our understanding of sleep disorders that either predispose to substance use or are the result of chronic substance use, we may be better able to prevent and treat substance use disorders.

Understanding the sleep problems related to substance use disorders requires characterizing them both

subjectively and objectively, while considering how sleep responds to periods of use and abstinence. This review will describe such research with regard to alcohol, cannabis, cocaine, and opioids. In addition, this review will discuss evidence that sleep abnormalities predict use and relapse, and that sleep abnormalities can be modulated to improve clinical outcome. This paper will also review potential pharmacological agents that modulate sleep. Psychotherapy options, albeit evidence-based and of clear clinical value, will not be discussed in this review as these are addressed elsewhere [15, 110].

Methods

This is a narrative, non-systematic review of clinical trials conducted in humans. For the literature search, Pubmed, Ovid Medline, and Web of Science databases were used. For each drug (e.g., alcohol, cannabis/marijuana, cocaine, and opioids/heroin) keywords included terms describing abnormal/pathological use (e.g., alcohol use disorders, alcohol abuse, alcohol dependence, and alcohol addiction, etc.) combined with terms referring to sleep or sleep abnormalities [e.g., sleep, insomnia, polysomnography, total sleep time, slow-wave sleep, rapid eye movement (REM) sleep, sleep latency, REM latency; these terms are defined in Table 1]. In addition to extracting data available in each of the retrieved articles, reference lists from

Table 1 Sleep terminology

Homeostatic sleep drive	The drive to sleep that progressively builds with continued wakefulness
Insomnia	A sleep disorder in which the quantity or quality of sleep is less than desired, usually characterized by difficulty falling or staying asleep, or waking too early, and experiencing daytime consequences of reduced sleep
Polysomnography (PSG)	A technique that records brain activity, eye movements, and muscle tone in order to study sleep and diagnose sleep disorders
Rapid eye movement (REM) sleep	The phase of sleep characterized by conjugate eye movements, paralysis of other muscles, and brain activity that is most similar to wakefulness
REM density	The frequency of rapid eye movements occurring during REM sleep. REM density increases over the course of the sleep period and is greatest when homeostatic sleep drive (sleep pressure) is lowest
REM latency	The amount of time from the onset of sleep to the onset of REM sleep
REM rebound	The characteristic increase in REM sleep after REM sleep deprivation
Self-administration	A method involving research participants administering a substance to themselves under observation in a clinical setting
Sleep architecture	The structure of sleep, including non-REM (stages N1, N2, and N3) and REM (stage R) sleep
Sleep efficiency (SE)	The percent of time in bed spent sleeping, calculated as total sleep time divided by time in bed
Sleep fragmentation	Disruption in sleep characterized by awakenings and transitions to light (stage N1) sleep from deeper sleep
Sleep latency (SL)	The amount of time from lights out to sleep onset
Slow-wave sleep (SWS)	Also known as stage N3 sleep, slow wave sleep is characterized by low frequency and high amplitude waves
Total sleep time (TST)	The amount of sleep in one complete episode of sleeping, usually reported in minutes
Wake after sleep onset (WASO)	The amount of time awake after the onset of sleep and before final waking

each retrieved article were examined to identify articles missed by the initial search. For each drug, the available literature on subjective measurements, objective measurements, the relationship between subjective and objective measurements, clinical and laboratory correlates of sleep outcomes, and pharmacotherapies related to sleep were summarized.

Alcohol

Subjective measurements

Alcohol is widely used as a sleep-promoting agent. However, as the consumption of alcohol becomes chronic, alcohol has less of an hypnotic effect [196]. Significant, self-reported sleep problems are highly prevalent among alcohol users with rates of clinical insomnia between approximately 35 and 70 % depending on the setting and stage of use, among other parameters [35, 48]. These rates are substantially higher than those observed in the general population (i.e. ~15 to 30 %) [32]. Complaints typically include difficulty falling asleep, frequent awakenings, daytime sleepiness, and abnormal sleep quality [15, 34, 196], but could also include hypersomnia [196]. Notably, sleep complaints associated with alcohol use disorders are one of the most refractory problems to resolve [34, 69, 82], and insomnia is the most frequent complaint among alcoholics after they stop drinking [132].

Objective measurements

Objective measurement of sleep in persons with alcohol use disorders confirms self-reported sleep problems in

many respects, and provides additional insight into the nature of the underlying sleep abnormalities.

Sleep latency (SL)

Although it is known that alcohol can decrease sleep latency when consumed by healthy persons [124], chronic use leads to increased sleep latency, consistent with individual self-report. Published studies show that SL is prolonged during periods of drinking [9, 33, 85, 199, 221], during acute withdrawal (e.g., weeks 1 and 2 of abstinence) [9, 33, 85, 199, 221], and during post-acute withdrawal (e.g., weeks 2 through 8) [33], (Table 2) with evidence for sleep latency prolongation in inpatient and outpatient settings (e.g., [83, 123, 183]), and when controlled for age and sex, among other variables [26]. After the second month of abstinence, sleep latency may still be increased [213], or normalized [174], with evidence for normalization also present after five [69] and 9 months of abstinence [213].

Total sleep time (TST)

Congruent with increased sleep latency, total sleep time is reduced in persons with alcohol use disorders during periods of drinking, acute withdrawal, and post-acute withdrawal [33, 85, 86, 199, 221], with very few exceptions [9]. Numerous studies examining total sleep time from 2 to 4 weeks of abstinence document reduced sleep time compared to healthy controls [69, 83, 183] (Table 2). Reduced total sleep time has also been observed in study

Table 2 Objective sleep changes during early and late abstinence, in comparison to healthy sleepers

	Alcohol		Cocaine		Cannabis		Opioids	
	Early Abs	Late Abs						
Sleep latency	?	↑	?	↑	↑	?	↑	↑
Total sleep time	?	↓	?	↓	↓	↓	↓	↓

REM sleep	?	?	?	↓	↑	↓	↓	?
REM latency	?	?	↓	?	↓	?	↑	?

Early Abs Early Abstinence or acute withdrawal

Late Abs Late Abstinence or subacute withdrawal

? Insufficient data or conflicting results across studies

designs that control for age and sex, among other variables [26].

Total sleep time in persons with alcohol use disorder may improve after sustained abstinence. For instance, one group found decreased yet gradually improving TST among alcoholic subjects after 19 weeks, 14, and 27 months of abstinence (312, 335, and 349 min, respectively) [69]. Another study examined TST after 1–2 years of abstinence and found no abnormalities among subjects recruited from Alcoholics Anonymous vis-à-vis controls [2].

Slow-wave sleep (SWS)

Considerable evidence points to deficits in slow wave sleep time (i.e. stage 3 and stage 4 sleep, or stage N3 sleep in the newer nomenclature) or slow-wave sleep activity (i.e. EEG spectral power in the slow wave frequency range) in persons with alcohol use disorders [33]. Most of this evidence comes from studies reporting results from the first few weeks of abstinence, including acute withdrawal [196], subacute withdrawal (i.e. days 8 and 12); [106] (Table 2), and beyond [26, 69, 83, 127].

Although there is evidence that SWS deficits are recovered with prolonged abstinence, current literature does not provide a definitive time frame for these improvements, yet does suggest that it may be between 3 and 14 months [33] or longer. While one study found no difference between alcohol users and controls at 25 days abstinent [183], other studies found that SWS had improved at 3 months, and normalized at 9 months of abstinence [196]. In contrast, other studies have reported persistent deficits [69] or a trend toward deficits [2] after as long as 1–2 years of abstinence, with complete recovery occurring only after 1–4 years of abstinence [199].

Intriguingly, acute alcohol use has been shown to reverse the chronic slow wave sleep deficits observed in chronic alcohol users [33, 86]. Given the widespread importance of slow-wave sleep [65] in factors including

sleep continuity, learning, and memory, as well as other types of cognitive performance, the deficits associated with chronic use (and their reversal with acute use of alcohol) suggests the particular importance of slow-wave sleep in alcohol use disorders. More specifically, as the brain processes that underlie the generation of these slow waves appear to be chronically altered by chronic alcohol use, and to be temporarily restored by acute use, this chronic alteration is implicated as a potential factor in relapse.

Rapid eye movement (REM)

For both persons without alcohol use disorders (AUD) [118, 219] and individuals with alcohol use disorders, drinking alcohol acutely suppresses REM sleep time. For persons with AUD, REM rebound occurs several days later [33]. An early study of sleep in persons with AUD who were exposed to alcohol found that REM sleep, measured as a percentage of total sleep time (REM%) was less, relative to baseline, after 2–3 days of abstinence, but then rebounded after 5–6 days of abstinence [7]. This rebound in REM sleep has been explained as reflecting both an increased number of REM periods as well as shorter intervals between each REM cycle [196]. REM rebound has been documented after 2–3 weeks of abstinence [26, 69, 83, 127], and even after 27 months of abstinence [69].

Notwithstanding the above findings, the literature on alcohol and REM sleep has some inconsistencies (Table 2). For example, a meta-analysis examined six studies that did not consider covariates and four studies that controlled for variables such as age and sex (all participants abstinent for at least 3 weeks). Even though the analyses among all subjects showed no differences in REM measured as the percentage of total sleep (REM%), the analyses did find increased REM% in persons with AUD compared to controls when controlling for some variables [26]. Other studies have found

no difference in REM% between chronic alcohol users and normal controls in the second [106] and third [83] week of abstinence. Additionally, supporting the finding of no difference in REM between chronic alcohol users and controls, a study examining REM time after 4 weeks of abstinence found no difference between subjects with AUD and normal controls [183]. Another discrepancy appears in the form of a study that found REM% among participants with AUD to be reduced after 12 weeks of abstinence in comparison with REM% after 4 weeks of abstinence, arguing against a lasting REM rebound [171].

Possibly contributing to differences in REM sleep findings are variations across studies in how control participants were recruited [183] and how well these control subjects matched the subjects with AUD in terms of measures relevant to sleep architecture such as age. An example of this is a meta-analysis exhibiting different results depending on whether authors controlled for those variables or not [26]. Another factor could be that several studies report REM%, thus, the numbers are also a reflection of not one, but two sleep architecture measurements (e.g., REM and TST) that are both undergoing dynamic changes as subjects with AUD progress in abstinence [69].

REM latency

Data on REM latency in persons with alcohol use disorders is more limited but also show some discrepancies. For instance, while some studies report that REM latency is decreased during the second week of abstinence [69, 106], as well as up to two years later [69], other studies do not report differences in REM latency [26, 32] (Table 2). One potential explanation for the inconsistencies in this measure could lie in the heterogeneity of subjects with AUD with regard to co-occurring conditions like depression. Supporting this idea is the finding that AUD subjects with secondary depression exhibit shorter REM latency compared to AUD subjects who do not have secondary depression [83].

Objective sleep quality or consolidation of sleep

Several studies examining sleep in persons with alcohol use disorders also reported data on fragmentation of sleep. Sleep fragmentation reflects awakenings or switching from a deeper to a lighter stage of sleep, and is measured by the number of switches from one stage of sleep to another, the number of awakenings, and the time spent awake after sleep onset. The measurements of sleep fragmentation provide some insight into the objective quality of sleep. Results from these studies show consistent deficiencies in objective sleep quality, with an increase in sleep stage switches compared to healthy controls from day 2 of abstinence to as far out as 1–2 years of abstinence [2, 106, 196].

Sleep stage switches, number of awakenings and time awake after sleep onset were also found to be increased on the second night of abstinence compared to the second week of abstinence, which suggests greater abnormalities in objective sleep quality occur during the withdrawal period [106]. In addition, increased sleep fragmentation was observed after 3 and 9 months of abstinence [196].

Relationship between subjective and objective outcomes

Although there is limited published data on the relationship between subjective and objective sleep measurement in persons with alcohol use disorders, one group studied 172 individuals with alcohol use disorders of whom 104 had insomnia as determined by the Sleep Disorders Questionnaire [35]. They found that participants with baseline insomnia had longer sleep latency and lower sleep efficiency at an average of approximately 1 month abstinent than those without, suggesting a correspondence between self-report and objective measurement.

Clinical and laboratory correlates of subjective and objective sleep outcomes

In a small study, increased sleep latency associated with chronic alcohol use was linked with lower overall melatonin levels as well as with a delay in the onset and peak of melatonin [123]. A much larger study found an association between increased sleep latency and decreased sleep efficiency among persons with AUD and sleep disorder breathing [6].

In patients with AUD, insomnia is also correlated with amount of alcohol use [22], severity of alcohol use disorder [35], and self-report of alcohol use as a sleep aid [35]. An association between insomnia and severity of self-reported depression symptoms has also been recognized [35].

Relationship between subjective measurements and clinical outcomes

Several studies among alcohol AUD subjects have documented the relationship between self-reported insomnia and clinical outcomes. These studies examined the effects of 1 week of abstinence while undergoing inpatient admission (e.g., subjects who self-reported insomnia during this week had higher likelihood of choosing to drink as part of a subsequent inpatient period in which this option was allowed) [182], and showed similar results after following subjects for 3 months post-detoxification (e.g., compared to subjects who did not relapse during this period, subjects who did relapse were more likely to answer “yes” to the statement, “It takes me a long time to fall asleep” from the Nottingham Health Profile [NHP] or, “I sleep badly at night,” as part of their baseline assessments) [76], or after

following subjects for 5 months (e.g., having insomnia based on the Sleep Disorders Questionnaire after 2 weeks of abstinence was a predictor of relapse). Also, subjects who relapsed after 5 months had more baseline complaints of difficulties falling asleep and abnormal sleep than the group who did not relapse [34, 35].

Relationship between objective measurements and clinical outcomes

Mixed findings implicate objective sleep measurements as predictors of clinical outcomes in AUD. For example, increased sleep latency measured within the first 2 weeks of inpatient admission increased the odds of relapse to alcohol use within the following 5 months [34]. Similarly, increased sleep latency and decreased sleep efficiency after 16 days and 19 weeks of abstinence were associated with lower rates of abstinence at 14 months [69]. However, one study found no difference in sleep latency at 5 days abstinent between persons who subsequently relapsed and those who remained abstinent [82].

Two studies have reported a connection between slow-wave sleep and clinical measures in persons with AUD. Slow-wave sleep time was inversely correlated to the maximum number of withdrawal symptoms reported during subacute withdrawal (8–32 days of abstinence) [83], and lower percent of stage 4 NREM sleep was associated with relapse [34]. However, another study found no difference in slow-wave sleep between relapsers and abstainers [82].

Similar to clinical studies examining sleep latency and SWS, REM sleep measurements appear to be important in clinical outcomes, but with conflicting results. The differences observed here might be consistent with the differences in the measurement of REM sleep in persons with AUD described above. For instance, while one study indicated a positive correlation between low REM% with response rate in a button-press task to obtain an alcoholic drink [8], Gillin et al. showed increased REM% and shorter REM latency upon admission and upon discharge from a four-week admission among relapsers in comparison with abstainers [82]. Another study showed that increased REM latency decreased the odds of relapsing [34], and one study found no connection between REM latency measured at 19 weeks of abstinence and subsequent relapse [69]. The variation in results regarding REM sleep may be due to the different effect that acute and chronic use, have on REM sleep, and be due to changes in REM sleep as the number of days abstinent increases. Another important consideration is that achieving long periods of abstinence (e.g., like 19 weeks) is in general a good predictor of abstinence and does so to a much greater degree than the predictive qualities of other physiological measurements obtained early in abstinence.

Pharmacotherapy options targeting sleep abnormalities

Because of the profound effects of chronic alcohol use and sleep and the apparent connection between sleep measures and clinical outcome, several studies have examined the role of sleep-promoting medications in treating persons with AUD (for review see [119]). In double-blind, placebo-controlled and other trials, gabapentin has been studied with largely [112, 136, 137] but not entirely [39] positive results. These studies suggest that gabapentin may promote both sleep outcomes and abstinence [137] in persons with alcohol use disorders.

Given the suggestion that melatonin levels are decreased in alcoholics [177, 212], the melatonin receptor agonists ramelteon and agomelatine have been examined in case series. Among patients who had been abstinent for 2–13 weeks, ramelteon was associated with decreased scores on the Insomnia Severity Index (ISI), decreased sleep latency, and increased total sleep time measured by actigraphy [36]. Similarly, agomelatine was associated with improved sleep as measured by the Pittsburgh Sleep Quality Index after 6 weeks [87].

Another potential pharmacotherapeutic agent that has been studied in this population is quetiapine. In a double-blind, placebo-controlled trial, quetiapine was associated with improvements in time awake after sleep onset and subjective insomnia [53]. In addition, a retrospective study showed an improvement on the insomnia subscale of the HAM-D [173] with quetiapine. The effect of quetiapine on alcohol-related clinical outcomes has been mixed, with evidence for improvement in abstinence rates in one study [142], and increased risk of re-hospitalization in another [143].

Trazodone is widely prescribed as a sleep aid in persons with addictions because of its lack of addictive potential. Although studies of trazodone in persons with AUD has shown benefits in sleep measurements [125] in a large, placebo-controlled trial, those benefits on sleep quality did not result in clinical improvement, but rather trazodone was associated with less abstinence during treatment and an increase in drinking after cessation of treatment [79]. Findings like these suggest that the relationship between sleep physiology and alcohol use and relapse is not simple. Rather, treatments directed at sleep that improve qualitative sleep but do not address the underlying physiological changes associated with chronic alcohol use may not be expected to promote abstinence.

Unlike trazodone, the popular benzodiazepine and benzodiazepine-like agents are often avoided in persons with alcohol use disorders because of their addictive potential and the increased risk of toxicity or overdose when these medications are mixed with alcohol [16, 90].

Cannabis

Subjective measurements

Like alcohol, cannabis may improve subjective sleep complaints [56], particularly when used over short periods of time. For instance; in studies using self-report questionnaires (e.g., Leeds Sleep Evaluation Questionnaire) participants report greater ease in getting to sleep [50]. However, like alcohol, chronic cannabis use is associated with negative subjective effects on sleep that are manifested most prominently during withdrawal. Notably, these subjective effects are present during discontinuation of cannabis use even among persons who were exposed to low dosages [97], and are common among regular users [61, 188]. Symptoms reported include sleep difficulties [61] such as strange dreams, insomnia, and poor sleep quality. Such symptoms occur in anywhere from 32 % [58] to 76 % [27, 222] of persons experiencing withdrawal. These studies have been conducted in both the inpatient (residential) [61, 97, 98] and outpatient levels of care [42, 44], and in studies with as many as 450 participants [222]. Placebo-controlled studies have examined what happens after discontinuation of oral THC use [97] or after discontinuation of smoked marijuana [98]. Regardless of design, studies of the effects of chronic use have consistently shown reliable and significant changes in subjective reports of sleep during abstinence in comparison to baseline [42].

Among the problems with sleep in chronic cannabis users is the presence of strange dreams [44]. Such dreams typically begin 1–3 days after cannabis discontinuation—when sleep quality is particularly poor [42, 44, 195], peak after 2–6 days, and last 4–14 days [44], coincident with other subjective sleep complaints. However, large studies have found sleep difficulties lasting for longer periods, such 43 days [58], and strange dreams in particular lasting for as long as 45 days [44]. Returning to cannabis use (or using alcohol or other sedatives) to promote sleep is commonly observed [58].

However, the sleep-promoting effect of cannabis is lessened in the chronic user compared to naïve users [50–52, 91], while the negative effects of cannabis on sleep intensify with chronic use as noted above. This scenario leaves the chronic user in a potential catch-22: heavier use of cannabis may be necessary to receive its subjective sleep-promoting effects in the chronic user, but at the same time this increased use contributes to worsening overall sleep and therefore leads to continued and greater use.

Objective measurements

Studies examining the effect of cannabis on objective sleep measurements obtained either by an experienced observer rating sleep by polysomnography (PSG)

largely confirm the subjective reports. For instance, an observer-rated study showed that administration of 10, 20, or 30 mg of THC decreased total time to fall asleep [60], and a PSG study showed both shorter sleep latency (SL) [150], and decreased time awake after sleep onset (WASO) [160]. However, other studies have not observed a decrease in sleep latency or wake time after sleep onset [75]. One possible explanation for the difference in findings may be related to disparate effects of THC (sleep promoting) and cannabidiol (a non-euphorogenic cannabinoid preferred in some medical preparations), which may increase alertness [150].

Several studies of PSG-measured sleep report increased SWS [25, 75], decreased REM sleep [74, 75, 160], and decreased REM density (e.g., number of eye movements during REM sleep) [74, 75]. However, this pattern is not always replicated [150].

In chronic users of cannabis, the effects of cannabis on objectively measured sleep are notably different. With chronic use, individuals develop tolerance to most of the effects observed in naïve users, including its sleep-inducing effects and slow-wave sleep enhancement [25, 78, 111, 163]. Sleep efficiency is similarly unimproved [163] or worsens [111]. The tolerance to REM sleep changes, however, appears to be relatively muted [75]. However, no consensus exists with respect to REM time and studies have reported decreased, no change [163], or increased [111] REM time.

PSG studies of cannabis withdrawal have demonstrated increases in sleep onset latency and wakefulness after sleep onset [27, 28, 75, 77, 78, 175] (Table 2). Total sleep time, sleep efficiency, and slow-wave sleep time is reduced [1, 27, 28, 75, 78] (Table 1), and REM sleep is increased (REM rebound) [74, 75, 77, 108, 160, 175]. Shorter REM latency has also been reported [27, 77].

Changes in the objective PSG measurements during withdrawal can start as soon as the first night of abstinence (e.g., the decrease in SWS time [74]). Changes during withdrawal are more noticeable among heavy marijuana users (marijuana use ≥ 5 times per week over the past 3 months) [27]. With continued abstinence, TST, SE, and amount of REM sleep decline (Table 2), while WASO increases. These disturbances progress over the first 2 weeks of abstinence [28, 44, 120] and persist for more than 45 days into a marijuana abstinence period [44].

There are conflicting reports with regard to REM sleep in sustained abstinence. Initially it appears that REM sleep time increases/rebounds early in abstinence, but decreases as abstinence progresses [28] (Table 2). The reason for this continued worsening of sleep with decreasing REM sleep during abstinence is unclear, but could reflect a pre-existing, underlying sleep problem and/or the long-term effects of chronic use.

Relationship between subjective and objective outcomes

As noted above, the desirable effects of cannabis on sleep are reported less frequently in chronic cannabis users compared to naïve users [91]. Chronic users also report difficulty sleeping and strange dreams among other symptoms associated with abstinence [11, 28, 43, 58, 175, 194]. These subjective findings have been correlated to longer sleep onset latency, reduced slow-wave sleep, and REM rebound observed in PSG studies [27, 198].

Clinical and laboratory correlates of subjective and objective sleep outcomes

Sleep difficulties appear to be a predisposing factor for cannabis use, and baseline sleep problems are a significant predictor of later cannabis use, doubling the risk of future use [139, 155, 166, 211, 214]. This latter finding has led some to describe cannabis use as “coping oriented use” [21].

The sleep disturbances encountered in marijuana withdrawal may play a crucial role in treatment outcomes. Higher rates of relapse have been correlated with sleep problems and other withdrawal symptoms [43]. In a study focused on military veterans, Babson et al. showed that poor sleep quality prior to the quit attempt was a predictor of higher rates of later cannabis use [19–21]. Similarly, poor sleep quality during abstinence also contributes to relapse [44, 46, 195]. Evidence from a limited number of studies suggests that objective findings, like increased periodic limb movements during abstinence, are correlated with quantity and duration of cannabis use [28].

Pharmacotherapy options targeting sleep abnormalities

Sleep disturbances associated with withdrawal improve with oral administration of THC or resumption of cannabis use [42, 44, 45, 95, 97, 108]. THC exerts a dose-dependent effect in reducing withdrawal symptoms [45], but as noted above, the beneficial effects of THC on sleep diminish with chronic use, and chronic use leads to more severe problems with sleep.

Haney et al. found the greatest benefit regarding sleep symptoms and relapse using combination therapy with lofexidine (an alpha-2 agonist) and oral THC. However they did not report any benefit from 10 days of oral THC alone [94]. Nabilone, a FDA-approved synthetic analog of THC, has the potential to reverse withdrawal-related irritability and disruptions in sleep, and promotes abstinence [92]. Nabiximols, a synthetic combination of THC and cannabidiol has a non-significant positive effect on these parameters [10].

The use of valproic acid resulted in no benefit and even some worsening of symptoms in chronic cannabis users

[95, 128]. No definitive benefits have been reported with Lithium [107], nefazodone [96], or bupropion [49, 99].

Subjective and/or objective sleep parameters have been shown to improve with the use of zolpidem [195], mirtazapine [93], gabapentin [135], and quetiapine [57], but none of these agents have conclusively reduced the relapse rate.

Cocaine

Subjective measurements

Withdrawal from cocaine is characterized by numerous subjective complaints, including sleep and sleep-related complaints. The first several days to 1 week after cocaine cessation are characterized by sleep disturbances, hypersomnia, bad dreams, depressed mood, psychomotor agitation and retardation, fatigue, and increased appetite [38, 59, 80]. With continued abstinence, however, there is subjective improvement of sleep as well as improvements in other cocaine withdrawal measures [209], with apparent normalization of subjective sleep over the course of several weeks [80].

Numerous studies have indicated an improvement in self-reported sleep quality over the first few weeks of abstinence [13, 55, 81, 138, 147, 148, 153, 172, 209], with improvements in measures such as overall sleep quality, daytime alertness, concentration/confusion, depth of sleep, and energy/fatigue. However, the possibility that such improvements may be related to acclimation to a new environment (e.g., the treatment setting [209]) and not actually reflect good sleep relative to healthy persons [55] has been raised. Possibly providing some answers to these questions, a laboratory study that included self-administration of cocaine either early or late in a 3-week period of abstinence showed that subjective sleep quality was at its worst in the first few days following cocaine use and improved with continued abstinence [148]. In addition, whereas chronic cocaine users show impairment in self-reported but quasi-objective sleep measurement like the Pittsburgh Sleep Quality Index (PSQI), visual analog scale ratings of subjective sleep quality in the third week of abstinence are no different from healthy sleepers [147]. Hence there is evidence that chronic cocaine users have chronically impaired sleep as measured by instruments like the PSQI, that self-reported sleep quality improves with continued abstinence, and that self-reported sleep quality after an extended period of abstinence is similar to that in healthy sleepers. However, this last finding may only show that chronic cocaine users' intrinsic scale for self-report of sleep quality is different from healthy sleepers, with 'good' subjective sleep in chronic cocaine users seemingly good only in comparison with the much worse sleep experience they have at other times.

Objective measurements

Although self-reported sleep improves following the initial withdrawal from cocaine, polysomnographic findings have consistently shown deterioration in sleep to insomnia-like levels in the same period [13, 81, 104, 121, 138, 145, 148, 152, 192]. The co-occurring deterioration in PSG-measured sleep and improvement in self-reported sleep quality was termed ‘occult insomnia,’ as poor sleep as measured by PSG was associated with poor performance on sleep-dependent learning and other cognitive tasks [148, 149]. These findings suggest that the PSG-measured deterioration in sleep and not the subjective improvement in sleep better reflects what is happening during abstinence from chronic cocaine use, and supports the notion that the intrinsic, subjective scale used by chronic cocaine users to report sleep quality is altered relative to healthy persons.

Sleep latency

Acute cocaine administration can increase sleep latency [104, 162, 207], but the first few days of abstinence from cocaine in chronic users is associated with short sleep latencies relative to later in abstinence [81, 121, 138, 148, 153, 192], when sleep latency may be as long as 30–60 min or more (Table 2).

Total sleep time

Total sleep time during abstinence is reduced in chronic cocaine users [147] but appears to be at its greatest sometime in the early abstinence period (first week of abstinence) in laboratory studies including cocaine self-administration [148]. Total sleep time decreases with continued abstinence (Table 2), however [81, 104, 121, 138, 147–149, 153, 162, 192, 207], with total sleep times around the third week of abstinence as low as 300–330 min despite prohibitions against daytime napping and the opportunity to sleep 8 h or more. Sleep efficiency follows a similar pattern, with insomnia-like levels apparent in the third week of abstinence [153]. Limited evidence suggests that chronic cocaine users able to maintain outpatient abstinence for as long as 54 days show some improvement in total sleep time [13].

Slow-wave sleep

Chronic cocaine users appear to have dramatically diminished slow-wave sleep time relative to age-matched healthy sleepers [13, 147] (Table 2). More limited evidence suggests that slow-wave activity is increased by cocaine self-administration earlier in the day, with a subsequent loss of slow-wave activity in the first several days of abstinence followed by a rebound over the next 2 weeks of abstinence [148]. More substantial evidence indicates that slow-wave sleep time increases modestly

from the first to the third week of abstinence [138], but at 3 weeks of abstinence is still 50 % less than age-matched healthy sleepers [13]. This deficit in slow-wave sleep generation is associated with impaired slow-wave sleep specific, sleep-dependent learning [149], and is consistent with or more profound than similar findings in chronic users of alcohol, cannabis, other stimulants, and heroin [25, 27, 175, 192] suggesting an abnormality in sleep homeostasis [145] that may be common to chronic, regular use of addictive substances.

Rem

Cocaine administration acutely suppresses REM sleep [104, 162, 207], with a subsequent rebound evident as an increase in REM sleep time and/or percent of total sleep time spent in REM (REM%), and a decrease in REM latency [81, 104, 121, 149, 153, 192, 207]. However, in chronic cocaine users, REM sleep decreases following the rebound, with low REM times observed during the second and third weeks of abstinence [13, 104, 138, 147, 149, 153, 192] (Table 2). This diminished REM sleep time is associated with cognitive consequences like poor procedural learning [149], suggesting an abnormality of REM homeostasis during abstinence from chronic use. Consistent with this idea is the observation that REM latency is higher in the third week of abstinence relative to the first [149] and at 3 weeks abstinence does not differ substantially from healthy sleepers [147] (Table 2), despite low REM sleep time.

Relationship between subjective and objective outcomes

What is now clearly shown to be a mismatch in subjective and objective experience during acute and subacute abstinence was once perceived as an inconsistency [104, 153]. One possible cause for the mismatch may be dysregulation of the homeostatic sleep drive in chronic cocaine users, wherein the ‘sleepiness’ and other negative effects of increased wakefulness are not experienced subjectively [148]. Additionally, or alternatively, the rebound in delta power after acute withdrawal [148], despite poor sleep and decreased slow-wave sleep time, may improve the subjective experience of sleep quality [122, 148]. The poor subjective experience in acute withdrawal may also be related to the decreased REM latency and increased REM sleep time, leading to increased dreaming [38, 59] and correlated with symptoms of withdrawal [13].

Clinical and laboratory correlates of subjective and objective sleep outcomes

Cognitive correlates of sleep outcomes

Chronic cocaine use is associated with various cognitive performance deficits (e.g., see [152]) that may

predict treatment retention and other outcomes [3–5]. As described briefly above, poor sleep associated with abstinence from chronic use may contribute to poor cognitive performance including decreased attention or vigilance [148, 149, 152]. The most direct associations between poor sleep and cognitive deficits, however, are observed in sleep-dependent procedural learning. In such tasks, overnight learning is strongly correlated with objective sleep measurement, such as slow-wave sleep time [189], REM time [189], and stage 2 (N2) sleep time (M. P. [202]). In chronic cocaine users, similar correlations are present; in nights with relatively normal sleep, normal sleep-dependent learning takes place, but in nights with impaired sleep, such learning is similarly impaired [148, 149]. Hence, sleep abnormalities associated with abstinence from chronic cocaine use may be responsible for significant impairment in normal, sleep-dependent learning, as well as more immediate cognitive function like attention. Intriguingly, cocaine administration is associated with temporary reversal of these deficits [148, 149, 152], further implicating such deficits in risk for relapse.

Relationship between objective measurements and clinical outcomes

Recent evidence supports the assertion that poor sleep associated with abstinence from cocaine not only impairs cognitive performance, but also contributes to increased cocaine use or relapse [13]. In this study, the homeostatic response to continued abstinence (which was measured as change in slow-wave sleep time from the first week of abstinence to the second or third week) predicted the amount of cocaine self-administered in a laboratory experiment and clinical outcome in a clinical trial. In addition, REM sleep time and total sleep time during the third week of abstinence predicted the amount of cocaine self-administered. In all cases, improvements in sleep were associated with less self-administration or better clinical outcome.

Pharmacotherapy options targeting sleep abnormalities

Although several medications such as modafinil, topiramate, tiagabine, gaboxadol and vigabatrin [145] have been suggested as potential options for targeting the sleep abnormalities associated with chronic cocaine use, few studies have examined the effects of medications on sleep in chronic cocaine users, and several of the suggested medications have potentially significant safety issues (i.e. tiagabine, gaboxadol, and vigabatrin). Hypothesizing that the REM rebound associated with initial withdrawal from cocaine was caused by dopamine insufficiency [62], Gillin et al. [81, 82] examined the effect of lisuride, a high affinity dopamine D_{2,3,4} receptor agonist, on sleep. While lisuride had the desired effect on REM

sleep (decreasing REM% and increasing REM latency), it had no effects on other withdrawal-related phenomenon [81]. In light of the clinical findings in Angarita et al. [13] and the effect of prolonged abstinence on REM sleep, it seems unlikely that reduction in REM sleep time would be beneficial during extended abstinence, but *increasing* REM to normal values could be beneficial.

Another medication that has been tested is tiagabine, a GABA-reuptake inhibitor. Since tiagabine is known to increase slow-wave sleep time, which is implicated in improved cognitive performance in sleep-restricted persons [203], it was hypothesized that tiagabine may improve slow-wave sleep time in chronic cocaine users [146]. While tiagabine had dramatic effects on slow-wave sleep time, sleep architecture appeared unnatural, with slow-wave sleep occurring throughout the sleep period. Additionally, there was no apparent benefit to total sleep time, and no consistent benefit in cognitive performance [146].

Perhaps the most promising, and most studied medication to be tested for correcting sleep abnormalities related to cocaine is modafinil. A stimulant and cognitive enhancer that appears to act at least partially through dopamine transporter blockade, modafinil appears to share some important properties with cocaine while being a relatively safe medication with low abuse potential [140]. In chronic cocaine users, modafinil has been shown to normalize slow-wave sleep time, as well as other sleep parameters [147]. Though effects of modafinil on clinical outcome have been mixed (e.g., [12, 63, 64, 176]), its effects on sleep and its pro-cognitive effects position it as the best candidate at present for a viable pharmacotherapy for cocaine use disorders.

Opioids

Subjective measurements

Short-term opioid use can cause sedation and daytime drowsiness [130, 159, 216, 217]. Dizziness and sleepiness are common side effects of opioid pain medications [41, 109]. With a stable dose, tolerance to the subjective, sedative effects of opioids develops within 2–3 days and some studies find that cognition normalizes after that [103, 129], supporting the notion of tolerance to the sedative effects. However, there is also evidence that unpleasant sedative effects, decreased alertness and increased reaction time in a variety of cognitive tasks continue to be experienced by some patients on a stable dose of narcotic medication [23, 24, 54, 181]. These differences in findings may be related to inconsistencies in how the sedative effects are defined [217].

Xiao et al. [215] studied the quality of sleep in persons with heroin use disorder on early methadone maintenance therapy (MMT) after a median of 5.4 days of

treatment [215]. Patients without pre-existing chronic sleep disturbances demonstrated lower ratings of sleep (Pittsburgh Sleep Quality Index [PSQI]) and daytime sleepiness (Epworth Sleepiness Scale [ESS]) compared to healthy sleepers. Oyefeso et al. [151] reported inadequate sleep quality and quantity as well as difficulty initiating and maintaining sleep in persons with opioid use disorders in early stages of methadone detoxification. Similar studies have shown some increased daytime drowsiness and below normal sleep measures in this patient population [113, 114, 134, 204]. After longer periods of MMT, however, there is some degree of tolerance to these effects [206], and sleep difficulty is shown to be present only in the first 6–12 months of MMT [158, 193].

There is a limited number of reports studying the effects of withdrawal and abstinence from chronic opiate use. Asaad et al. reported insomnia, hypersomnolence, increased sleep latency, and reduced sleep duration in individuals with opioid use disorder after 3 weeks of abstinence [17].

Objective measurements

Sleep architecture in healthy adults can be significantly altered even after a single dose of oral opioids [67]. Using electroencephalography (EEG) and electromyography (EMG), Kay et al. [117] reported that acute intoxication with heroin, morphine, or methadone resulted in dose-dependent enhancements in arousal during sleep–wake periods. Heroin use demonstrated a stronger effect particularly on reduction of theta waves and REM sleep [117, 204]. Morphine and methadone reduce slow-wave sleep and increase stage 2 sleep [67]. Several studies have shown that acute use of various opioids results in increased REM latency [115, 159], decreased REM sleep time [113–117, 130, 159, 180], increased stage 1 [67, 130, 180] and stage 2 sleep [67], and decreased slow-wave sleep [113–117, 159]. Acute use of opioids also leads to increased sleep latency [116, 130], increased wakefulness after sleep onset (WASO) [113–117, 130, 159, 215], and concomitant decreases in total sleep time (TST) [116, 215] and sleep efficiency (SE) [116, 159, 215].

There is a partial tolerance to the effects of opioids with some evidence for increased REM sleep time in acute use [113, 114, 130], and less pronounced changes in SWS, wakefulness, and arousal observed after chronic use. However, vocalization during REM sleep, delta bursts, and increased daytime sleepiness may be observed in this phase [204]. Tolerance to sleep problems is more prominent in MMT [113, 134, 159, 204], with evidence that persons in treatment for more than 12 months exhibit better recovery sleep following sleep deprivation than persons in shorter-term treatment [193].

Nevertheless, abnormal PSG findings are commonly reported in chronic opioid users despite development of tolerance. These abnormalities include increased sleep latency [100, 185], increased awakening [100, 113, 185, 190], decreased total sleep time [100, 185], and decreased sleep efficiency [100, 190]. Slow-wave sleep time [113, 114, 185, 190] and REM sleep are decreased compared to baseline [113, 185, 190, 205], while duration of stage 2 sleep is increased similar to acute use [190, 205]. Analysis of actigraphy data from patients with prescription opioid use disorders indicated poor sleep in terms of total sleep time, sleep efficiency, sleep latency, total time awake, and time spent moving [100].

Several studies have reported changes in patterns of sleep with progressive abstinence from opiates. At around 5–7 days of acute abstinence from chronic heroin use, Howe et al. reported decreased total sleep time, slow-wave sleep, REM, and stage 2 sleep and increased sleep latency, wake after sleep onset, and REM latency compared to healthy sleepers [101] (Table 2). During the first 3 weeks of abstinence, prolonged sleep latency, decreased sleep efficiency, decreased TST, increased arousal index, increased stage 1 and 2, and decreased slow-wave sleep (SWS) were prominent compared to healthy sleepers [17] (Table 2). After 6 weeks and up to 6 months of abstinence from methadone, there is a rebound increase in SWS and REM time to a higher level than baseline [113, 114, 134].

Relationship between subjective and objective outcomes

Using PSG data, Xiao et al. showed an inverse relationship between the Epworth Sleepiness Scale (ESS) scores and SWS time in patients with heroin use disorder who were in early methadone treatment [215]. They reported poor initial quality of sleep based on the PSQI scores which were significantly correlated with their methadone dosages [102]. PSQI score were also found to be significantly correlated with average diary-reported sleep time, subjective ratings of feeling rested, and PSG sleep efficiency in MMT patients [179]. Overall the high prevalence of sleep complaints in this population along with documented abnormal objective findings argue that these complaints are more likely to be secondary to pathology rather than sleep misperception.

Clinical and laboratory correlates of subjective and objective sleep outcomes

Opioids and sleep disordered breathing

Acute use of small doses of opioids does not appear to significantly increase the risk for increased sleep-disordered breathing [167, 180]. However, chronic opioid use has been associated with several abnormalities including nocturnal oxygen desaturations, abnormal breathing patterns, and Biot's respiration pattern

which ultimately may lead to hypercapnia and hypoxia [29, 73, 88, 126, 164, 165, 191, 201, 204, 218]. Chronic opioid treatment, particularly with extended release preparations is associated with increased risk of central and obstructive sleep apneas compared to BMI and age-matched controls [73, 88, 141, 190, 200, 201, 204, 205, 208]. Between 30 and 90 % of patients on chronic opioid therapy display signs of central apnea in a dose-dependent fashion [73, 190, 200, 201, 205]. Several studies have indicated that chronic opioid use is an independent risk factor for irregular breathing, central apneas, and hypopneas [88, 154, 200, 201]. Additional abnormalities associated with MMT include sleep-disordered breathing, lower arterial oxygen saturation and higher carbon dioxide concentration [178, 190, 205]. There is a positive correlation between the duration of MMT and plasma methadone levels with frequency of sleep apnea [190, 205].

A multivariate analysis of the relationship between demographic factors, mental health and drug use with sleep disturbances on 225 MMT patients found that depressive and anxious symptoms, greater nicotine use, bodily pain, and unemployment were all significant predictors of poorer global sleep quality [186].

Using PSG, Asaad et al. found that severity of depression in MMT patients was inversely correlated with SWS. They reported that SWS in moderate and severe depression was significantly lower than in milder depressive states. However, duration of opioid abuse or type of opioid did not show a significant correlation with the abnormalities in the sleep profile [17].

Relationship between subjective measurements and clinical outcomes

Peles et al. [156] used a logistic regression model and showed that a higher methadone dose (defined as greater than 120 mg/day) was associated with poor sleep quality, higher rate of sleep disturbance, more frequent use of sleeping medications, and higher rate of daytime dysfunction [156]. However in a later study (2009), they found no direct correlation between the methadone dose and worse objective and perceived sleep parameters. Rather they suggested that duration and intensity of opioid abuse before admission to MMT was directly correlated with sleep abnormalities [157].

Quality of sleep in substance users who are trying to quit plays an important role in predicting the treatment outcome and poor sleep quality is associated with higher risk of relapse [40, 204]. Predictive factors for abstinence 1 month after detoxification with naltrexone may include sleeping problems upon discharge and any changes in sleeping problems [66]. In MMT patients, psychiatric disorders, greater nicotine and benzodiazepine use,

bodily pain, and unemployment are associated with poorer global sleep quality [156, 186].

Relationship between objective measurements and clinical outcomes

Using PSG, Peles et al. evaluated patients with heroin use disorder who were being treated with high and low dose methadone [157]. Of the objective sleep indices, percentage of non-REM deep sleep (i.e. SWS) inversely correlated with number of years of opioid abuse. They found that a lower percentage of SWS and more years of opioid abuse were observed in the group who received higher methadone dose during MMT.

Positive effects of opioids on sleep

Judicious use of opioid medications might improve pain-related sleep disorders [14, 30]. Subjective reports of improved sleep after pain control with extended-release morphine sulfate use to treat patients with chronic hip or knee arthritis are backed by objective evidence obtained from PSG indicating better sleep quality [170]. Opioids have also been used to treat a sleep disorder known as periodic limb movement (PLMS), which is often associated with restless legs syndrome [144].

Pharmacotherapy options targeting sleep abnormalities

Modifiable psychological and medical risk factors associated with sleep disturbance should be identified and corrected in order to improve quality of life in drug treatment. Treatment of sleep disorders among MMT patients, particularly in those with psychiatric disorders, benzodiazepine abuse, chronic pain, and patients who are on high methadone dose is of crucial importance.

Methadone

Methadone maintenance is widely used and a standard pharmacotherapy for treating patients with opioid use disorders [18, 68, 71, 197, 220]. Chronic methadone use is more commonly associated with tolerance to the sleep problems compared to other opioids [113, 134, 159, 204]. However, more than three-quarters of persons receiving methadone maintenance therapy (MMT) still report sleep complaints [151, 156, 186]. This is complicated by the fact that about 50 % of MMT patients report use of both illicit drugs and legal medications to help with sleep [156, 186]. Methadone and electrostimulation (ES) have been used to treat insomnia in the first 30 days of opioid withdrawal [84]. In the first 2 weeks of withdrawal patients treated with electrostimulation had shorter sleep time and more awakenings than patients receiving methadone. They also found that subjects in the ES group who remained in treatment experienced more sleep disturbance than those who dropped out prematurely. Overall

methadone and ES were not efficient in treating insomnia associated with withdrawal. Stein et al. tested whether trazodone (50 mg/night), one of the most commonly prescribed medications for treatment of insomnia, improved sleep among methadone-maintained persons with PSQI score of six or higher [187]. They found that trazodone did not improve subjective or objective sleep problems in this group of patients.

Buprenorphine

Buprenorphine was FDA approved as a pharmacotherapy for opioid use disorders in 2002. Buprenorphine has the advantage of being available from office-based practices [131]. There are limited numbers of studies looking at the effect of buprenorphine on sleep. One study suggests that buprenorphine is comparable to methadone in improving sleep quality in patients involved in long-term treatment [133]. In another study, forty-two patients with opiate use disorder were treated with either methadone or buprenorphine and gradually tapered down over the course of 2–3 weeks. Buprenorphine-treated patients had 2.5 % lower sleep efficiency and 9 % shorter actual sleep time. These significant group differences were most pronounced with the lowest doses toward the late withdrawal phase [161]. The time course of tapering buprenorphine during detoxification might also play a role in the quantity of sleep. A randomized controlled trial of buprenorphine for detoxification from prescription opioid use evaluated sleep time among patients assigned to receive 1, 2, and 4-week buprenorphine tapers. The 4-week taper group reported significantly less loss of sleep compared to the other groups [70].

In a study of 70 patients with chronic opioid use, the effect of buprenorphine on sleep disordered breathing was measured polysomnographically [72]. Patients in this study tended to be young (mean age of 31.8) and non-obese (mean body mass index 24.9 ± 5.9). However, treatment with buprenorphine was associated with mild to severe sleep-disordered breathing in this population, with a substantial rate of associated hypoxemia [72].

Although information on the effect of other medications on sleep in chronic opiate users is limited, Srisurapanont and Jarusuraisin [184] explored the effect of amitriptyline (57.7 ± 12 /night) versus lorazepam (2.1 ± 0.5 /night) to treat insomnia in 27 patients with opioid withdrawal in a randomized double-blind study [184]. The Sleep Evaluation Questionnaire and three insomnia items of the Hamilton Depression Rating Scale were used to assess sleep. All aspects of sleep (including ease of getting to sleep, perceived quality of sleep, integrity of early morning behavior following wakefulness and Hamilton Depression Rating Scale insomnia items), except for ease of awakening from sleep, were not significantly different in the two treatment

groups. These findings suggest that apart from the hangover effect, amitriptyline is as effective as lorazepam in the treatment of opioid-withdrawal insomnia.

Conclusion

Overwhelming evidence points to chronic alterations in sleep from chronic use of addictive substances that may be distinct from some or all of the acute effects of those substances. Interestingly, the effects of chronic use on sleep are similar among both CNS stimulants and depressants. Decreased sleep time, increased sleep latency and wake time after sleep onset, and deficiency in slow-wave sleep generation appear to be common to chronic use of alcohol, cocaine, cannabis, and opiates. REM sleep is also affected by acute and chronic use, but may be more sensitive to the pattern or quantity of recent use and time from last use, as results vary more among studies. Also linking these abnormalities are connections with ongoing use and relapse. However, treatment with typical sleep promoting agents that increase sleep time or efficiency by increasing light sleep may be counterproductive. Agents that address deficiency in slow-wave sleep generation and alterations in REM sleep may prove to be more useful in addressing the connection between chronically-altered sleep physiology and ongoing use and relapse, but substantial research still needs to be done to explore this possibility.

Authors' contributions

GA performed the initial literature review and drafted the introduction and alcohol sections and coordinated the work of NE and SH. NE drafted the cannabis and opiate sections. SH drafted the cocaine section. PM oversaw the work of the other authors and re-worked the manuscript into its final form, contributing to each section. All authors read and approved the final manuscript.

ABSTRACT

Objective/Background: College students are at an increased risk for poor sleep and associated sleep problems. Emerging evidence suggests that a substantial subset of college students self-medicate with alcohol, marijuana, or over-the-counter medications to help sleep. The current study identified demographic, psychosocial, and sleep- and alcohol-related correlates of self-medication for sleep, and assessed its concurrent and prospective associations with insomnia symptoms, alcohol drinking, and negative drinking consequences. *Participants:* Undergraduate students ($N = 171$; mean age = 19 years [$SD = 1.35$], 32% male, 74% White) enrolled in a four-year university in the northeastern United States. *Methods:* Data were drawn from a short-term two-wave longitudinal study. Participants completed two online surveys, separated by an average interval of 68 days ($SD = 10.22$). *Results:* At Time 1, 25% of students reported using at least one substance (alcohol, marijuana, or over-the-counter medications) for sleep aid in the past two weeks. Male and older students were more likely to report using substances for sleep. Sleep aid use at Time 1 was concurrently associated with greater levels of alcohol frequency, negative drinking consequences, and insomnia symptoms. Further, sleep aid use at Time 1 was associated with an increase in negative drinking consequences from Time 1 to Time 2, but not with changes in alcohol frequency or insomnia symptoms. *Conclusions:* These findings indicate that substances are widely used among college students for sleep aid. Sleep aid use is associated with greater concurrent drinking and insomnia symptoms, and increases in negative drinking consequences over a short time period.

College students are at an increased risk for poor sleep and associated sleep problems. Approximately two thirds of college students do not get the recommended amount of sleep for their age group (i.e., 7–9 hr; Hirshkowitz et al., 2015; Lund, Reider, Whiting, & Prichard, 2010). Further, 12–23% of college students have endorsed clinically significant insomnia according to validated screening cutoffs (Gellis, Park, Stotsky, & Taylor, 2014; Gress-Smith et al., 2015). Poor sleep among college students has been concurrently associated with a plethora of problem behaviors, including increased alcohol consumption and physical illness (DeMartini & Fucito, 2014; Lund et al., 2010), fighting and risky sexual behaviors (Vail-Smith, Felts, & Becker, 2009), and motor vehicle accidents (Taylor & Bramoweth, 2010).

Emerging evidence suggests that a substantial subgroup of college students opt to self-medicate their sleep with substances such as alcohol, marijuana, and over-the-counter medications. In a large college student sample ($N = 1,125$), 10% of poor-quality sleepers endorsed using alcohol, and 33% endorsed using over-the-counter or prescription medications to help sleep (Lund et al., 2010). In another large study of college students ($N = 1,039$), 11% of all students endorsed the use of alcohol as

a sleep aid and 2% endorsed the use of over-the-counter medications, regardless of sleep quality (Taylor & Bramoweth, 2010). Despite the drastic increase in marijuana use among college students in recent years (Johnston, O'Malley, Bachman, Schulenberg, & Miech, 2015), however, no research has assessed marijuana use for sleep aid among college students. Given the limited number of extant studies, further research is needed to reconcile discrepancies in the prevalence of alcohol and over-the-counter medications for sleep aid and assess the likely prevalent trend of marijuana use for sleep aid among college students.

According to Brower's model of the reciprocal associations between insomnia and alcoholism (2003), self-medication for sleep is an integral part of a negative feedback loop of exacerbating insomnia and alcohol problems over time. This model maintains that insomnia increases alcohol use in an effort to self-medicate sleep; at the same time, however, alcohol use causes or worsens insomnia due to ethanol's toxicity on sleep-related brain systems. The troubling implication of this model is that the use of alcohol for sleep aid increases in response to worsening insomnia, thereby increasing the risk of worsening or relapsing alcohol problems over time. However, this model was developed for alcoholics and has not been applied to a college student sample. Thus, it remains unknown how insomnia and diverse alcohol behaviors synergistically influence each other over time among this group. Further, this feedback model has focused exclusively on alcohol and has not encompassed other substances commonly utilized for sleep aid such as over-the-counter medications or marijuana. The current study sought to apply this promising model to self-medication for sleep (alcohol, marijuana, and over-the-counter medications) among college students and examine its correlates and short-term insomnia- and alcohol-related outcomes.

Brower (2003) proposed several demographics (e.g., sex), depression and anxiety symptoms, sleep-related characteristics (e.g., sleep duration), and alcohol use patterns as correlates of co-occurring insomnia and alcoholism. However, it has yet to be examined whether the same set of factors along with other potentially relevant individual characteristics are associated with self-medication for sleep among college students. Such findings regarding demographic, sleep, and alcohol use characteristics associated with sleep aid use would be valuable in identifying at-risk students, potentially allowing for earlier intervention. Regarding demographics, a finding from the limited research of college students supports that male sex is indeed associated with alcohol sleep aid use (Taylor & Bramoweth, 2010). Given that full-time college students are homogeneous in terms of age (typically 18–25 years old; National Center for Education Statistics, 2016), and increases in alcohol frequency are not observed over time among college students (Nealis et al., 2017), age or legal drinking status may not be associated with substance use for sleep; however, these associations have yet to be tested empirically. Empirical evidence from insomnia and alcohol studies of college students suggests that negative mood and sleep- or alcohol-related characteristics may be associated with self-medication for sleep. Depression and anxiety symptoms have been associated with both insomnia (Gress-Smith et al., 2015), and alcohol or substance use and negative drinking consequences (Geisner, Mallett, & Kilmer, 2012; Kenney, Lac, LaBrie, Hummer, & Pham, 2013) among college students. Also, because sleep aid use is associated with poor sleep (Lund et al., 2010), it would be useful to characterize specific sleep-related characteristics that are associated with college students to self-medicate with substances. Presleep arousal (Nicassio, Mendlowitz, Fussell, & Petras, 1985), inconsistent sleep scheduling (Gellis et al., 2014), and evening circadian preference (Fernández-Mendoza et al., 2010) have been associated with poor sleep among college students and therefore worthy of exploring to establish their association with sleep aid use. Further, risky drinking patterns might predispose students to sleep aid use, as alcohol sleep aid has been concurrently associated with greater quantity of alcohol use (Lund et al., 2010).

Self-medication for sleep among college students is especially concerning, considering its potential role in the development of exacerbated alcohol and substance use and associated consequences over time. While alcohol, marijuana, and over-the-counter medications possess sedative qualities and are thus temporarily effective in initiating sleep onset (Chait & Perry, 1994; Rickels et al., 1983; Roehrs, Papineau, Rosenthal, & Roth, 1999), the use of sleep aids is shown to

negatively impact objective sleep measures. For example, alcohol use before bed typically results in more awakenings and restlessness during the second half of the night (Roehrs, Yoon, & Roth, 1991). Likewise, over-the-counter sleep aid use is associated with residual sedation during the following day and can also result in rebound insomnia, making it difficult to fall asleep naturally without sleep aid use (Katayose et al., 2012). Thus, self-medication for sleep may contribute to a dangerous feedback loop by which students hurt their sleep and continue to compensate with alcohol or substances, thereby increasing their risk of developing risky alcohol and substance use habits (Brower, 2003). This effect might be exacerbated by the fact that the desired effects of sleep aids reduce or extinguish over time (Bedi et al., 2010; Rundell, Lester, Griffiths, & William, 1972; Schweitzer, Muehlbach, & Walsh, 1994), likely leading sleep aid users to increase consumption to combat tolerance. For example, the desired effects of marijuana on sleep efficiency and satisfaction were found to last for only the first 8 days of intake, after which a higher dose would be required achieve similar effects (Bedi et al., 2010). However, research regarding sleep aid use among college students remains exclusively cross-sectional in nature, and therefore its prospective effects on subsequent insomnia symptoms, alcohol use, and alcohol problems over time are unknown.

Study aims and hypotheses

This study aimed to characterize prevalence of self-medication (alcohol, marijuana, and over-the-counter medication) for sleep among college students, identify its demographic, psychosocial, sleep, and alcohol-related correlates, and assess its short-term prospective associations with alcohol and sleep behaviors. Specifically, the current study examined differences between sleep aid users and nonusers in concurrent demographic, psychosocial, sleep-related, and alcohol-related characteristics. It was hypothesized that, compared to non-sleep aid users, sleep aid (i.e., alcohol, marijuana, and over-the-counter medication use for sleep) users would more likely be male, and report greater concurrent levels of depression or anxiety symptoms, poor sleep (i.e., shorter sleep duration, greater insomnia severity), sleep characteristics associated with poor sleep (i.e., greater sleep scheduling inconsistency, greater presleep arousal, and more evening circadian preference), alcohol frequency, and negative drinking consequences. Additionally, short-term prospective associations of sleep aid use with changes in insomnia severity, alcohol frequency, and negative drinking consequences were examined. It was hypothesized that sleep aid use would be associated with greater increases in insomnia severity, alcohol frequency, and negative drinking consequences over a short period of time.

Method

Participants and procedure

Data were drawn from a two-wave longitudinal study of 171 undergraduate students (mean age = 19 years [$SD = 1.35$, range = 18–28], 32% male) at a four-year university in the northeastern United States (Gellis et al., 2014; Park, Kim, Gellis, Zaso, & Maisto, 2014). Students were eligible to participate if they were 18 years of age or older and endorsed having had at least one alcoholic drink in the past 30 days. The sample consisted of 74% White, 12% Asian, 6% Black or African American, 6% multiracial, 1% American Indian or Alaska Native, and 1% missing on race. Participants were recruited from psychology classes and offered course credit incentive. Participants completed two online surveys, with an average interval of 68 days ($SD = 10.22$). Of the 171 participants at Time 1 (T1), 157 (92%) also participated at Time 2 (T2). A logistic regression including all T1 variables showed that attrition was predicted only by insomnia severity (OR = 1.24; 95% CI [1.04, 1.48]), indicating that students reporting greater insomnia severity at T1 were more likely to drop out from study.

Measures

Sleep aid use

Three investigator-developed items assessed past two-week frequencies of using alcohol, marijuana, and over-the-counter medications to help sleep at T1 and T2, such as, “How many days per week in the past 2 weeks have you taken alcohol to help you sleep at night?” In the absence of a standardized measure for sleep aid use, we utilized items from the Consensus Sleep Diary (Carney et al., 2012), modified wording appropriately for each substance, and adapted the response timeline for the past 2 weeks for consistency with the Insomnia Severity Index (Bastien, Vallieres, & Morin, 2001). Participants responded based on a 5-point scale (0 = 0 days, 1 = 1–2 days, 2 = 3–4 days, 3 = 5–6 days, 4 = 7 days). For main analyses, scores from these three items were combined to create a dichotomized variable representing any use of substances for sleep aid (0 = no sleep aid use, 1 = any sleep aid use). Test–retest reliability coefficient of this dichotomized sleep aid use measure from T1 to T2 was $r = .40$, $p < .001$, suggesting a moderate level of stability of sleep aid use over a 2-month period. The dichotomized score of each of these substance use items was utilized for ancillary analyses (see Data Analytic Strategies).

Demographics

Age, sex (0 = female, 1 = male), and legal drinking status (0 = under 21, 1 = 21 or older) were assessed at T1.

Depression or anxiety

The 4-item Patient Health Questionnaire was used at T1 and T2 to assess self-reported depression or anxiety symptoms in the past 2 weeks (Kroenke, Spitzer, Williams, & Löwe, 2009). Participants indicated how often during the past two weeks they experienced each symptom according to a 4-point scale (0 = not at all to 3 = nearly every day). A sum score (Cronbach's $\alpha = .79$) was used for analyses. This scale is a reliable and valid measure of depression and anxiety symptoms among college students (Khubchandani, Brey, Kotecki, Kleinfelder, & Anderson, 2016).

Sleep schedule

Four investigator-developed items assessed average sleep duration and the difference in sleep schedule between weekdays and weekends (i.e., social jet lag; Wittmann, Dinich, Mellow, & Roenneberg, 2006) in the past 2 weeks at T1 and T2. Participants identified times that they typically go to bed and wake up on weekdays and weekends (e.g., “During the past 2 weeks, what time have you usually gone to bed at night during the weekdays?”). Typical weekday and weekend sleep durations were calculated as time elapsed between bed times and wake times. Participants' weighted average sleep duration was calculated by averaging typical weekday sleep duration (multiplied by five days) and weekend sleep duration (multiplied by two days) over a seven-day period. Difference in weekday versus weekend bedtime was calculated as the absolute value after subtracting weekday bedtime from weekend bedtime. The use of comparable items and variable calculations are standard among college student samples (e.g., Singleton & Wolfson, 2009).

Morning–evening preference

The 19-item Morningness-Eveningness Questionnaire was used at T1 to identify participants' circadian preference (Horne & Ostberg, 1976), by assessing tiredness during the day, and preferred times to do diverse activities and to go to sleep. A sum score was utilized for the current analyses (range = 16–86; Cronbach's $\alpha = .72$), with a higher score indicating a morning (versus evening) circadian preference.

Insomnia severity

The 7-item Insomnia Severity Index was administered at T1 and T2 to assess a number of insomnia-related behaviors and their severity (Bastien et al., 2001). Participants indicated the extent to which

insomnia problems (e.g., difficulty falling asleep, waking up too early) impacted their following day based on a 5-point scale (0 = *None* to 4 = *Very severe*). The scale is a widely used assessment of insomnia severity (scores 0–7 = no clinically significant insomnia, 8–14 = subthreshold insomnia, 15–21 = moderate severity clinical insomnia, 22–28 = severe clinical insomnia; Buysse, Ancoli-Israel, Edinger, Lichstein, & Morin, 2006; Smith & Wegener, 2003). A sum score (Cronbach's $\alpha = .86$) was used for analyses.

Pre-sleep arousal

The 16-item Pre-sleep Arousal Scale was administered at T1 and T2 to assess participants' typical state of arousal before sleep (Nicassio, Mendlowitz, Fussell, & Petras, 1985). Participants rated the severity of certain behaviors that may elicit pre-sleep arousal based on a 6-point scale (1 = *not at all* to 5 = *extremely*). A sum score (range = 16–18; Cronbach's $\alpha = .91$) was used for main analyses, with higher scores indicating a larger degree of difficulty in initiating sleep onset.

Alcohol frequency

One of the alcohol consumption items recommended by the National Institute on Alcohol Abuse and Alcoholism (2003) was used to measure alcohol frequency at T1 and T2. This item is widely used in college drinking studies and validated in college samples (e.g., Cranford, McCabe, & Boyd, 2006; Whiteman, Barry, Mroczek, & MacDermid Wadsworth, 2013; Zaso et al., 2016). The time frame was adapted from the past 12 months to the past 2 months to accommodate the two-month time lapse between T1 and T2 assessments, and response scales were adjusted accordingly (0 = *I did not drink any alcohol in the past 2 months*, 1 = *Once in the past 2 months*, 2 = *Once a month (twice in the past 2 months)*, 3 = *2 to 3 times a month (less than once a week)*, 4 = *Once or twice a week*, 5 = *3–4 times a week*, 6 = *5–6 times a week*, 7 = *Nearly every day*, 8 = *Every day*).

Negative drinking consequences

The 23-item Rutgers Alcohol Problem Index was administered at T1 and T2 to assess experiences of diverse negative consequences of alcohol consumption during the past two months (White & Labouvie, 1989). The time frame of this measure was modified from the past 12 months to accommodate the 2-month time frame of the current study. Participants indicated the frequency of experiencing alcohol-related problems (e.g., Had a bad time; Had a fight, argument, or bad feelings with a friend; Noticed a change in your personality; Neglected your responsibilities) based on a 7-point scale (0 = *Never in the past 2 months* to 6 = *Six times or more in the past 2 months*; Park et al., 2014). A sum score (Cronbach's $\alpha = .87$) was used for analyses. The sum score of the 23 items reflects the degree of experience of a range of diverse consequences (White & Labouvie, 1989), which has been demonstrated to map onto a single latent construct of negative drinking consequences (see Arterberry, Chen, Vergés, Bollen, & Martens, 2016; Cohn, Hagman, Graff, & Noel, 2011).

Data analytic strategies

Data analyses were computed using SPSS Version 23. Descriptive statistics and bivariate Pearson correlations were computed (see Table 1). Independent-sample *t*-tests and chi-square difference tests were conducted to compare sleep aid users to nonusers regarding all study variables at T1 and T2 (see Table 2). These group comparisons were for descriptive purposes to characterize the subgroup of college students who self-medicate for sleep versus those who do not without consideration of potential covariates (rather than identifying unique effects of sleep aid use over and above covariates, which were examined in the prospective regression analyses described below).

Using complete data of T1 and T2 ($n = 157$), regression analyses were utilized to examine short-term prospective relationships between T1 sleep aid use and T2 insomnia symptoms, alcohol frequency, and negative drinking consequences (see Table 3). The respective outcome variable at T1 was included as a covariate in each model (e.g., predicting Time 2 alcohol frequency after

controlling for Time 1 alcohol frequency). Sex, legal drinking status, and depression or anxiety symptoms were also included as covariates to control for their associations with insomnia and alcohol behaviors (Galambos, Vargas Lascano, Howard, & Maggs, 2013; S. R. Kenney, Jones, & Barnett, 2015; Lund et al., 2010). Linear regressions were used for normally distributed outcome variables of insomnia severity (skewness = 0.80; kurtosis = -0.16; range = 0–21) and alcohol frequency (skewness = -0.57; kurtosis = 1.35; range = 0–7; 0.6% did not drink any alcohol in the past 2 months at T2). Standardized regression coefficients were used for an effect-size measure of predictor variables. Negative binomial regressions were used for the over-dispersed outcome variable of negative drinking consequences (mean = 12.10; variance = 243.54; dispersion parameter = 0.96; skewness = 2.43; kurtosis = 6.35; range = 0–77; 9% reported no negative drinking consequences in the past 2 months at T2) as recommended by (Hilbe, 2011), and incidence rate ratios (IRR) were used for an effect-size measure of predictor variables.

Four sets of ancillary analyses were conducted. First, path analyses were conducted with all available data (*N* = 171) using missing data procedure of full-information maximum-likelihood estimation with robust standard errors (Graham, Cumsille, & Elek-Fisk, 2003) to assess the degree to which attrition at T2 (*n* = 14) affected results from regression analyses of complete data (*n* = 157). Second, to test for distinct patterns of specific substance used for sleep aid, separate regression analyses were conducted for each of alcohol, marijuana, and over-the-counter medication for sleep aid. Third, in order to rule

out polysubstance sleep aid use as a unique predictor of prospective sleep and alcohol use outcomes, regression analyses were repeated using number of sleep aids used (i.e., none, one, two, or all three) rather than dichotomized sleep aid use as the independent variable. Fourth, to test for the effect of sleep aid use initiation at T2 on changes in insomnia symptoms, alcohol frequency, and negative consequences over time, regression analyses were repeated using initiation of sleep aid use at T2 (instead of sleep aid use at T1) as the independent variable.

Results

Descriptive analyses

Descriptive statistics and bivariate Pearson correlation coefficients of study variables are reported in [Table 1](#). Participants reported 8 hr of sleep on average, subthreshold insomnia severity, and drinking alcohol 1–2 times per week at T1. At T1 and T2 assessments, 23–25% reported using any alcohol, marijuana, or over-the-counter medication for sleep aid in the past 2 weeks. Sleep aid use was significantly associated with alcohol frequency at Time 1 ($r = .21, p = .01$) but not at Time 2 ($r = .12, p = .15$), demonstrating a small to medium sized association at both time points. Regarding T1 alcohol variables, T1 sleep aid users reported drinking more frequently and experiencing more negative drinking consequences than nonusers.

Regarding specific substance used as sleep aid (data not shown in tables), 7–10% reported using alcohol, 14–15% reported using marijuana, and 14–16% reported using over-the-counter medications for sleep aid at T1 and T2 assessments. The average frequencies of all the three substances among users were 1–2 nights per week at T1 and T2. Of all participants, 19–21% reported using only one substance for sleep aid in the past two weeks, while 3–6% used two substances and 3–4% used all three. Among sleep aid users at T1 ($n = 43$), 63% also endorsed sleep aid use at T2. Out of nonsleep aid users at T1 ($n = 128$), 19% endorsed initiating sleep aid use at T2. Initiation of sleep aid use at T2 was not associated with insomnia symptoms at T1 ($r = -.06, p = .43$) or at T2 ($r = -.04, p = .63$) or any sleep-related characteristics at T1 (including morning–evening preference, $r = -.04, p = .58$; sleep duration, $r = .07, p = .42$).

Group comparisons between sleep aid users versus nonusers

[Table 2](#) presents results from independent-sample *t*-tests and chi-square tests to compare T1 sleep aid users and nonusers. Regarding demographics, T1 sleep aid users were more likely to be male, older, and at legal drinking age. Regarding T1 sleep variables, sleep aid users also reported higher insomnia severity and presleep arousal compared to nonusers, but no group differences were found in sleep duration, difference in weekday or weekend bedtime, or morning–evening preference. Regarding T1 alcohol variables, T1 sleep aid users reported drinking more frequently and experiencing more negative drinking consequences than nonusers.

Regarding T2 sleep and alcohol variables, T1 sleep aid users reported more negative drinking consequences and higher insomnia severity at T2 than nonusers. Groups did not differ in insomnia diurnal impact, presleep arousal, alcohol frequency, or heavy-drinking days at T2.

Prospective analyses

Results from regression analyses predicting insomnia symptoms, alcohol frequency, and negative drinking consequences at T2 from sleep aid use at T1 are presented in [Table 3](#). Sleep aid use at T1 was significantly and positively associated with T2 negative drinking consequences, even after accounting for T1 negative drinking consequences (i.e., changes in negative consequences over time) as well as sex, legal drinking age, and depression or anxiety symptoms. However, sleep aid use at T1 was not significantly associated with T2 insomnia severity or alcohol frequency after controlling for covariates.

Ancillary analyses

Path analyses of all available data using missing data procedure ($N = 171$) yielded the same patterns of significance as aforementioned linear and negative binomial regression analyses of complete data only ($n = 157$), suggesting that attrition at T2 ($n = 14$) was not likely to have affected overall findings.

Analyses of specific substance use for sleep aid showed that both alcohol ($IRR = 2.80, p = .006$) and marijuana ($IRR = 2.01, p = .004$) sleep aid use at T1 were significantly and positively associated with changes in negative drinking consequences, but not in insomnia symptoms or alcohol frequency. Time 1 over-the-counter medication use was not associated with any T2 outcomes at $p < .05$.

Analyses using number of sleep aids used (0 to 3) yielded results consistent with results from analyses using a dichotomized sleep aid use variable reported herein, indicating that the number of sleep aid use at T1 was positively associated with changes in negative drinking consequences, $IRR = 1.35, p = .01$, but not in insomnia symptoms and alcohol frequency at $p < .05$.

Analyses using the initiation of self-medication for sleep at T2 also yielded results consistent with results from analyses using T1 sleep aid use, indicating that the initiation of self-medication at Time 1 was significantly and positively associated with changes in negative drinking consequences ($IRR = 2.00, p = .003$), but not in insomnia symptoms or alcohol frequency at $p < .05$.

Discussion

This is the first prospective evaluation of sleep aid use and associated outcomes, broadening the knowledge of co-occurring sleep problems and substance use among college students. Of the current sample, 25% endorsed sleep aid use (i.e., alcohol, marijuana, or over-the-counter medication), suggesting that a substantial group of college students self-medicate to help sleep. Compared to nonusers, sleep aid users were more likely to be male, older, at legal drinking age, and reported higher levels of presleep arousal, insomnia severity, alcohol frequency, and negative drinking consequences. Sleep aid use was associated with an increase in negative drinking consequences, but not in alcohol frequency or negative drinking consequences over a short period of time. Further, initiation into self-medication for sleep was also associated with an increase in negative drinking consequences (but not in improvement in insomnia symptoms) over a two-month period. Collectively, these findings suggest that students self-medicating for sleep experience more adverse drinking consequences over time without the intended benefit of improved sleep.

Over-the-counter medications (14–16%) and marijuana (14–15%) were more popular choices of sleep aid than alcohol (7–10%), all of which were used 1–2 nights per week. A large study of college students (Taylor & Bramoweth, 2010) found prevalence and frequency of alcohol use for sleep aid relatively consistent with the current study, though over-the-counter medication use for sleep aid was notably less prevalent (2%) but more frequent (3–4 nights per week) than the current sample. Little is known about the frequency of over-the-counter medication use for sleep among college students, which makes it difficult to gauge potential reasons of this drastic difference in over-the-counter medication use for sleep (while a rate of alcohol use for sleep is comparable). Future multicampus studies of larger sample sizes should assess differences in diverse sleep aid preferences as a function of student demographics and campus characteristics.

Importantly, 7–9% of students endorsed utilizing multiple substances for sleep aid during the past two weeks. When consumed in combination, substances such as alcohol and marijuana have an additive effect on behavioral impairment (Chait & Perry, 1994). Further, polysubstance-using young adults are more likely to experience alcohol-related harm such as blackouts and acute memory loss (Hingson, Zha, Simons-Morton, & White, 2016). Therefore, these students potentially represent a group at increased risk of dangerous substance combinations. However, given the current study design, it cannot be determined whether students used multiple substances for sleep aid on a single evening. In order to investigate the prevalence and potential risk-associated polysubstance sleep aid

use, future studies should assess daily patterns of substance use, sleep aid selection, and negative consequences of substance use.

Several individual characteristics associated with this pattern of substance use (i.e., correlates) were identified. Sleep aid use was more common among men, consistent with extant findings (Taylor & Bramoweth, 2010). Sleep aid use was also more prevalent among older students and at legal drinking age. These unexpected results, which are not in line with findings in college drinking, may be due to the fact that students at legal drinking age have better access to alcohol than underage students, or that male and older students are more likely to be experienced alcohol or substance users, and therefore more readily opt to use alcohol or substances for sleep. This is consistent with our finding of a positive association between sleep aid use and concurrent alcohol frequency, suggesting that sleep aid users may use more substances for sleep mainly because they use more substances for a wider array of reasons in general. Extant literature has demonstrated that risky-drinking college students endorse higher levels of diverse drinking motives in general (e.g., coping and enhancement) compared to low-moderate risky-drinking peers (Littlefield, Vergés, Rosinski, Steinley, & Sher, 2013; Merrill et al., 2016). However, substance use for sleep motives has historically not been included in widely used alcohol or substance use motives assessments, which makes it difficult to assess unique effects of substance use for sleep over and above substance use for other reasons. Also, sleep aid users concurrently endorsed significantly more insomnia symptoms and presleep arousal compared to nonusers, but did not differ in average sleep duration, inconsistent sleep scheduling, or circadian preference. Students may use sleep aids to manage presleep arousal and insomnia symptoms (which may be improved by the sedative effects of sleep aids in a short term), but not sleep duration and inconsistent sleep scheduling (which are largely controlled by external factors such as class schedules and social events). Interestingly, sleep aid use was not concurrently associated with depression or anxiety symptoms, suggesting that sleep aid use is more driven by presleep factors and heavy and problematic substance use than mood-related problems. Overall, these findings suggest that some correlates of sleep aid use may differ from correlates of poor sleep (e.g., depression or anxiety, sleep duration, inconsistent sleep scheduling, or circadian preference) and of drinking behaviors (e.g., age or legal drinking age) among college students, albeit with some overlaps (e.g., male sex for drinking, and presleep arousal for insomnia). Further research is necessary to replicate these novel findings and investigate a more comprehensive set of correlates and proximal antecedents to sleep aid use.

The current findings also have significant implications for potential adverse consequences of sleep aid use over time. Sleep aid use was associated with increases in subsequent negative drinking consequences, but not with frequent drinking patterns. Despite the hypnotic effects of alcohol, alcohol use before bed negatively impacts sleep architecture, and tolerance to the hypnotic effects of alcohol develops rapidly (Roehrs et al., 1999), at which point associated functional impairments likely become exacerbated. Therefore, although students do not appear to increase the frequency of alcohol consumption over time, they may become more susceptible to the accompanying negative consequences (such as impaired school or work performance) due to repeated sleep aid use. Future research should examine the nuanced, day-to-day changes in the experiences of sleep, substance use, and associated consequences.

Contrary to a priori hypotheses, self-medication for sleep was not associated with changes in insomnia symptoms over this short period of time. Despite well-documented acute sleep disturbance following substance use for sleep aid (Katayose et al., 2012; Roehrs et al., 1991; Williams, MacLean, & Cairns, 1983), there appears to be no subjective detriment to sleep over a two-month period in college students. However, current findings do not rule out the possibility of long-term consequences of occasional or chronic sleep aid use among college students. Prospective longitudinal studies of a longer time lapse between assessments are needed to elucidate long-term sleep-related outcomes. Further, sleep aid users at T1 may have developed problematic sleep aid use habits prior to T1, and therefore the negative feedback loop outlined by Brower (2003) may have already begun, where self-medication for sleep leads to exacerbated insomnia symptoms and therefore increased self-medication over time. However, ancillary analysis results also provide preliminary evidence for the exacerbation of negative drinking consequences (but not of insomnia symptoms or alcohol frequency) from T1 to T2 as a result of initiation into sleep aid use at T2. Multiwave longitudinal studies with younger or inexperienced samples (e.g., adolescents) to track sleep aid users from the point of

initiation would help to resolve whether sleep aid use plays a unique role in the trajectory toward developing risky substance-use habits or dependence.

Limitations of the current study must be considered. Although this prospective design allows for a better assessment of temporal relationships than cross-sectional designs, the current study remains correlational in nature and thus causal inferences are speculative. Also, findings of the current study are based on subjective reports of sleep. Future investigators might consider the incorporation of objective sleep measures, such as actigraphy and polysomnography, which may be affected by sleep aid use. Also, the current analyses of self-medication for sleep did not account for potential confounding effects of using prescription medications for sleep (e.g., zolpidem, antidepressants, and benzodiazepines) that may be associated with sleep and alcohol or substance-use behaviors in complex ways. Another limitation is that items used to assess sleep aid use cannot isolate timing of use (i.e., initial sleep onset versus sleep reinitiation) or primary motivation for use (i.e., sleep aid versus other substance use reasons such as social, coping, and mood enhancement). These items also cannot determine a specific sleep problem for which individuals self-medicate (insomnia symptoms, other sleep-related disorders such as Delayed Sleep Phase Syndrome or obstructive sleep apnea, nightmares, etc.). Future studies should consider revising the phrasing of these items to explicitly assess timing of sleep aid use, as well as including additional items to investigate the primary motives of substance use before bed. Event-level investigations of motivation for substance use are necessary to isolate self-medication for sleep from alcohol and substance use for other purposes and to characterize the nuanced and dynamic associations among sleep, substance use, and associated consequences. Also, data were drawn from a predominantly White, first-year sample of students enrolled in a Northeastern private university. Because substance use and sleep patterns vary by diverse individual and school characteristics (Johnston et al., 2015; Lichstein, Durrence, Riedel, Taylor, & Bush, 2004), these sample characteristics should be considered in interpreting the findings of this study. Replication with larger and more representative samples is necessary for generalization of our findings, and further multicampus research may help to characterize how different school-level characteristics may be associated with distinct patterns of sleep aid use and its consequences over time. Additionally, students were eligible for participation only if they had consumed alcohol in the last 30 days; thus, the current findings might not be applicable to students who abstain from alcohol use (such as students utilizing exclusively marijuana or over-the-counter medications for sleep aid). In general college samples, approximately 80% of students endorse having used alcohol (Johnston et al., 2015). Further, mean levels of insomnia severity and alcohol use for sleep aid found in the current study were remarkably similar to prior studies of college students (Gress-Smith et al., 2015; Taylor & Bramoweth, 2010), suggesting that this sampling bias may not be substantial. Nonetheless, these sample characteristics should be considered when interpreting the current findings, and replication with more representative samples is necessary for generalization.

Despite the aforementioned limitations, the current findings present a significant step toward characterizing sleep aid use and its association with exacerbated negative drinking consequences over time. The current findings highlight the potential role of sleep aid use in the maintenance of co-occurring sleep problems and exacerbated substance problems among college students.

Delta-9-tetrahydrocannabinol and synhexl: Effects on human sleep patterns

A series of experiments was conducted to determine the effects of orally administered 1-trans- Δ -9-tetrahydrocannabinol (THC) on both undisturbed and experimentally altered (by rapid eye movement [REM] deprivation) sleep patterns of young adult male volunteers. In the deprivation experiments, the effects of a semisynthetic Δ -6a-10-THC homologue, synhexl, were also studied. In the normative studies, 4 subjects received THC in doses ranging from 61 to 258 μ g per kilogram shortly before sleep onset, while in the deprivation experiments 2 subjects received either THC (244 μ g per kilogram and 259 μ g per kilogram) or synhexl (733 μ g per kilogram and 777 μ g per kilogram) the morning after the second of 2 consecutive nights of REM deprivation. In both normative and deprivation experiments, all-night sleep recordings were taken during base-line, drug, and postdrug conditions. The results of both types of experiments were consistent in demonstrating increments in Stage 4 sleep and decrements in REM sleep. In the normative experiments, reduction in Stage 1 and time awake after sleep onset were observed at the highest dose level. Interpretation of these results and their relation to the effects of other psychoactive compounds upon sleep patterns are discussed.

The many recent studies dealing with the behavioral and psychological effects of marijuana have served mainly to corroborate previous findings, prominent among which are reports of sedation and hallu-

cinatory-like behavior in lower animals^{12, 15, 31} and sleepiness, hallucinations, and fragmentation of thought in man.^{13, 14, 23} In one study, after oral ingestion of 1-trans- Δ -9-tetrahydrocannabinol (THC), subjects reported “. . . frequent bursts of disconnected dreams during brief periods of sleep between clinical trials.” These observations prompted the suggestion that THC might “enhance . . . dreaming sleep.”¹³ Empirical knowledge of the effects of THC on sleep is limited, however, to the observations

that it prolongs hexobarbital sleeping time in mice and rats^{9, 23} and, in rats, induces abnormal spiking discharges during sleep²² and reduces paradoxical sleep.²⁴ Only the latter studies used electrographic recording techniques and drew upon knowledge provided by recent studies which have established that mammalian sleep consists of the predictable cyclical alternation of two electrophysiologically different types of sleep: REM (rapid eye movement) and NREM (non-rapid eye movement).⁴ REM sleep is defined by the concomitance of a low-voltage, mixed-frequency electroencephalogram (EEG), electromyographic (EMG) atonia, and rapid eye movement. NREM sleep encompasses the remaining EEG variations occurring during sleep which extend from a low-voltage, mixed-frequency pattern to one of predominantly high-amplitude, slow waves. NREM sleep is associated with some degree of EMG activation and the general absence of eye movement. In man, reports of dreaming can be elicited from both kinds of sleep, but those from REM sleep are typically more numerous, more hallucinatory, and less conceptual than those from NREM sleep.⁷ Presumably, the suggestion that THC might enhance dreaming sleep refers to an increase in the amount of REM

sleep. We report here on a series of experiments conducted with the aim of gathering normative data on the effects of synthetic THC on human sleep patterns and examining the effects of this compound and a semisynthetic Δ -6a-10-THC homologue, synhexl, on sleep after REM deprivation.

Normative studies

Methods Four young adult male volunteers who had not used drugs for the preceding 2 month period served as subjects in the initial normative experiment. Three of the 4 were also the subjects in the remaining normative experiments. They abstained from drug use throughout. All subjects were directed to abstain from alcoholic beverages and daytime napping during the course of the experiments and not to eat during the 3 hours prior to reporting to the laboratory. All the normative studies, the designs of which are detailed in Table I, were double blind. Placebos were administered on all nondrug nights. Individual experiments were conducted with an intervening period of at least 2 months.

Marihuana extracts were prepared by alcoholic extraction of native marihuana on the basis of Δ -9-THC content determined by means of gas = liquid chromatography. Doses were based on THC con-

tent; other cannabinoids, such as cannabidiol and cannabinol were present in undetermined amounts. A placebo which mimicked the extract in color and obnoxious taste was prepared by re-extracting with alcohol marijuana from which all cannabinoid had been removed by prior extraction. All materials were taken orally just prior to the beginning of sleep recordings. Subjects slept in separate sound-attenuated, darkened rooms and continuous recordings were taken from EEG, electrooculogram (EOG), and EMG electrodes placed in accordance with recommendations of the Rechtschaffen and Kales²⁸ standardized manual. These recordings were subsequently coded and scored blind according to the system set forth in the same manual.

All experiments were successfully concluded without the subjects experiencing any difficulty falling asleep or remaining so after initial sleep onset on any of the recording nights. That none of the subjects was able to differentiate drug nights from those on which placebos were given is noteworthy.

Results.

Effects on REM sleep. The mean percentages of total sleep time spent in REM sleep during base-line and postdrug recording periods, as well as the individual values for the last base-line night preceding the drug night and the first night subsequent to the latter, are shown in Table II. Values from the 3 nights were ranked

for each subject at every dose level, and in 7 of the 10 possible comparisons the drug night ranked lowest. The probability of obtaining such a series of relationships is 0.016 (binomial test). If a similar comparison is made substituting for the individual base-line and postdrug values their respective mean values, the drug nights still rank lowest most often (0.034, binomial).

Although there was almost always some reduction in REM time on drug nights, the decrement was relatively slight, i.e., the average reduction relative to the last base-line night was 2.1 percentage points for all comparisons and 4.38 percentage points for those 7 instances in which drug night ranked lowest.

To determine if the REM impairment was localized to a particular portion of the night, REM time occurring during the first and second halves of the last base-line night were compared (matched t test) with similar values from the drug night. The results indicated no significant difference between the first halves of the nights, but they did indicate a reduction ($p < 0.10$) in the amount of REM sleep during the second half of the drug night relative to that during the last base-line night. This effect was present for all subjects at the 17 mg. and 13 mg. dose levels ($p < 0.05$), but internal analyses revealed that only one subject consistently demonstrated the effect at the lower dose levels.

Effects similar to those reported above

might occur if total sleep time (TST) on the drug night was shortened relative to that on the preceding base-line night, thereby effectively reducing the amount of time available for REM sleep. Table III presents the mean total sleep times for all base-line and postdrug nights, as well as individual values for the last base-line night, the drug night, and the first post-drug night. Significantly more ($p < 0.01$) sleep was obtained on the drug night than on the last base-line night, whereas the differences between drug and first post-drug nights were not significant. A reduction of REM time concurrent with an increase in sleep time enhances the significance of the observed decrease.

Undisturbed sleep after a period of reduced REM sleep is generally characterized by increased REM relative to base-line levels.^{3, 5} A comparison between base-line and postdrug mean REM percentage values in these experiments revealed the presence of this effect on postdrug nights ($p < 0.05$). Internal analyses for the several dose levels indicated that the REM increment on postdrug nights tended to occur during the first half of the night—a tendency significant only at the 17 mg. dose level ($p < 0.05$). Although postdrug TST was greater than comparable base-line values ($p < 0.05$), the observation that the postdrug increase in REM time tended to occur in the initial portion of the night decreases the probability that the increase in REM time was due only to increased

TST. The probability is also challenged by the results of an analysis routinely used as an indicator of the presence of REM rebound—the latency from sleep onset to the first REM period. The reduction in latency values which typically occurs after REM deprivation has been interpreted as indicating an increased pressure for the expression of REM sleep.⁴ Postdrug latency values in these experiments were significantly less ($p < 0.05$) than were base-line values.

The data were examined for the presence of individual dose-dependent effects based on the effective microgram per kilogram dosage (see Table I). Aside from a general trend toward greater REM reduction with increased dosage, analyses based upon this variable were unremarkable. Individual variations in response to the drug were interesting. Subject 3 responded in an opposite manner to identical doses on two separate occasions, while Subject 1 had a more marked REM reduction at the lowest dosage level than at the highest.

Effects on NREM sleep. Mean percentages of NREM sleep stages on base-line and postdrug nights as well as individual drug night values are given in Table IV. Comparisons between last base-line or mean base-line and drug night values revealed no significant differences. Similar results were obtained from comparisons of base-line and postdrug NREM sleep stage values, with the single exception of Stage 1 sleep which demonstrated a sig-

nificant postdrug reduction at the 17 mg. dose level ($p < 0.05$).

Since an analysis of the data in terms of halves of nights proved to be discriminative for REM sleep, similar analyses were conducted for NREM sleep stage data. The values on which these analyses were based were absolute amounts (minutes) of NREM sleep. Viewed in this way, the following effects were noted: (1) at the 17 mg. dose level only, significantly less ($p < 0.05$) Stage 2 sleep during the first half of the drug night relative to the first half of the last base-line night, and more ($p < 0.02$) of this sleep stage during the second half; (2) at all dose levels an increase ($p < 0.10$) in the amount of Stage 4 during the first half of the drug night relative to that time period on the last base-line night. This effect was most conspicuous at the 17 mg. level, at which

the amount of Stage 4 sleep obtained in the initial portion of the drug night exceeded comparable values for all subjects on all base-line nights by an average of 21 percentage points (47 per cent).

Half-night sleep stage comparisons between base-line and postdrug means of absolute values indicated postdrug reduction in Stage 1 sleep at the 17 mg. level which was greater during the first half of the night ($p < 0.05$) but which extended into the second portion of the night ($p < 0.10$). Although there were no other significant variations between base-line and postdrug NREM sleep stage mean values, slow-wave sleep (Stages 3 and 4 combined), which is normally concentrated during the first half of the night, was shifted in concentration to the second portion of the postdrug nights ($p < 0.02$).

Previous reports suggesting that THC might have sleep-inducing properties prompted the inspection of three variables commonly taken to indicate the presence of such an influence^{9, 14}: latency to sleep onset, time awake after sleep onset, and body movements during sleep of at least 15 second duration. The only significant change noted was a reduction at the 17 mg. dose level in the amount of time awake after sleep onset ($p = 0.016$); the average reduction on the drug night being 68 per cent of the base-line average (disregarding the first base-line night¹). It is noteworthy that postdrug values of this measure remain reduced.

Summary of normative studies. The results of these experiments indicate two main effects of THC on undisturbed sleep: increase in Stage 4 sleep and reduction in REM sleep. Both effects, including their sequential nature and time of onset with respect to drug ingestion, became more apparent when analyses were conducted on half- rather than whole-night sleep stage values. REM reduction, though slight, was of sufficient magnitude to permit the detection of "REM rebound" manifested by increased postdrug REM time and decreased latencies to the first REM

period. Other variations in sleep measures on drug and postdrug nights may be simply explained as displacements resulting from the two main effects. The decrease in Stage 2 on the first half of the drug night, for example, paralleled the increase in Stage 4, the increase in Stage 2 during the second half of the drug night was accompanied by a decrease in REM, and the postdrug redistribution of slow-wave sleep to the second half of the night was attended by an increased expression of REM sleep during the first half of the night.

A soporific effect of THC is suggested by the postdrug decrease in Stage 1 and the reduction in awake time after sleep onset on the drug night which was sustained in some measure through the postdrug nights. Since THC metabolites have been shown to be retained in plasma and excreted in urine for several days after administration,²⁰ such residual effects are possible. Similar variations in Stage 1 and the time spent after sleep onset are regularly observed during the course of adaptation to sleeping in the laboratory,¹ and such adaptation probably accounts in part for the effects observed here.

REM deprivation studies

A procedure to determine the potency of REM-reducing chemicals or manipulations is to introduce the REM-depriving agent during a period of REM rebound, i.e., immediately after REM deprivation. This postdeprivation period is characterized by REM sleep which is intensified both quantitatively and qualitatively relative to predeprivation levels.⁴⁻⁶ The procedure was used to test the extent of the REM-depriving capability of THC and to compare it with that produced by a semisynthetic Δ -6a-10-THC homologue, synhexl. The latter drug is similar to THC in its behavioral and physiological effects, including the production of dreamlike states, differing mainly in being less potent (potency ratio of synhexl to THC being about 3:1) and slower acting.¹⁴

Methods. Two young adult male volunteers (not participants in any of the normative experiments) underwent 3 separate REM deprivation procedures, each consisting of 2 nights of arousals. Each deprivation procedure was followed by 5 nights of undisturbed recovery sleep. Prior to the initial deprivation, 5 nights of baseline recordings were taken. Subjects were given either 20 mg. of THC or 60 mg. of synhexl orally (the effective microgram per kilogram doses being 244 and 259 for THC and 733 and 777 for synhexl) the morning after 2 of the 3 deprivation procedures. The third REM deprivation served as a control. Order of drugs was varied for the 2 subjects—one being control, synhexl, THC, the other, synhexl, THC, control. Electrode placements, scoring methods, and recording conditions, as well as all restrictions regarding daytime napping and ingestion of other drugs imposed during the earlier studies, were retained for these experiments. The REM deprivation procedure itself consisted of the artificial curtailment of each REM period by arousing the subject as near as possible to its onset as determined by electrographic criteria.

The amounts of REM sleep from each of the 3 recovery periods were compared with each other and with base-line data in a two-way analysis of variance with repeated measures.³³

Results. The data presented in Table V validate the REM deprivation manipulation and draw attention to the tremendous range of individual variation in immediate response to REM deprivation. The average reduction in percentage of total sleep time occupied by REM on deprivation nights relative to the average base-line value was 71.1 for Subject 5 and 91.9 for Subject 6. The degree of REM reduction was similar within subjects across the 3 different conditions. The between-subject difference in the extent of deprivation as well as the variation in the number of arousals necessary to implement the deprivation (overall deprivation days 3.2 times as many

arousals for Subject 5 as for Subject 6) reflect individual differences in response to the deprivation manipulation which are not subject to experimental control.

The results of the analysis of variance (Table VI) indicated the presence of a significant difference between the condition means, and Tukey's (a) test revealed that

the only significant difference (p < 0.05) among the means was that between control and base-line conditions. These results may be interpreted as demonstrating that: (1) under control condition these subjects responded to REM deprivation in the usual manner, i.e., with an increment in post-deprivation REM time which was significantly greater than base line, or (2) THC and synhexl, although not completely obviating the postdeprivation REM increase, diminished it substantially.

Since the normative studies indicated an increase in Stage 4 sleep subsequent to THC administration, an attempt was made to determine if a similar effect was obtained in the deprivation experiments. Fig. 1 illustrates changes in amounts of Stage 4 sleep across conditions as a function of treatment. These pooled data are based on 2 day totals (i.e., last 2 base-line days, the 2 deprivation days, and the first 2 recovery days) of Stage 4. The data corroborate the Stage 4 enhancing effect of THC and suggest a minimal capability in this respect for synhexl.

Discussion

The paucity of knowledge on the gastrointestinal rate of absorption of THC was a limitation which was relevant to the initial series of studies, since it precluded the possibility of specifying a priori the onset

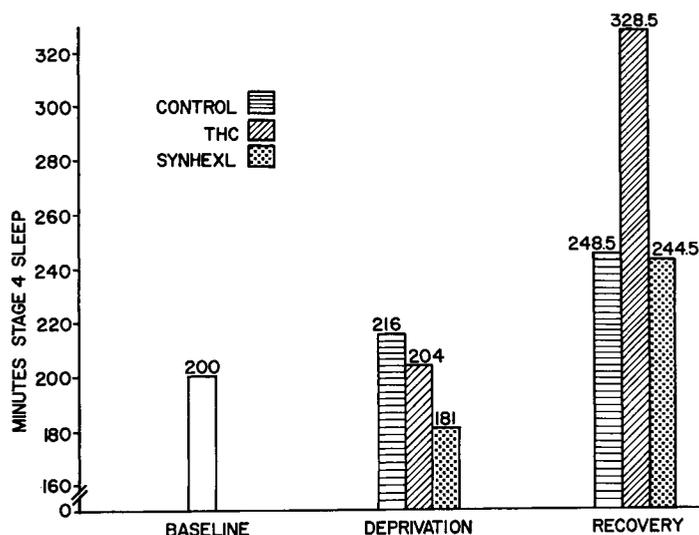

Fig. 1. Changes in amounts of Stage 4 sleep across conditions as a function of treatment. Pooled data are based on 2 day totals (i.e., last 2 base-line days, the 2 deprivation days, and the first 2 recovery days) of Stage 4.

of drug action. Although subjective effects of oral THC are reported to appear within 30 to 60 minutes,^{14, 16} the increment in Stage 4 sleep suggests that the onset of drug action occurred about 3 hours after ingestion. These observations indicate the insensitivity of the latency to sleep onset measure to any initial hypnotic properties of THC, since subjects were asleep well before the drug could have taken effect. The decrease in time spent awake after sleep onset and the increase in Stage 4 sleep, however, could be interpreted as indicating, respectively, less disturbed and "deeper" sleep,* thereby empirically supporting the attribution of sedative properties to THC.

Although both the normative and deprivation experiments indicate that THC reduces REM sleep, the degree of compensation was relatively less after the deprivation procedure. The simplest reconciliation of these data is one which regards the difference in terms of a delayed recovery phenomenon, i.e., a compensatory

process ultimately of normal proportions, but one whose full expression was in excess of the 5 day recovery period in these experiments. In the enforced deprivation condition, this process could have resulted from the convergence of several factors during the drug conditions which might have extended the deprivation effect, for example, the serial administration of REM-depriving agents (i.e., enforced arousals and REM-reducing drugs), drug action extending beyond the night of administration,²⁰ and a possible stress factor resulting from the daytime physiologic testing (including the taking of blood samples) which was not present during the control condition. Others have reported REM recovery periods extending over several weeks subsequent to the administration of psychoactive materials when such factors as listed above were not present.^{21, 26} Therefore, it is possible that our postdrug observations did not measure the full extent of the recovery process.

The notion that the hallucinations of both REM sleep and wakefulness are reflections of a single process is rooted in the phenomenological similarities of hallucinations from these 2 behavioral states^{8, 18} and has been enhanced by reports demonstrating

*For a discussion of the difficulties and nuances involved in defining depth of sleep see: Williams, H. L.: In Kety, S., Evarts, E., and Williams, H. L., editors: Sleep and altered states of consciousness, Baltimore, 1967, The Williams & Wilkins Company, pp. 277-287.

the hallucinogenic capability of several drugs derived from structurally dissimilar chemical groups (e.g., LSD, mescaline, phencyclidine, Ditran). If there is a mechanism common to all forms of hallucinogenesis, then REM sleep presents an unusual opportunity to pursue it. However, experimental evidence indicates that, with one exception—low doses of LSD enhance REM sleep in man,^{10, 25} while relatively high doses reduces REM sleep in the cat^{11, 32}—psychoactive drugs which induce walking hallucinations reduce REM sleep.^{2, 29} Furthermore, it has been demonstrated that the electrographic manifestations of walking hallucinations or hallucinatory-like behavior are more like those of slow-wave sleep^{12, 17, 34} than REM sleep.³⁰ It has long been known² that slow-wave sleep is capable of sustaining mental activity of a highly emotional nature, and the relative absence of recall of mentation from this kind of sleep²⁷ is suggestive of the diminished awareness which accompanies deeper hallucinogenic states during wakefulness.³⁴ It is possible, therefore that the naturally occurring state most comparable to that represented by induced waking hallucinations is slow-wave sleep rather than REM sleep. The results of both the normative and deprivation experiments, indicating an increase in Stage 4 sleep subsequent to ingestion of THC, are compatible with such a view.

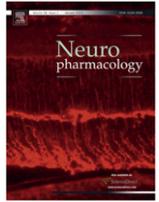

To place the results of these studies in proper perspective, an assessment of the potency of the doses used needs to be made. The effective dose levels in these experiments, which range from 61 μg per kilogram to 268 μg per kilogram, is below the level at which psychotomimetic effects are generally reported when THC is administered orally (300 to 480 μg per kilogram¹⁶). By these standards, our studies are based on low doses. This points up the sensitivity of sleep mechanisms to THC and synhexl and indicates that even subhallucinogenic doses exert relatively persistent effects.

Dr. Leo E. Hollister provided chemical compounds for these experiments. Δ -9-THC was obtained from the National Institute of Mental Health and was synthetic material provided by contract with Prof. R. Mechoulam, School of Pharmacy, Hebrew University, Jerusalem. The THC homologue, synhexl, was obtained from Dr. R. Gwinn, Abbott Laboratories, North Chicago, Ill.

Sleep

ABSTRACT

Patients with post-traumatic stress disorder (PTSD) frequently complain of having sleep disturbances, such as insomnia and rapid eye movement (REM) sleep abnormality. Cannabidiol (CBD), a psychoinactive constituent of marijuana, reduces physiological non-REM (NREM) sleep and REM sleep in normal rats, in addition to generating its anxiolytic effect. However, the effects of CBD on anxiety-induced sleep disturbances remain unclear. Because anxiety progression is caused by persistent stress for a period of time, we employed the repeated combination tests (RCT) consisting of a 50-min open field (OF) and a subsequent 10-min elevated plus-maze (EPM) for four consecutive days to simulate the development of anxiety. Time spent in the centre arena of OF and during open arms of the EPM was substantially decreased in latter days of RCT, suggesting the habituation, which potentially lessens anxiety-mediated behavioural responses, was not observed in current tests. CBD microinjected into the central nucleus of amygdala (CeA) significantly enhanced time spent in centre arena of OF, increased time during the open arms and decreased frequency of entry to the enclosed arms of EPM, further confirming its anxiolytic effect. The decrease of NREM sleep during the first hour and the suppression of REM sleep during hours 4–10 after the RCT represent the similar clinical observations (e.g. insomnia and REM sleep interruption) in PTSD patients. CBD efficiently blocked anxiety-induced REM sleep suppression, but had little effect on the alteration of NREM sleep. Conclusively, CBD may block anxiety-induced REM sleep alteration via its anxiolytic effect, rather than via sleep regulation *per se*.

1. Introduction

Anxiety disorders are the most common psychiatric disorders associated with sleep disruptions. In fact, sleep disturbances are included in the diagnostic criteria in two categories of anxiety disorders: general anxiety disorder (GAD) and post-traumatic stress disorder (PTSD) (American Psychiatry Association, 1994). Patients with GAD frequently complain to have difficulties falling asleep,

difficulties staying asleep, restless sleep, and unrefreshing sleep (American Psychiatry Association, 1994; Anderson et al., 1984), and persistent symptoms of increased arousal, insomnia, nightmares and disrupted rapid eye movement (REM) sleep are common sleep disorders in patients with PTSD (American Psychiatry Association, 1994; Horowitz et al., 1980; Mellman et al., 2002; Mellman and Davis, 1985; Neylan et al., 1998). Although anxiousness and worries are usually the causes of sleep disturbances in anxiety patients, sleep-specific pathologies and the other factor, such as stress *per se*, may develop and exacerbate sleep disruptions. The causal connection between sleep problems and anxiety are difficult to determine in the clinical aspect, and therefore the employment of an animal model of anxiety to study this relationship becomes adequate. The open field (OF) has been widely used to assess the behavioural effects of anxiety in rodents (Hall, 1936). Confrontation of the novel environment provided by the OF produces conflicting motivations between fear and exploration (Prut and Belzung, 2003; Welker, 1957). More thigmotaxis and less locomotion activity indicate greater anxiety, whereas greater exploration and more ambulation

Abbreviations: cAMP, cyclic AMP; CBD, cannabidiol; CeA, central nucleus of amygdala; DMSO, dimethyl sulfoxide; EEG, electroencephalogram; EMG, electromyogram; EPM, elevated plus-maze; GAD, general anxiety disorder; 5-HT, 5-hydroxytryptamine; ICV, intracerebroventricular; NREM, non-rapid eye movement; OF, open field; PTSD, post-traumatic stress disorder; RCT, repeated combination test; REM, rapid eye movement; SD, sleep deprivation; SWA, slow wave activity; Δ^9 -THC, Δ^9 -tetrahydrocannabinol.

to the centre arena of the OF reflect less emotion (Choleris et al., 2001). The elevated plus-maze (EPM), which is another rodent model for anxiety and used as a screening test for putative anxiolytics, consists of two open and two enclosed arms elevated 60 cm from the floor. This model is based on rodent's aversion of height and openness (Pellow et al., 1985; Treit et al., 1993). Because the progression of anxiety may be caused by the persistence of stress for a long period of time, we would like to mimic this anxiety development by exposing the animals to repeated stressors. However, a habituation behaviour may occur after repeated exposure to the OF. This anxiety-like behaviour is greater expressed during initial exposure to the OF, and exploration behaviour is increased as exposure time in the OF increases or with repeated exposure to the OF, indicating the lessened anxiety (Ivinskis, 1970; Makino et al., 1991). In contrast, anxiety behaviours expressed in the EPM have demonstrated a lack of habituation of exploration in the open arms because of the innate aversiveness of openness and height (Graeff et al., 1998; Treit et al., 1993). We herein employed the repeated combination tests (RCT), consisting of a 50-min of OF and a subsequent 10-min of EPM, for four consecutive days to simulate the anxiety development and anxiety-induced sleep disruptions.

Δ^9 -tetrahydrocannabinol (Δ^9 -THC) and cannabidiol (CBD) are two major constituents of the *Cannabis sativa* (ElSohly, 2002; Mechoulam, 1970). Two cannabinoid receptors, CB₁ and CB₂, are coupled to the pertussis toxin-sensitive G-protein, G_{i/o}, which inhibits adenylate cyclase and subsequently reduces the conversion of ATP to cyclic AMP (cAMP) (Chevalleyre et al., 2006). Δ^9 -THC has a strong binding affinity for central CB₁ receptors and produces psychoactive properties, including the anxiogenic effect (Grotenhermen, 2006), whereas CBD exhibits a low binding affinity for CB₁ receptors and has a non-psychoactive property (Grotenhermen, 2006; Mechoulam et al., 2002). The pharmacological property of the anxiolytic effect of CBD has been demonstrated in both animal researches (Guimaraes et al., 1990; Mechoulam et al., 2002; Pickens, 1981) and human studies (Crippa et al., 2004; Fusar-Poli et al., 2010), and becomes significant for therapeutic purposes. CBD also possesses sleep modulation effects; intracerebroventricular (ICV) administration of CBD during the light period increases wakefulness and decreases REM sleep in rats (Murillo-Rodríguez et al., 2006). We previously demonstrated that microinjection of CBD into the central nucleus of amygdala (CeA) decreases NREM sleep with limited effects on REM sleep suppression in normal rats (Yi et al., 2008). However, effects of CBD on anxiety-induced sleep disturbances have not been elucidated yet. CeA plays a key role in emotional processing, anxiety-related physiological and behavioural responses (Graeff et al., 1998), and its related behavioural responses, i.e. sleep–wake activity (Sanford et al., 1995). Here we determined the sleep disturbances induced after exposure of rats to RCT. Both effects of CBD, microinjected into the CeA, on sleep disturbances and the anxiolytic were evaluated. Comparing to the effects of CBD on spontaneous sleep regulation, present results would further elucidate whether the action of CBD on anxiety-induced sleep disturbance is mediated by its sleep regulation *per se* or is the consequence of anxiolytic action.

2. Materials and methods

2.1. Substances

Stock solution of CBD (Tocris, Bristol, UK) was dissolved in 2% dimethyl sulfoxide (DMSO). These stock solutions were stored at -20°C until administration. The doses of CBD used in these experiments were 0.5 and 1.0 μg . The total volume for each injection was 1 μl .

2.2. Animals

Male Wistar rats (250–300 g; National Laboratory Animal Breeding and Research Center, Taiwan) were used in these experiments. These animals were

anesthetized (ketamine/xylazine; 87/13 mg/kg), and injected with an analgesic (morphine) and antibiotic (penicillin G benzathine). Rats were surgically implanted with three electroencephalogram (EEG) screw electrodes (on the right hemisphere of the frontal and parietal lobes and the left hemisphere of the occipital lobe) as previously described (Chang and Opp, 1998), two neck electromyogram (EMG) electrodes, a thermistor (model: Pt100; Enercrop, Toronto, Canada) and a microinjection guide cannulae (26 gauge, O.D. 0.46 mm, I.D. 0.24 mm) directed into the CeA (AP, -2.8 mm from bregma; ML, 4.2 mm; DV, 7.8 mm relative to bregma). The coordinates were adopted from the Paxinos and Watson rat atlas (Paxinos and Watson, 1998). Insulated leads from EEG and EMG electrodes and the thermistor were routed to a Teflon pedestal (Plastics One, Roanoke, VA, USA). The Teflon pedestal was then cemented to the skull with dental acrylic (Tempron, GC Co., Tokyo, Japan). The incision was treated topically with polysporin (polymixin B sulphate–bacitracin zinc) and the animals were allowed to recover for seven days prior to the initiation of experiments. The rats were housed separately in individual recording cages in the isolated room, in which the temperature was maintained at $23 \pm 1^{\circ}\text{C}$ and the light:dark rhythm was controlled in a 12:12 h cycle (40 Watt \times 4 tubes illumination). Food and water were available *ad libitum*. We made our best effort to minimize animal suffering and to reduce the number of animals used in current study. All procedures performed in this study were approved by the National Taiwan University Animal Care and Use Committee.

On the second postsurgical day, rats were connected to the recording apparatus (see later) via a flexible tether. The location of the microinjection cannula was confirmed by injecting 0.5% trypan blue dye at the end of experiment. The recording data could be included for the subsequent analyses only when the injection target has been confirmed inside the CeA in rats. Animals were habituated by daily handling and injections of PFS timed to coincide with scheduled experimental administrations.

2.3. Apparatus and recording

Signals from the EEG electrodes were fed into an amplifier (Colbourn Instruments, Lehigh Valley, PA; model V75-01). The EEG was amplified (factor of 5000) and analogue bandpass was filtered between 0.1 and 40 Hz (frequency response: ± 3 dB; filter frequency roll off: 12 dB/octave). The EMG signals were also fed into an amplifier (CyberAmp 380; Axon Instruments, Union City, CA). Gross body movements were detected by custom-made infrared-based motion detectors (Bioobserve GmbH, Germany), and the movement activity was converted to a voltage output which was digitized and integrated into 1-s bins. The values of brain temperature were also converted to a voltage output by an analogue signal isolation transmitter (model: YT-TT3-A4; Yuden Electric Co., Ltd., Taiwan). These conditioned signals (EEGs, EMGs, brain temperature and gross body movements) were subjected to analogue-to-digital conversion with 16-bit precision at a sampling rate of 128 Hz (NI PCI-6033E; National Instruments, Austin, TX). The digitized EEG waveform and integrated values for body movement and brain temperature were stored as binary computer files pending subsequent analyses.

Postacquisition determination of the vigilance state was done by the visual scoring of 12-s epochs using custom software (ICELUS, M. R. Opp) written in LabView for Windows (National Instruments). The animal's behaviour was classified as either NREM sleep, REM sleep or waking based on previously defined criteria (Chang and Opp, 1998). Briefly, NREM sleep is characterized by large-amplitude EEG slow waves, high power density values in the delta frequency band (0.5–4.0 Hz), a relax muscle tone from EMGs, lack of gross body movements, and declining brain temperature before and during entry. During REMS, the amplitude of the EEG is reduced, the predominant EEG power density occurs within the theta frequency (6.0–9.0 Hz), the EMGs exhibit muscle atonia with low EMG amplitudes, brain temperature increases rapidly at onset, and there are phasic body twitches. During waking, the rats are generally active and brain temperature gradually increases. There are protracted body movements with robust EMG amplitudes. The amplitude of the EEG is similar to that observed during REM sleep, but power density values in the delta frequency band are generally greater than those in theta frequency band.

2.4. Behavioural tests

The OF chamber is a transparent Plexiglas squared box (100 cm \times 100 cm \times 50 cm), elevated at a height of 60 cm from the floor. The total areas of the OF were divided into nine arenas, including 4 corner arenas (30 cm \times 30 cm), 4 peripheral arenas (40 cm \times 30 cm) and one centre arena (40 cm \times 40 cm). The behavioural activities and movement traces were recorded by a digital camera, and this video file was imported to and analyzed by the custom software of Ethovision[®] (Version XT; Noldus, Wageningen, Netherlands). The time duration spent in the centre arena of the OF was determined as the major index for anxiety, and more ambulation towards the centre arena of the OF reflected less anxiety. Rats were placed in the centre arena of the OF at the beginning of the light (rest) period and exposed to the OF for 50 min. Activities were analyzed every 5-min and were represented by two 25-min time blocks.

After the 50-min exposure to the OF, rats were then placed in the cross area of the four arms and faced towards an open arm. The EPM consisted of two

open (50 cm long × 10 cm wide) and two enclosed arms (50 cm long × 10 cm wide × 40 cm height), and was elevated 60 cm from the floor. The performance of the EPM lasted for 10 min, and the traces of movement and activities in the EPM were recorded by a digital camera and analyzed by Ethovision®. The parameters of the movement traces in the EPM were classified as the time spent in the open arms, the frequency of entry to the open arms and the frequency of entry to the enclosed arms. The repeated combination tests (RCT) refer to the tests consisting of a 50-min OF and a subsequent 10 min EPM performed from the beginning of the light period in four consecutive days. The RCT was performed under 40 Watt × 4 tubes illumination, without noise and changing of environmental cues.

2.5. Experimental procedures

A total of 28 Wistar rats were used and divided into four groups as depicted in Fig. 1. A 24-h undisturbed baseline sleep recording was acquired before initiating experiments in all groups. Rats in group 1 (DMSO group; *n* = 7) received PFS and 2% DMSO 20 min prior to the beginning of the light period on the 1st and 2nd experimental days, respectively, and the sleep–wake activities were acquired for 24 h beginning from the light onset. The RCT of a 50-min OF and a 10-min EPM were performed during the first hour of the light period on the following 3rd, 4th, 5th and 6th days, and 2% DMSO was also administered 20 min prior to the light onset in these four consecutive days. The sleep–wake activities were recorded from the

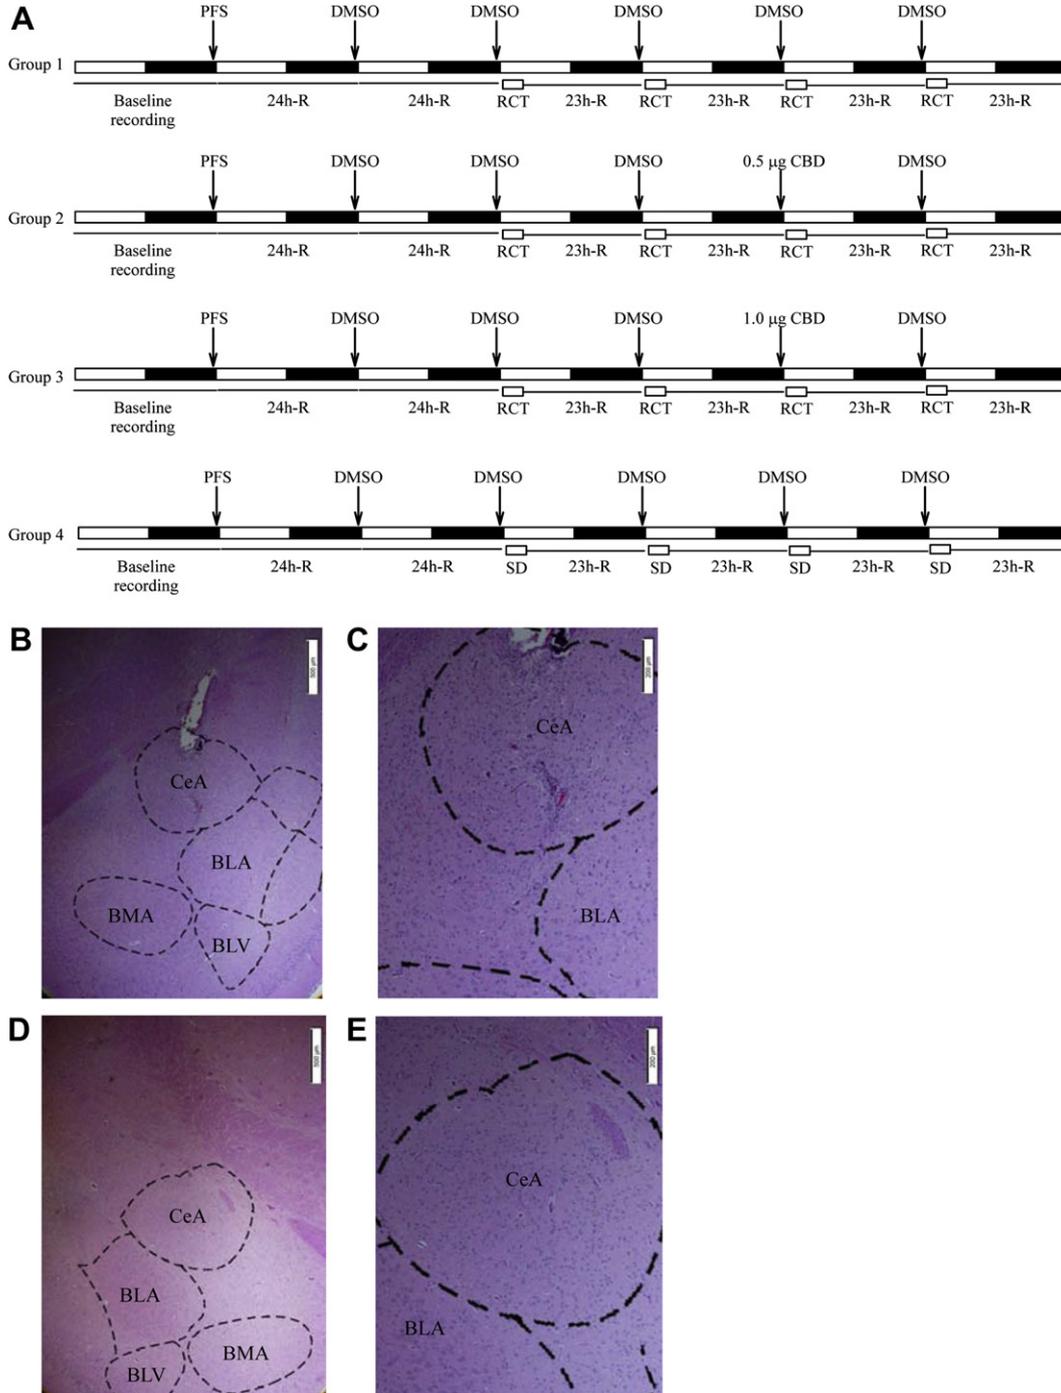

Fig. 1. A: The diagram for the experimental protocol. Close bar indicates the dark period and the open bar represents the light period of the 12:12 h light:dark cycle. Arrow depicts the timing of microinjection, “R” means recording, RCT represents the repeated combination test, and SD indicates sleep deprivation. B and C: the left CeA slides (with cannulae implantation); D and E: the right CeA slides (without implantation). CeA: central nucleus of amygdala; BLA: basolateral amygdala nucleus, anterior; BLV: basolateral amygdala nucleus, ventral; BMA: basomedial amygdala nucleus, anterior.

2nd-hour of the light period and lasted for 23 h. Rats in group 1 were used to determine the anxiogenic effect of the RCT and to evaluate the sleep disturbances. Rats in group 2 (low-dose CBD group; $n = 7$) received a protocol similar to those in group 1, except they were administered 0.5 μg CBD at the 5th days (the 3rd-day of RCT). Rats in group 3 (high-dose CBD group; $n = 7$) received a protocol similar to those in group 2, except they were administered 1.0 μg CBD at the 5th days (the 3rd-day of RCT). Groups 2 and 3 were used to determine the anxiolytic effect and the sleep effects of the CBD. Rats in groups 4 (sleep deprivation (SD) group; $n = 7$) were administered 2% DMSO 20 min prior to the beginning of the light period and were gently deprived of their total sleep for 1 h beginning from the light onset. The sleep-wake activities were recorded from the 2nd-hour of the light period and lasted for 23 h. Performing the RCT may have caused sleep deprivation during the first hour of the light period; however, results obtained from the rats in group 4 would eliminate the influence of sleep deprivation.

Additional 7 rats were used to verify the lesion of CeA after cannulae implantation and vehicle injection. Rats were implanted with a microinjection cannulae in the left hemisphere and received DMSO injection as those in group 1. Both left and right CeA regions were sliced, stained with haematoxylin and eosin, and the cell numbers were counted. Fig. 1B indicated the left CeA with cannulae implantation and Fig. 1D was obtained from the right CeA. Fig. 1C and E were the magnifications from Fig. 1B and D. The cell numbers counted from the left CeA and from the right CeA were 557.1 ± 29.9 and 554.4 ± 36.1 , respectively, suggesting there is no significantly physical damage to the CeA after implantation of microinjection cannulae and DMSO injection. Another 7 rats received the same protocol as those in group 1 and were used to clarify the level of anxiety by determining the urination and defecation.

2.6. Statistical analyses for experiment protocol

All values acquired from sleep-wake recording and the parameters of behaviour tests were presented as the mean \pm SEM for the indicated sample sizes. One-way repeated measures analyses of variance (ANOVA) for the duration of each vigilance state (NREM sleep, REM sleep, wakefulness), for sleep-architecture parameters, and for the parameters of behavioural tests were performed by comparing before, during and after manipulation within group and between groups, and across the two 12-h time blocks and specific time blocks as mentioned later in the result section. An α level of $p < 0.05$ was taken as indicating a statistically significant difference. If statistically significant differences were detected, a Tukey's multiple comparison was made to determine which values during experimental conditions deviated from those obtained from the control conditions. The correlation between the parameters obtained from the RCT and the number of days for exposing to the RCT was determined by the Spearman correlation coefficient.

3. Results

3.1. Behavioral measures of the repeated combination tests (RCT)

The values represented in Fig. 2 were the time differences for rats spending in the centre arena of the OF between second-day and first-day exposures of combination tests (Δ -day2), between third-day and first-day exposures (Δ -day3), and between fourth-day and first-day exposures (Δ -day4). The measures during the OF exposure were also divided into two 25-min blocks. The time for rats spending in the centre arenas of the OF during the total 50 min of exposure was gradually decreased as rats were repetitively exposed to the combination tests in the DMSO group; the Δ durations in the centre arena for Δ -day2, Δ -day3 and Δ -day4 were -0.7 ± 1.6 s, -3.3 ± 1.1 s and -3.5 ± 1.2 s, respectively (closed bars in Fig. 2C). Analysis for the durations in centre arena revealed it to be gradually and significantly decreasing when rats were repetitively exposed to the combination tests in four consecutive days ($F_{(3,207)} = 4.00$, $p < 0.01$). When comparing the values obtained from day-3 exposure to those acquired from day-1 exposure, a statistically significant difference was detected ($p < 0.05$; Fig. 2C). A similar result was observed when comparing the values between day-4 exposure and day-1 exposure ($p < 0.05$; Fig. 2C). The Spearman correlation coefficient (r) between the Δ duration in centre arena and the number of exposure to the OF was -0.19 ($p < 0.01$), indicating a negative correlation. Furthermore, the immobilization time was increased, and the total distance of movement and movement distance in the centre arena were consistently decreased following the repeated OF exposure

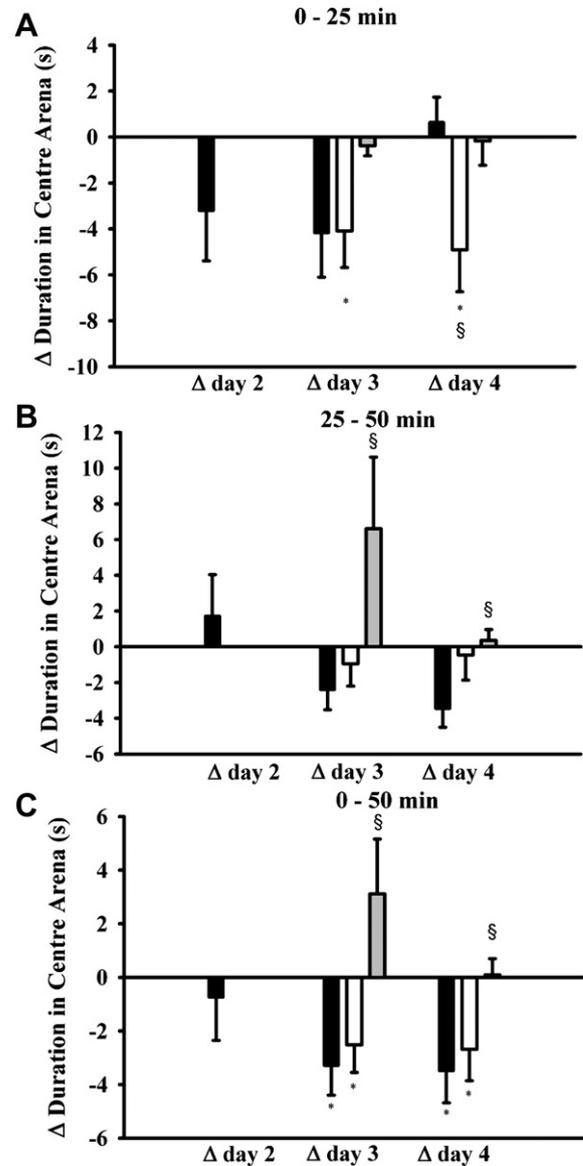

Fig. 2. The OF of RCT decreases the time spent during the centre arena and CBD increases rats' exploration in the central arena. The difference (Δ) of time duration spent in the centre arena of the OF is represented as mean \pm SEM in two 25-min blocks (A and B) and the whole 50-min block (C). Values in Δ -day2, Δ -day3 and Δ -day4 represent the differences determined after subtracting those acquired from day-1. Closed bars depict the values obtained from the DMSO group, open bars represent the values acquired from the low-dose (0.5 μg) CBD group, and grey bars demonstrate the values acquired from the high-dose (1.0 μg) CBD group. *represents a statistically significant difference when compared to the values obtained from day-1. § depicts a statistically significant difference when compared between the DMSO group and the CBD group on the same day.

(Table 1). This result suggests habituation learning as previous reports (Ivinskis, 1970; Makino et al., 1991) is not observed in the OF of the RCT and the anxiousness of rats also gradually increased as the stress exposure was repeated. We also found that the ambulation to the OF centre arena during the first 25-min time block was decreased during the day-2 and day-3 RCT exposures, whereas the anxiousness gradually increased during the second 25-min time block in the day-3 and day-4 exposures, which was indicated by the decrease of duration in the centre arena of the OF (closed bars in Fig. 2A and B).

The data (Δ -day2, Δ -day3 and Δ -day4) demonstrated in Fig. 3 were values of open arm durations, frequency of entry to the

open arms, frequency of entry to the enclosed arms and movement distance in the open arms in the EPM obtained from day-2, day-3 and day-4 exposures subtracting those acquired from day-1. Rats significantly spent less time in the open arms ($F_{(3,12)} = 4.3972$, $p < 0.05$; Δ -day2: $p < 0.05$; Δ -day4: $p < 0.05$) and decreased the frequencies of entry to the open arms of the EPM in day-2 and day-4 RCT exposures when compared to those obtained from day-1 in the DMSO group ($F_{(3,12)} = 5.9512$, $p < 0.05$; Δ -day2: $p < 0.05$; Δ -day4: $p < 0.05$; closed bars in Fig. 3A and B). The Spearman correlation coefficient (r) between Δ duration spent in the open arms and number of exposure to the EPM ($r = -0.45$, $p < 0.05$), and r between Δ frequency of entry to open arms and number of exposure to the EPM ($r = -0.48$, $p < 0.05$) revealed the negative correlation. The frequencies of entry to the enclosed arms of the EPM was sustainably decreased (Fig. 3C). The movement of distance in the open arms was also decreased following the repeated exposure of EPM, although it did not reach statistical significance (Fig. 3D). An example of trace analysis indicated the increase of avoidance of open arms when rats were repetitively exposed to the EPM (Fig. 3D, left panel).

Furthermore, the level of anxiety was additionally determined by the defecation and urination after exposing to RCT. Our results indicated that the volume of urine, number of defecation and weight of defecation were consistently increased following the RCT, indicating the level of anxiety did not diminished after the RCT, although these alterations did not reach statistical significance (Fig. 4).

3.2. Effects of CBD on repeated combination tests-induced behaviours

Microinjection of 1.0 μ g CBD directly into the CeA prior to the combination tests at the day-3 exposure statistically significantly enhanced the duration for rats exploring the centre arena of OF during the total of 50-min exposure (Δ -day3 = $+3.1 \pm 2.0$ s; grey bar in Fig. 2C) when compared to the values obtained from DMSO group rats at the day-3, which received 2% DMSO (Δ -day3 = -3.3 ± 1.1 s; $F_{(1,138)} = 7.55$, $p < 0.05$; closed bar in Fig. 2C). In addition, the Δ durations in the centre arena of the OF obtained from Δ -day4 significantly differ between the DMSO group and the high-dose CBD group, in which both groups received 2% DMSO

prior to the combination tests at day-4 exposure. The Δ duration in the centre arena obtained from Δ -day4 in the high-dose CBD group was $+0.1 \pm 0.6$ s, and the value acquired from Δ -day4 in the DMSO group was -3.5 ± 1.2 s ($F_{(1,138)} = 7.13$, $p < 0.01$; Fig. 2C). Further analyzing the alterations in the first and second 25-min time blocks revealed that CBD effect is significantly observed during the second 25-min time blocks (DMSO versus high-dose CBD groups at Δ -day3: $F_{(1,68)} = 4.69$, $p < 0.05$; DMSO versus high-dose CBD groups at Δ -day4: $F_{(1,68)} = 9.64$, $p < 0.01$; Fig. 2B). Administration of 0.5 μ g CBD exhibited no significant effect on OF-induced anxiousness as shown in Fig. 2. CBD did not change other parameters, including immobilization time, total distance of movement and velocity in the centre arena, obtained from repeated OF (Table 1). The OF-induced decrease of movement in the centre arena was suppressed by 1.0 μ g CBD, although it did not reach statistical significance. Notably, the OF-induced decreased movement in the centre arena was significantly suppressed at Δ -day4 in the high-dose CBD group ($p < 0.05$; Table 1).

Administration of CBD 1.0 μ g into the CeA reversed the decrease of the Δ durations in the open arms of EPM obtained from Δ -day3 and Δ -day4 in the DMSO group, although they did not reach statistical significance (Fig. 3A). The frequencies of entry to the enclosed arms of EPM were significantly decreased after receiving 1.0 μ g CBD at day-3, and 2% DMSO at day-4 of exposure in the high-dose CBD group when compared to those acquired at day-1 of exposure in the CBD group rats ($F_{(2,12)} = 14.61$, $p < 0.001$; Fig. 3C), and Tukey's multiple comparison indicated a statistically significant difference between values obtained at day-3 versus day-1 exposures ($p < 0.001$), and day-4 versus day-1 exposures ($p < 0.01$). Administration of CBD 1.0 μ g into the CeA suppressed the decrease of the Δ movement distance in the open arms of EPM obtained from Δ -day3 and Δ -day4 in the DMSO group, although they did not reach statistical significance (Fig. 3D). An example of trace analysis indicated that 1.0 μ g CBD blocked the avoidance of open arms when rats were repetitively exposed to the EPM in four consecutive days (Fig. 3D, right panel).

3.3. Sleep alterations induced after repetitive exposure to the combination tests

NREM sleep was not significantly altered during hours 2–12 after exposure to the RCT (Fig. 5B), except for the first hour after RCT. NREM sleep during the first hour after exposure to the RCT was significantly decreased in four consecutive days; the amounts of time spent in NREM sleep during hour-2 (the hour after RCT) were $50.1 \pm 6.7\%$ obtained after DMSO control, $13.0 \pm 5.7\%$ after day-1 exposure to tests, and $27.4 \pm 4.3\%$ after day-4 exposure to RCT in DMSO group ($F_{(2,12)} = 19.17$, $p < 0.001$; Fig. 5A), and Tukey's multiple comparison indicated a statistically significant difference when comparing the values after day-1 exposure versus control ($p < 0.001$), and day-4 exposure versus control ($p < 0.01$). Decreases of NREM sleep during the first hour after RCT were gradually decremented as the times of exposure to the RCT increased (Fig. 5A). Slow wave activities (SWAs) during NREM sleep was not significantly changed by the RCT; SWAs obtained from the control, day-1 exposure, day-2 exposure, day-3 exposure and day-4 exposure were $1069.1 \pm 2.9 \mu V^2/Hz$, $1079.2 \pm 4.2 \mu V^2/Hz$, $1073.5 \pm 2.8 \mu V^2/Hz$, $1075.5 \pm 3.4 \mu V^2/Hz$, and $1077.7 \pm 3.5 \mu V^2/Hz$, respectively. On the other hand, REM sleep was significantly reduced during hours 2–12 after exposure to the RCT (Fig. 5C and D). Analysis of sleep-architecture parameters across hours two to twelve revealed that the decrease in REM sleep after exposure to the RCT was primarily due to a decrease in REM sleep bout duration (Table 2). Further analysis of the first 5-h time block (hours 2–6) and second 6-h time block (hours 7–12) revealed that the RCT

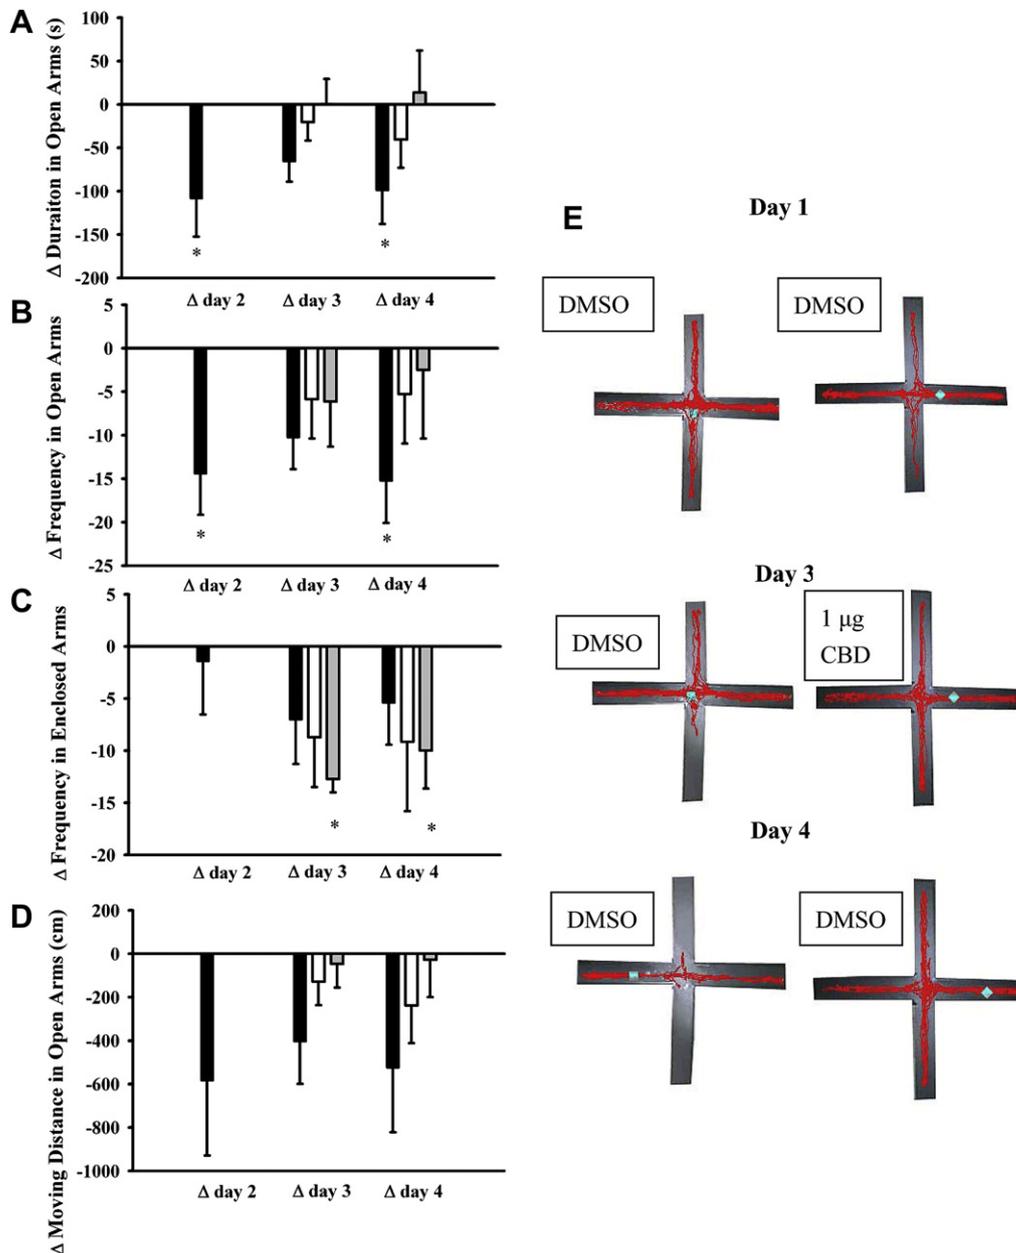

Fig. 3. The effects of CBD on the time rats spend in the open arms (A), the frequency of entering the open arms (B), the frequency of entering the enclosed arms (C), and movement distance in the open arms of the EPM (D). Values, represented as mean \pm SEM, in Δ -day2, Δ -day3 and Δ -day4 demonstrate the differences determined after subtracting those acquired from day-1. Closed bars depict the values obtained from the DMSO group, open bars represent the values acquired from the low-dose (0.5 μ g) CBD group, and grey bars demonstrate the values acquired from the high-dose (1.0 μ g) CBD group. *represents a statistically significant difference when compared to the values obtained from day-1. The red trace in panel E represents the track of rat's motion in the EPM. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

significantly decreased REM sleep during both time blocks (for hours 2–6: $F_{(4,136)} = 8.14$, $p < 0.001$; for hours 7–12: $F_{(4,164)} = 6.21$, $p < 0.001$; Fig. 5D), Tukey's multiple comparison indicated a statistically significant difference when comparing the values after day-1 exposure versus control (for hours 2–6: $p < 0.05$; for hours 7–12: $p < 0.05$), day-2 exposure versus control (for hours 2–6: $p < 0.01$; for hours 7–12: $p < 0.001$), day-3 exposure versus control (for hours 2–6: $p < 0.01$; for hours 7–12: $p < 0.001$), and day-4 exposure versus control (for hours 2–6: $p < 0.001$; for hours 7–12: $p < 0.001$). Further analysis of the alteration of REM sleep induced by the RCT has shown that the propensity of decrease in REM sleep was gradually augmented during the time block of hours

4–10 as the times of exposure to the RCT increased ($F_{(4,192)} = 7.02$, $p < 0.001$); the amounts of time spent in REM sleep obtained from the control, day-1 exposure, day-2 exposure, day-3 exposure and day-4 exposure were $21.1 \pm 1.1\%$, $18.8 \pm 1.0\%$ ($p > 0.05$: comparing with control), $16.5 \pm 1.2\%$ ($p < 0.01$: comparing with control), $15.6 \pm 1.2\%$ ($p < 0.001$: comparing with control), and $15.1 \pm 1.2\%$ ($p < 0.001$: comparing with control; $p < 0.05$: comparing with day-1 exposure), respectively.

Since performing the RCT during the first hour of the light period may deprive sleep, results obtained from the SD group were used to eliminate the influence of sleep deprivation. Our results indicated that NREM sleep was not significantly altered after 1-h

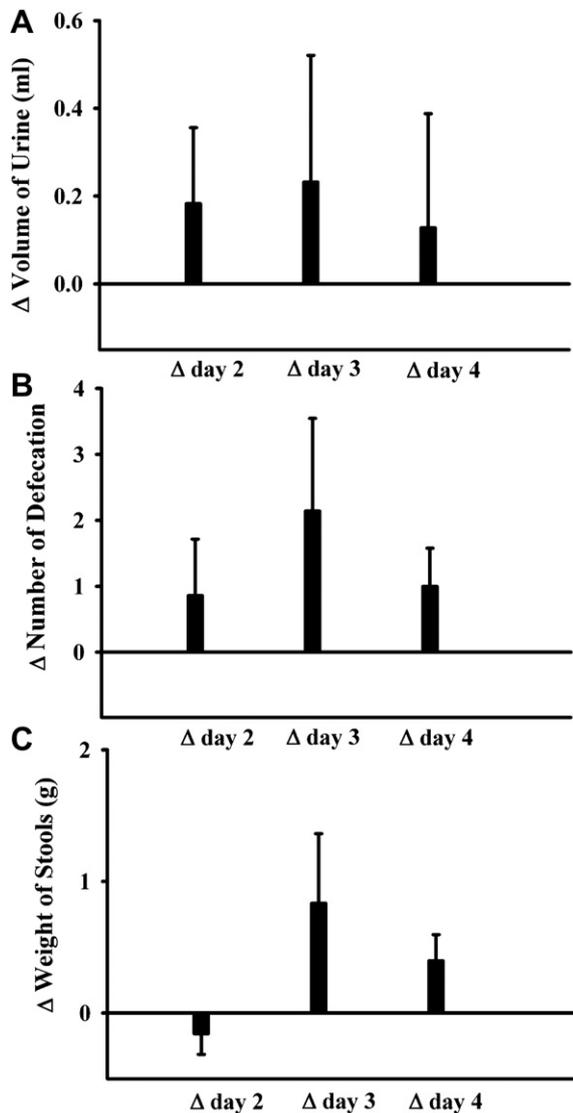

Fig. 4. The level of anxiety determined by urination and defecation after exposing to the RCT.

total SD, except for those during hour-1 after deprivation (Fig. 5E and F). The decrease of NREM sleep was gradually augmented as the times of SD increased; the percentages of time spent in NREM sleep obtained from the control, day-1 SD, and day-4 SD were $47.9 \pm 4.2\%$, $39.2 \pm 3.8\%$ and $24.5 \pm 8.6\%$ ($p < 0.01$: comparing with control; $p < 0.05$: comparing with day-1 SD; Fig. 5E). REM sleep was also not altered during hours 2–12 after SD, except the decrease of REM sleep was aware during the first few hours after SD (Fig. 5G and H). Significant rebounds of NREM sleep and REM sleep were noticed during the subsequent 12-h dark period as the times of SD increased (Fig. 5F and H).

3.4. CBD blocked RCT-induced suppression of REM sleep

Microinjection of 1.0 μg CBD directly into the CeA reversed the RCT-induced decrease of REM sleep during hours 4–10 when compared with the DMSO group (Fig. 6G). The amounts of time spent in REM sleep obtained from the control (2% DMSO), 2% DMSO + day-1 exposure, 1 μg CBD + day-3 exposure and 2% DMSO + day-4 exposure were $16.1 \pm 1.2\%$, $15.9 \pm 1.2\%$, $16.9 \pm 1.0\%$, and $19.0 \pm 1.1\%$ (no significance (n.s.); Fig. 6H), respectively.

However, 1.0 μg CBD had no effect on the initial suppression of NREM sleep and REM sleep after the RCT (Fig. 6E and F). Administration of 0.5 μg CBD also blocked RCT-induced decrease of REM sleep during hours 4–10 when compared with the DMSO group (Fig. 6C and D). Similarly, 0.5 μg CBD had no effect on the initial suppression of NREM sleep after the RCT (Fig. 6A).

4. Discussion

Persistent sleep disturbances, such as increased arousal, reduced sleep efficiency caused by increased wakefulness from sleep, insomnia, nightmares, disrupted REM sleep, and periodic limb movements, are highly prevalent in PTSD patients (American Psychiatry Association, 1994; Harvey and Bryant, 1998; Horowitz et al., 1980; Koren et al., 2002; Mellman et al., 2001, 2002; Mellman and Davis, 1985; Neylan et al., 1998). Growing evidence indicates that sleep disturbances are the core features of PTSD (rather than the secondary symptoms) and sleep disruption caused by the traumatic event may involve the pathological development of chronic PTSD (Germain et al., 2008). Although poor sleep efficiency, decrease of total sleep time, increase of sleep latency and increased number of awakenings are commonly found in the most of studies (Hefez et al., 1987; Lavie et al., 1979; Mikulincer et al., 1989), these findings are not observed in some other studies (Breslau et al., 2004; Ross et al., 1994). Disruption in REM sleep is also controversial; a shorter REM sleep time has been demonstrated (Hefez et al., 1987; Lavie et al., 1979; Mikulincer et al., 1989) but no change or a prolonged REM sleep was reported in others (Breslau et al., 2004; Fuller et al., 1994; Ross et al., 1994). The discrepant observations of sleep disruptions in PTSD patients may be due to the clinical variability, such as comorbidity, medication, age, sample size, and the time since the traumatic event (Fuller et al., 1994). Furthermore, whether disturbed sleep is the secondary symptom or the core feature of PTSD and the causal connection between sleep problems and anxiety are difficult to determine in the clinical aspect. Employment of a suitable animal model of PTSD becomes adequate for further investigation of the underlying mechanisms and for new drug development and screening. Exposure to psychological stress in humans is related to the increased incidence of PTSD (Brady and Sinha, 2005). Psychological stressors have a prominent effect on sleep alterations, particularly on REM sleep, although distinct stressors differ in REM alteration (Pawlyk et al., 2008). Pawlyk et al. summarize the effects of different stressors (including immobilization, footshock stress, and contextual fear conditioning) on sleep disruptions, and conclude that more intense stressors simulate anxiety and disrupt sleep (particularly REM sleep), although mild stressors might produce increases of REM sleep (Pawlyk et al., 2008). The OF is capable to induce anxiety in rodents and has been widely used to assess the behavioural effects of anxiety (Hall, 1936). The OF allows rodents to explore in a novel environment and produces conflicting motivations between fear and exploration with regards to the threatening environment. More thigmotaxis and less locomotion activity is thought to indicate greater anxiety, whereas greater exploration and more ambulation to the centre arena of the OF reflect less emotion (Choleris et al., 2001). EPM is another model to induce and assess anxiety based upon the confliction between exploration and aversion of height and openness (Pellow et al., 1985; Treit et al., 1993). Repetitive exposure to stress or exposure to a persistent stressor for a long period of time might participate in the development of anxiety. However, the OF exhibits the habituation behaviour after repetitive exposure to the OF or increased exposure time in the OF (Ivinskis, 1970; Makino et al., 1991). We employed RCT consisting of 50 min of OF and a subsequent 10-min of EPM for four consecutive days to simulate the development of

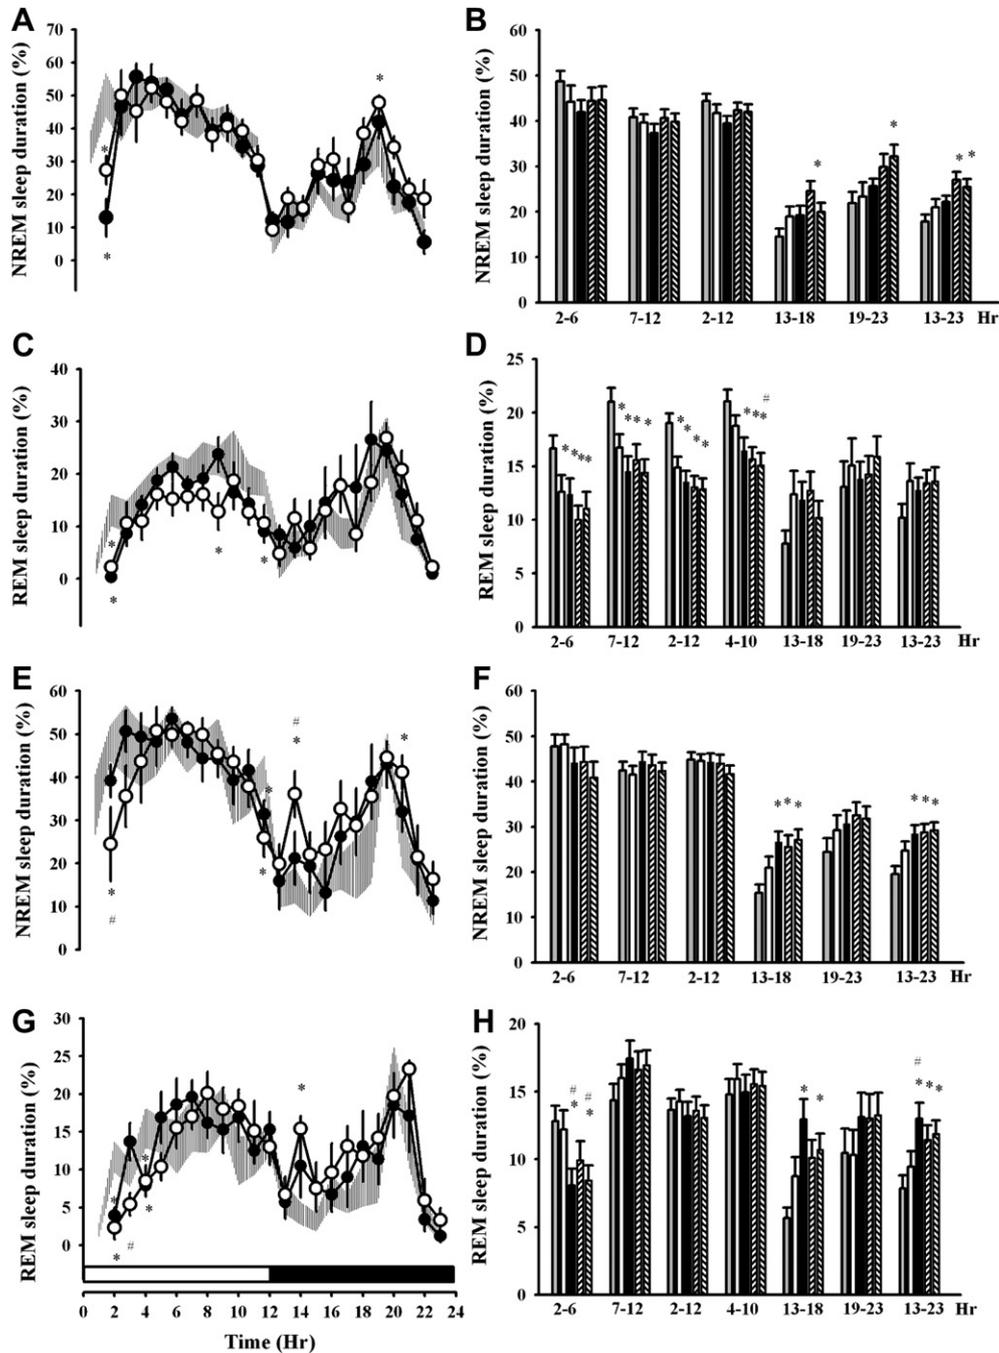

Fig. 5. The alterations of NREM sleep and REM sleep after the RCT (A–D) and sleep deprivation (E–H). Shaded areas represent the values obtained without RCT, closed circles depict the values acquired after the first-day RCT, and open circles demonstrate those gained after the fourth-day RCT in panels A and C. Whereas the shaded areas represent the values obtained without SD, closed circles depict the values acquired after the first-day SD, and open circles demonstrate those gained after the fourth-day SD in panels E and G. The bars on the histograms from left to right demonstrate the DMSO control, DMSO + day-1 RCT/or day-1 SD, DMSO + day-2 RCT/or day-2 SD, DMSO + day-3 RCT/or day-3 SD, and DMSO + day-4 RCT/or day-4 SD, respectively. *represents the statistically significant difference when compared to the values obtained after DMSO control, and # depicts the statistically significant difference when compared to the values obtained after day-1 RCT/or day-1 SD. The dark and open portions of the horizontal bars represent the dark and light periods of the 12:12 h light:dark cycle.

anxiety and anxiety-induced sleep disturbances. Our results indicate that the time spent in the centre arena of the OF decreased with the numbers of RCT exposure, immobilization time was increased, and the total distance of movement and movement distance in the centre arena were consistently decreased following the repeated OF exposure, suggesting that the habituation does not exist when performing the OF in these combination tests. Further analysis revealed that the anxiety level, indicated as the decrease of

time in the centre arena of the OF, was higher during the first 25-min OF exposure in day-2 and day-3, and increased during the second 25-min in the latter days (day-3 and day-4). The EPM also exhibited sustained anxiousness by decreasing time spent in open arms and reducing frequency of entry to the open arms after repetitive trials. In addition, consistent increases of the urination and defecation were observed after exposing to RCT. These observations suggest that the RCT did not cause rats to habituate

anxiety/stress and can act as a suitable model to induce persistent anxiety in rats.

Our results demonstrated that 1-h of RCT decreased NREM sleep during the first hour after each time of exposure, and the decrease of NREM sleep gradually declined when the times of exposure increased. REM sleep was decreased during the first hour after RCT, and the decrease of REM sleep during the time block of hours 4–10 was predominantly enhanced in accordance with the increased exposure numbers. There was no rebound of NREM or REM sleep obtained after the manipulation of RCT. These sleep alterations might resemble the features of decreased total sleep time and shorter REM sleep time observed in PTSD patients. The reduction of NREM sleep during the first hour after 1-h sleep deprivation only reached statistical significance after deprivation in day-4 and a rebound in NREM sleep was observed during the subsequent dark period. One-hour sleep deprivation also decreased REM sleep during the immediate 3 h after deprivation and a REM sleep rebound was also found in the dark period. Our previous results demonstrate that 1-h acute stressor, the physical restraint, applied at the beginning of the light period (but not the dark period) increases waking and decreases REM sleep immediately after the restraint, and does not dramatically alter NREM sleep (Chang and Opp, 2002). The initial decrease of REM sleep during the initial 3 h after 1-h sleep deprivation, considered as a mild stressor, observed in the current study is consistent with our previous findings (Chang and Opp, 2002). Others have reported that physical restraint primarily induces a REM sleep rebound; Rampin et al. reported that a 2-h period of physical restraint applied to rats at the beginning of the dark period induces a significant increase in REM sleep during the remaining 10 h of the dark period (Rampin et al., 1991). The REM sleep rebound after sleep deprivation might be due to the effect of acute stress, which was not observed after RCT manipulation. These SD-induced alterations in NREM and REM sleep differ from those acquired after RCT, suggesting the effect of RCT on the sleep alterations was not primarily due to the effects of

sleep deprivation. Decrement in REM sleep is thought to be an indicator of the anxiety level. Tang et al. (2004) have demonstrated that the anxiousness induced by OF decreases REM sleep which is greater in more anxious mice, such as BALB/cj mice; whereas the exploration activity in OF, associated with the delayed REM increase, increases greater in less anxious mice (e.g. C57BL/6J and CB6F1/J mice) (Tang et al., 2004). The gradual and continued decrease of REM sleep during hours 4–10, when rats were exposed to the 1-h RCT for four consecutive days, was consistent with the increased anxiety-like behaviours observed from the OF and EPM, further indicating the model of RCT resembles the features of REM disruption in PTSD patients.

The amygdala appears to be a critical brain structure which involves in emotional, behavioural, and physiological responses associated with fear and anxiety (Davis, 1992; Kim and Jung, 2006). During acquisition of fear conditioning, sensory information is transmitted from thalamus and sensory cortices to the lateral amygdala, and then is projected to the CeA, which is further transmitted to the hypothalamus and brainstem structures where there is response to autonomic and visceral fear [review (Germain et al., 2008)]. Growing evidence also indicates that the amygdala is an important modulator in both NREM and REM sleep, although it is not the primary brain region involved in sleep–wake regulation. Electrical stimulation of CeA suppresses delta wave activity in the frontal cortex and increases arousal (Kapp et al., 1994), and inactivation of CeA with tetrodotoxin decreases REM sleep and increases slow wave sleep (Tang et al., 2005). CBD is the first compound isolated from the cannabis plant and exhibits a broad pharmacological profile, including anti-convulsion, sedation, anti-anxiety, hypnotic effect, anti-psychosis and anti-inflammation (Mechoulam et al., 2002). Those pharmacological properties are more predominant for therapeutic purposes than other active compounds extracted from *C. sativa*, such as THC, because of its non-psychoactive effect (Grotenhermen, 2006). Systemic administration of CBD (2.5–10 mg/kg) exhibits an anxiolytic-like effect

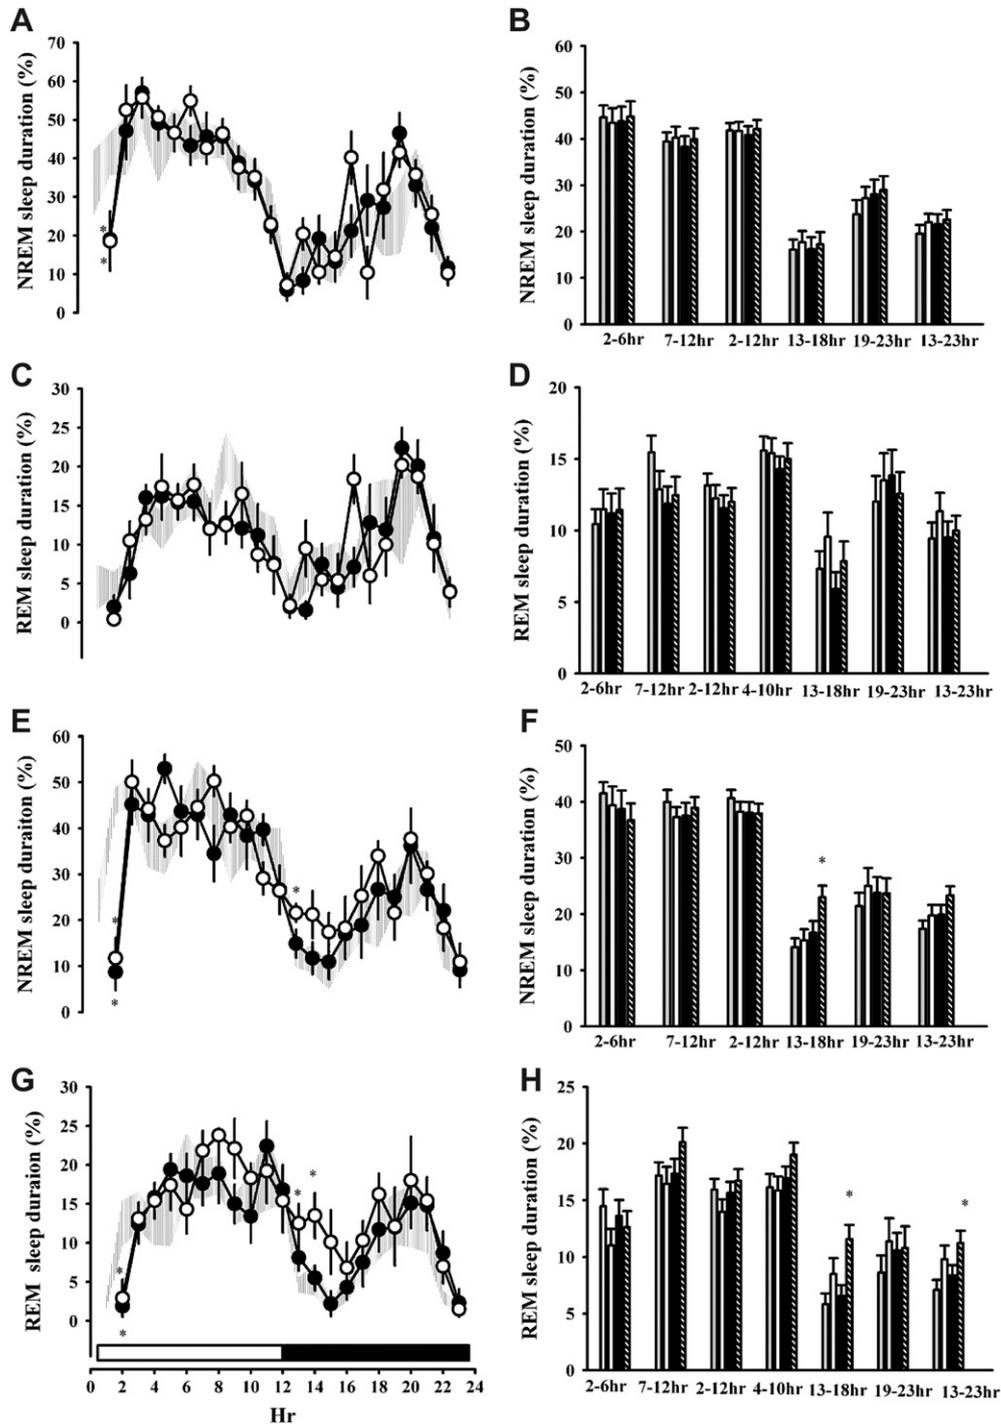

Fig. 6. The effects of CBD on RCT-induced sleep alterations. Panels A–D represent the data obtained from the low-dose (0.5 µg) CBD group and Panels E–H demonstrate the values acquired from the high-dose (1.0 µg) CBD group. Shaded areas represent the values obtained after DMSO administration but without RCT, closed circles depict the values acquired after the CBD + day-3 RCT, and open circles demonstrate those gained after DMSO + day-4 RCT in panels A, C, E and G. The bars of the histograms from left to right demonstrate the DMSO control, DMSO + day-1 RCT, CBD + day-3 RCT, and DMSO + day-4 RCT, respectively. *represents the statistically significant difference when compared to the values obtained after the DMSO control.

evaluated by the EPM assay (Guimaraes et al., 1990). CBD improves stress-induced avoidance learning and decreases response suppression in a punished response task (Musty, 1984). Comparing the anxiolytic effect of CBD with ipsapirone (a 5-HT_{1A} partial agonist) and diazepam reveals that three compounds are active with similar efficacies, although the dose of CBD needed is considerably higher than two other drugs (Zuardi et al., 1993). The

effects of CBD on sleep–wake regulation *per se* have been reported. Systemic administration of CBD reduces sleep (Monti, 1977), and intraventricular administration of CBD at the beginning of the light period increases wakefulness and decreases REM sleep (Murillo-Rodríguez et al., 2006). Furthermore, our previous results demonstrated that microinjection of CBD directly into the CeA prior to the beginning of the light period dose-dependently decreases NREM

sleep with limited effect on REM sleep suppression (Yi et al., 2008). However, the effect of CBD on anxiety-induced sleep–wake alteration hasn't been determined. Our current results indicate that the anxiety behaviours, including the decrease of time spent during the centre arena of OF and decrease of time exploring in the open arms of EPM, were suppressed after administration of CBD into the CeA. The frequency of entering the enclosed arms of EPM was also decreased by CBD. These observations further confirmed the anxiolytic effect of CBD. Our results also demonstrated that the RCT-induced REM suppression during hours 4–10 of the light period was blocked by microinjection of CBD directly into the CeA. Comparing the effects of CBD administered into the CeA on spontaneous sleep regulation (decrease of NREM sleep with limited suppression in REM sleep), present results suggest CBD blocks anxiety-induced REM sleep alteration via its anxiolytic effect, rather than via sleep regulation *per se*. The effect of CBD in anxiolytic might be due to the inhibition of endogenous endocannabinoid (anandamide) uptake and hydrolysis or the anti-oxidative effect (Mechoulam et al., 2002). Nevertheless, the underlying mechanism is worthy for further investigation. Furthermore, the decreases of NREM sleep and REM sleep during the first hour after RCT were not altered by CBD and a rebound of REM sleep appeared after CBD administration, suggesting the initial suppressions of NREM and REM sleep were caused by the sleep deprivation, since these features were similar to those of sleep deprivation.

In summary, our current results suggest that RCT may become a suitable rodent model to simulate the REM alteration after the PTSD. CBD may block anxiety-induced REM sleep alteration via its anxiolytic effect, rather than via sleep regulation *per se*.

ABSTRACT

Introduction: Anxiety and sleep disorders are often the result of posttraumatic stress disorder and can contribute to an impaired ability to focus and to demonstration of oppositional behaviors.

Case Presentation: These symptoms were present in our patient, a ten-year-old girl who was sexually abused and had minimal parental supervision as a young child under the age of five. Pharmaceutical medications provided partial relief, but results were not long-lasting, and there were major side effects. A trial of cannabidiol oil resulted in a maintained decrease in anxiety and a steady improvement in the quality and quantity of the patient's sleep.

Discussion: Cannabidiol oil, an increasingly popular treatment of anxiety and sleep issues, has been documented as being an effective alternative to pharmaceutical medications. This case study provides clinical data that support the use of cannabidiol oil as a safe treatment for reducing anxiety and improving sleep in a young girl with posttraumatic stress disorder.

INTRODUCTION

Cannabidiol (CBD) oil is a naturally occurring constituent of industrial hemp and marijuana, which are collectively called cannabis. CBD oil is 1 of at least 85 cannabinoid compounds found in cannabis and is popular for its medicinal benefits. After tetrahydrocannabinol (THC), CBD oil is the second-most-abundant component of cannabis. Other names for CBD oil include CBD-rich hemp oil, hemp-derived CBD oil, or CBD-rich cannabis oil. Considered to be generally safe, CBD has been used medicinally for decades. However, CBD is not medical marijuana and should be distinguished from high-CBD strains

of medical marijuana, which do contain THC, such as “Charlotte’s Web.”

The most abundant compound in cannabis, THC is also a cannabinoid. The THC component induces the psychoactive effect, “high.” A cannabis plant has different amounts of CBD and THC depending on the strain and thus provides different recreational or medicinal effects. The cannabinoid profile of industrial hemp or medical marijuana is ideal for people looking for the medical benefits of CBD without the “high” of the THC.

The mechanism of action of CBD is multifold.¹⁻³ Two cannabinoid receptors are known to exist in the human body: CB1 and CB2 receptors. The CB1 receptors are located mainly in the brain and modulate neurotransmitter release in a manner that prevents excessive neuronal activity (thus calming and decreasing anxiety), as well as reduces pain, reduces inflammation, regulates movement and posture control, and regulates sensory perception, memory, and cognitive function.^{4,2} An endogenous ligand, anandamide, which occurs naturally in our bodies, binds to the CB1 receptors through the G-protein coupling system. CBD has an indirect effect on the CB1 receptors by stopping the enzymatic breakdown of anandamide, allowing it to stay in the system longer and provide medical benefits.⁴ CBD has a mild effect on the CB2 receptors, which are located in the periphery in lymphoid tissue. CBD helps to mediate the release of cytokines from the immune cells in a manner that helps to reduce inflammation and pain.²

Other mechanisms of action of CBD include stimulation of vanilloid pain receptors (TRPV-1 receptor), which are known to mediate pain perception, inflammation, and body temperature.⁵ In addition, CBD may exert its anti-anxiety effect by

activating adenosine receptors which play a significant role in cardiovascular function and cause a broad anti-inflammatory effect throughout the body.⁵ At high concentrations, CBD directly activates the 5-HT1A serotonin receptor, thereby conferring an antidepressant effect.⁶ Cannabidiol has been found to be an antagonist at the potentially new third cannabinoid receptor, GPR55, in the caudate nucleus and putamen, which if stimulated may contribute to osteoporosis.⁷

Since the 1940s, a considerable number of published articles have dealt with the chemistry, biochemistry, pharmacology, and clinical effects of CBD.⁸ The last decade has shown a notable increase in the scientific literature on CBD, owing to its identification for reducing nausea and vomiting, combating psychotic disorders, reducing inflammation, decreasing anxiety and depression, improving sleep, and increasing a sense of well-being.⁹⁻¹² Findings presented at the 2015 International Cannabinoid Research Society at its 25th Annual Symposium reported the use of CBD as beneficial for kidney fibrosis and inflammation, metabolic syndrome, overweight and obesity, anorexia-cachexia syndrome, and modification of osteoarthritic and other musculoskeletal conditions.¹³⁻¹⁶

Although studies have demonstrated the calming, anti-inflammatory, and relaxing effects of CBD, clinical data from actual cases is minimal. This case study offers evidence that CBD is effective as a safe alternative treatment to traditional psychiatric medications for reducing anxiety and insomnia.¹⁷

CASE PRESENTATION

A ten-year-old girl presented in January 2015 for a reevaluation of behaviors related to her diagnosis of posttraumatic stress disorder (PTSD) secondary to sexual

Scott Shannon, MD, ABIHM, is an Assistant Clinical Professor of Psychiatry at the University of Colorado School of Medicine in Fort Collins. E-mail: scottshannon@cowisp.net. Janet Opila-Lehman, ND, is a Naturopathic Physician at the Wholeness Center in Fort Collins, CO. E-mail: j.opila.lehman@gmail.com.

abuse. Her chief issues included anxiety, insomnia, outbursts at school, suicidal ideation, and self-destructive behaviors. Her grandmother, who has permanent custody of the patient and her younger brother, accompanied her.

Our patient had been seen for an initial evaluation in January 2012 and received a diagnosis of PTSD secondary to sexual abuse on the basis of her history, clinical observations, and behaviors (Table 1).

Her father had died 6 months earlier in a motor vehicle accident, and our patient's maternal grandparents became her permanent guardians. Before her father's death, our patient had no supervision from her father and very little supervision from her mother. An 11-year-old boy had molested her when she was 3 years old. Her medical history included her mother having methadone addiction, alcoholism, bipolar disorder, and depression. Her mother used

marijuana her entire pregnancy with the girl. The patient presented in January 2012 as displaying aggressive, disobedient, impulsive, and sexually inappropriate behaviors. She also demonstrated low self-esteem and anxiety and had poor sleep (restless, interrupted, and unable to sleep alone).

Workup during 2012 included laboratory studies, which ruled out a thyroid dysfunction and an iron or vitamin D deficiency. The patient was started on a

Table 1. Timeline

Date	Presentation	Medications	Supplements	Other
January 31, 2012	New evaluation: 7.5-year-old girl. History of sexual abuse and neglect. Issues: Insomnia, sexual behaviors. Diagnosis: PTSD secondary to sexual abuse.	None	Melatonin, 1 mg/night	February 14, 2012, laboratory values: TSH, 2.46 mIU/L (reference range, 0.47-4.68 mIU/L); ferritin: 21 ng/mL (reference range, 10-150 ng/mL). February 16, 2012, laboratory values: Vitamin D ₃ : 39 ng/mL (reference range, 20-50 ng/mL)
February 20, 2012	Sleeping 2-3 hours/night. Started counseling; Cooperative and good behavior at counseling session. Anxious, traumatized.	Clonidine, 0.05 mg (half tablet) at bedtime	Inositol, 3 g 3 times/d; EPA fish oil, 500 mg/d	Eye movement desensitization and reprocessing therapy recommended
February 22, 2012	Did not do well with clonidine because of hallucinations, so she discontinued that treatment. Behavior still very rough; sleep poor.	Started imipramine therapy, 25 mg at bedtime		March 7, 2012: ECG was normal
August 8, 2012 ^a	Good summer. In play therapy. Overall better sleep and energy with imipramine therapy. Patient's 6-year-old brother also now in therapy.	Imipramine, 25 mg at bedtime		
January 21, 2015	Returned for evaluation and treatment after 3 years. Suicidal ideation; cut self on leg; defiant and stubborn. Had psychotherapy 3 years straight twice a month. Sleeps with brother; can't sleep alone.	Off all medications for past 18 months	Melatonin, 5 mg; St John's wort, 450 mg twice/d; magnesium, 300 mg/d; diphenhydramine, 25 mg/night	
February 16, 2015	Hard to manage. Has outbursts at school.		Magnesium and St John's wort: stopped treatment; EPA fish oil, 750 mg/d; diphenhydramine, 25 mg/night	February 11, 2015: Normal cortisol and DHEA levels
March 16, 2015	Better overall. Started animal-assisted therapy.		EPA fish oil, 750 mg/d; diphenhydramine, 25 mg/night	Started a regimen of CBD oil, 25 mg (1 capsule)/d at 6 pm
April 14, 2015	Sleeping better with CBD treatment. Getting biofeedback. Has stomachaches. Mood is more at ease.		EPA fish oil, 750 mg/d; diphenhydramine, 25 mg/night	CBD oil, 25 mg (1 capsule)/d at 6 pm
May 26, 2015	"Ghosts" waking patient up at night.		EPA fish oil, 750 mg/d	CBD oil, 25 mg (1 capsule)/d at 6 pm
July 22, 2015	Sleeping better; able to sleep in own room 3-4 nights/wk.		EPA fish oil, 750 mg/d	CBD liquid, 12 mg (in 4 sublingual sprays)/night; 12 mg more (in 4 sublingual sprays) during the day as needed for anxiety, typically 3 or 4 times/wk
August 24, 2015	Sleeping well. Handling school well.		EPA fish oil, 750 mg/d	CBD oil, 25 mg (1 capsule)/night; CBD liquid, 6-12 mg (in 2-4 sublingual sprays) as needed for anxiety, typically 2 or 3 times/wk

^a There were additional visits in 2012 with no substantial changes.

CBD = cannabidiol; DHEA = dehydroepiandrosterone; ECG = electrocardiogram; EPA = eicosapentaenoic acid; PTSD = posttraumatic stress disorder; TSH = thyroid stimulating hormone.

regimen of 1 mg/night of melatonin, which helped her sleep duration. Three grams of inositol 3 times a day and 500 mg/d of eicosapentaenoic fish oil were also helpful in reducing her anxiety. A trial of clonidine was implemented, which resulted in hallucinations and thus was discontinued. The patient was switched to a regimen of 25 mg of imipramine at bedtime to decrease her anxiety, which appeared to be helpful. Counseling sessions were started. The patient continued psychotherapy for 3 years, but she was not seen again in our clinic until the return visit in January 2015, when she was not receiving any of her medications and supplements.

CBD oil can be an effective compound to reduce anxiety and insomnia secondary to PTSD.

At the patient's return in January 2015, she demonstrated the same prominent symptoms as at her initial presentation. At that time, the initial treatment included the following supplements and medications to assist with her sleep and anxiety: melatonin, 5 mg/night; magnesium, 300 mg/d; and diphenhydramine (Benadryl), 25 mg/night. Our patient demonstrated slight gains but was still having outbursts at school and was reportedly difficult to manage at home. In addition, her underlying anxiety continued.

Cannabidiol oil was explored as a potential additional treatment to help her insomnia and anxiety, but we deferred for two months while we waited for a response from other interventions. The grandmother preferred reducing the pharmacologic load given her granddaughter's failure to respond long term to psychiatric medications.

In March 2015, CBD oil was recommended as a potential additional treatment to help her insomnia and anxiety, and her grandmother provided full informed consent. Our patient was administered the Sleep Disturbance Scale for Children¹⁸ and the Screen for Anxiety Related Disorders (SCARED)¹⁹ before taking the CBD oil and each month afterward for the next 5 months. Test scores on the Sleep Disturbance Scale for Children and Screen for

Anxiety Related Disorders demonstrated an improvement (Table 2).

A trial of CBD supplements (25 mg) was then initiated at bedtime, and 6 mg to 12 mg of CBD sublingual spray was administered during the day as needed for anxiety. A gradual increase in sleep quality and quantity and a decrease in her anxiety were noted. After 5 months, the patient was sleeping in her own room most nights and handling the new school year with no difficulties. No side effects were observed from taking the CBD oil.

DISCUSSION

Studies repeatedly recognize the prevalence of an anxiety-provoked sleep disorder after a traumatic experience.²⁰ Our patient was definitely experiencing this phenomenon, which was aggravated by daily stressful activities.

The main finding from this case study is that CBD oil can be an effective compound to reduce anxiety and insomnia secondary to PTSD. A review of the literature suggests some benefits from the use of CBD because of its anxiolytic and sleep-inducing effects.⁹ Animal studies support use of this treatment and report that "CBD may block anxiety-induced [rapid eye movement] sleep alteration via its anxiolytic effect on the brain."²¹

The strength of this particular case is that our patient was receiving no pharmaceutical medications (other than non-prescription diphenhydramine) but only nutritional supplements and the CBD oil to control her symptoms. Her scores on the sleep scale and the anxiety scale consistently and steadily decreased during a period of 5 months (see Table 2). She

was ultimately able to sleep through the night most nights in her own room, was less anxious at school and home, and displayed appropriate behaviors. The patient's grandmother (her caregiver) reported: "My granddaughter's behaviors are definitely better being on the CBD. Her anxiety is not gone, but it is not as intense and she is much easier to be around. She now sleeps in her own room most of the time, which has never happened before."

Further study will need to be conducted to determine the permanency of our patient's positive behaviors and how long she will need to continue taking the CBD oil. We do not have a reasonable foundation to recommend dosing from the scientific literature. However, in our experience, this supplement given 12 mg to 25 mg once daily appears to provide relief of key symptoms with minimal side effects. Our patient did not voice any complaints or discomfort from the use of CBD. We routinely asked about headache, fatigue, and change in appetite or agitation in addition to conducting a routine psychiatric evaluation. Although CBD is considered generally safe,¹⁷ the long-term effects are yet to be studied.

The ultimate goal is to gradually taper her off the use of CBD oil and transition our patient into lifelong coping strategies such as yoga, meditation, and various other therapeutic activities. ❖

Marijuana and Medicine

Scientific data indicate the potential therapeutic value of cannabinoid drugs, primarily [tetrahydrocannabinol], for pain relief, control of nausea and vomiting, and appetite stimulation; smoked marijuana, however, is a crude [tetrahydrocannabinol] delivery system that also delivers harmful substances.

Access to cannabis

ABSTRACT

Background: The authorized and unauthorized use of cannabis for therapeutic purposes (CTP) has increased dramatically in recent years, and physicians have called for further research to better clarify the parameters of effective and appropriate use. We report findings from a large cross-sectional study of the use of CTP in Canada and compare use across medical conditions and across authorized and unauthorized users.

Methods: We examined cannabis use history, medical conditions and symptoms, patterns of current use of CTP, modes of access and perceived effectiveness among 628 self-selected Canadians consumers of CTP. Participants were recruited from medical cannabis dispensaries and from organizations that assist users of CTP.

Results: Patients reported using cannabis to treat multiple symptoms, with sleep, pain, and anxiety being the most common. Cannabis was perceived to provide effective symptoms relief across medical conditions. Patterns of use were also consistent across medical conditions. Notable differences were observed with regard to modes of access.

Conclusion: Across medical conditions respondents reported using cannabis to effectively address diverse symptoms. Results indicate a substantial disconnect between the therapeutic use of cannabis and research on the risks and benefits of such use; particularly with regard to the anxiolytic and sedative use of cannabis. Authorized and unauthorized users exhibited few meaningful differences with regard to medical conditions and patterns of use, but faced substantial differences regarding access.

Cannabis has a long history of medical use (Abel, 1980; Earleywine, 2005; Iverson, 2008), and after decades of marginalization the therapeutic properties of cannabis and cannabis derivatives are receiving increased attention (Earleywine, 2005; Holland, 2010; Lucas, 2008). Indeed, robust and growing evidence indicates that cannabis has medical benefits for diverse conditions and an acceptable risk profile (Joy, Watson, & Benson, 2003). In response to legal recognition of the constitutional rights of Canadians to access cannabis for therapeutic purposes (CTP), the federal government enacted the *Marihuana Medical Access Regulations* and

initiated a centralized program in 2001, and in 2003 Health Canada began to provide CTP to patients. This program authorizes two categories of individuals to possess cannabis for medical purposes; Category 1 includes symptoms associated with HIV/AIDS, arthritis, spinal cord injury or disease, cancer, epilepsy, or MS, whereas Category 2 includes other symptoms and conditions assessed by a physician and a specialist. Those authorized can purchase dried cannabis from Health Canada, can purchase seeds to grow cannabis, or designate a person to grow cannabis on their behalf. In addition, medical cannabis dispensaries that operate under an ambiguous legal status provide CTP and related services to over 50,000 patients across Canada (Lucas, 2008).

Despite widespread concern with the efficiency of the Health Canada program (Holland, 2010), registration has grown exponentially from under 500 registrants in 2002 to over 26,000 in 2012 (Health Canada, 2012a). National surveys indicate substantial access outside of the Health Canada program; recent estimates

E-mail addresses: zachary.walsh@ubc.ca (Z. Walsh), rojocal@yahoo.ca (R. Callaway), LynneB@cdnaids.ca (L. Belle-Isle), rielle@telus.net (R. Capler), bekindok@hotmail.com (R. Kay), plucas@uvic.ca (P. Lucas), susan.holtzman@ubc.ca (S. Holtzman).

suggest that 400,000 to 1,000,000 Canadians use CTP (Health Canada, 2011). Diverse reasons for use and multiple modes of access complicate the characterization of use of CTP, and health care professionals have expressed concern regarding the dearth of information on CTP; a recent Canadian Medical Association-sponsored survey reported that over 80% of physicians wanted more information on therapeutic indications, clinical guidelines, and risks and benefits of CTP (CMA, 2012).

Several studies have examined CTP use among Canadians. A regional survey reported that approximately 2% of adults used CTP in the past year, primarily to relieve nausea and pain (Braitstein et al., 2001), and a more recent national survey estimated that one million Canadians, or 4% of those aged 15 and older, used cannabis to treat self-defined medical conditions in the previous 12 months (Adlaf, Begin, & Sawka, 2005). Studies of persons living with HIV/AIDS report rates of 15–30% use of CTP, primarily for treatment of nausea, pain, and mood-related symptoms (Belle-Isle & Hathaway, 2007; Ware, Rueda, Singer, & Kilby, 2003). Studies of patients with MS and patients with chronic pain report similar results; approximately 15% of respondents report use of CTP with high levels of perceived effectiveness for diverse symptoms including nausea, pain, and mood (Belle-Isle & Hathaway, 2007; Ware et al., 2003; Clark, Ware, Yazer, Murray, & Lynch, 2004). Studies of CTP from the US, Europe, and Australia report findings that are consistent with those of Canadian studies; CTP is perceived to be an effective treatment for symptoms including pain, nausea, and negative mood (Grotenherman & Schnelle, 2003; Harris et al., 2000; Lucas, 2012; Reiman, 2007; Reinerman, Nunberg, Lanthier, & Heddleston, 2011; Swift, Gates, & Dillon, 2005; Ware, Adams, & Guy, 2005).

In sum, patient-centered research provides evidence for the acceptability and perceived effectiveness of CTP. However, substantial knowledge gaps remain and health care professionals have explicitly called for further research to better specify the parameters for appropriate use of CTP (CMA, 2012). Indeed, to date no studies have directly compared use of CTP across medical conditions or across modes of access (i.e., authorized vs. unauthorized). In the present study we report demographic characteristics, medical conditions and symptoms, reasons for use, perceived effects, and authorized and unauthorized modes of accessing CTP among Canadians. Comparing users of CTP across symptoms and across medical conditions with regard to patterns of use, and perceived effectiveness may help direct future controlled studies of the efficacy of CTP for specific conditions, and inform the development of tailored CTP regimens. In addition, comparing authorized and unauthorized CTP users may elucidate factors that underlie patient adoption of the Canadian CTP program, and help to guide the refinement of the complex process of CTP distribution and monitoring.

Method

Design

We obtained cross-sectional data in 2011–2012 from 628 self-selected current CTP users. Participants were recruited from two contexts; *national* participants completed the survey online from the location of their choice, and *local* participants completed the survey at a cannabis dispensary in the Interior region of British Columbia (BC). This recruitment strategy was designed to allow for comparison of the relatively less controlled online *national* condition with the confirmed CTP users queried in-person in the *local* condition. A total of 702 *national* participants completed the consent form, of whom 541 (77%) reported current CTP use. All 87 *local* participants who completed the consent form reported current CTP use. The *national* survey was promoted via organizations and media

^a $p < .01$.

that serve users of CTP patients (e.g., Canadian AIDS Society, Canadian Aboriginal AIDS Network, Cannabis Culture), and by national advertisements at MC dispensaries. To preserve confidentiality, no identifying data (i.e. IP addresses) were collected for *national* participants. The *local* group was comprised of dispensary members who were either authorized to possess cannabis through Health Canada or had documented confirmation of a medical condition for which CTP is indicated. No confirmation of medical condition was provided for *national* participants; however such confirmation is required to obtain Health Canada authorization and to obtain dispensary membership. Participants in the *local* group were compensated \$10 and were aided by research assistants; participants in the *national* group were not assisted or financially compensated.

The survey was designed to be completed in less than one hour, and consisted of a total of 414 adaptive questions administered online without forced response. The survey was organized hierarchically such that many items were contingent on prior responses; as a result, respondents were presented with diverse item sets and response rates for specific items, and total response times varied accordingly. The survey was developed based on previous research, and on consultations with a community research board comprised of CTP patients and experts, and includes questions drawn from a prior study of CTP use (Belle-Isle & Hathaway, 2007). It queried access, perceived effectiveness, patterns and history of cannabis use, medical diagnoses and symptoms, mood, and demographics (a copy of the survey is available upon request from the first author). The study was approved by the Behavioural Research Ethics Board of the Okanagan campus of the University of British Columbia. All categorical data were compared using χ^2 . In light of varying response rates across items, total number of responses is reported for each analysis. Due to the large number of comparisons all significance testing was conducted at the $p < .01$ level to minimize the likelihood of interpreting chance results while maintaining power (Nakagawa, 2004).

Results

Preliminary analyses

We compared the responses of *local* participants who reported residency in the province of BC and accessing CTP via

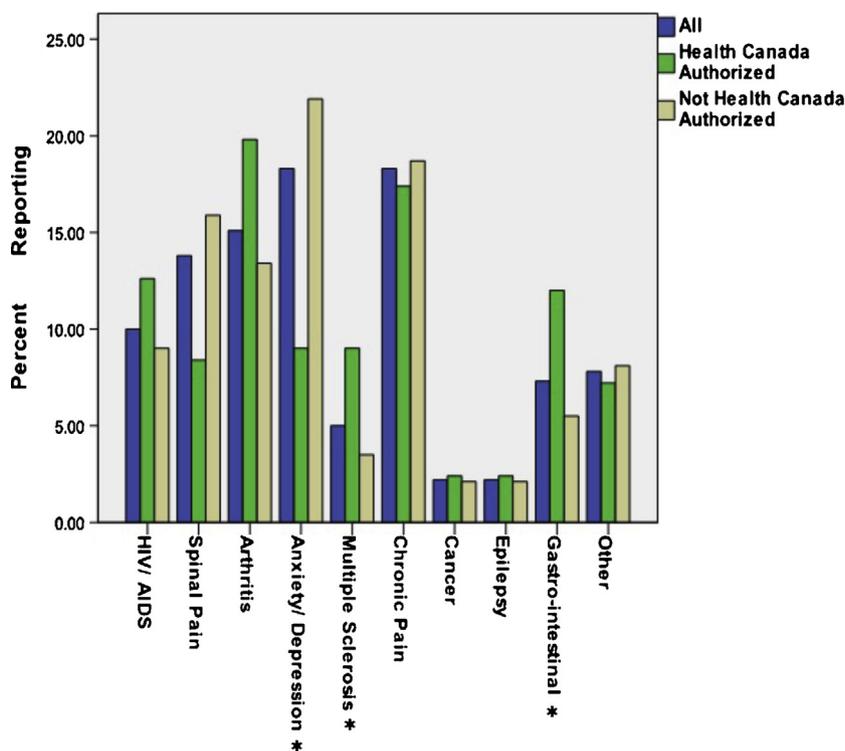

Fig. 1. Primary medical conditions treated with cannabis by authorization. *Note:* Sleep Disorders, Attention Deficit Disorder, Fibromyalgia, Hepatitis C, Parkinson’s Disease, Wilson’s Disease, Scleroderma, Tourette’s Syndrome, and unspecified Psychotic Disorder Conditions each comprised less than 2% of the sample and were aggregated into the category ‘Other’. The anxiety and mood disorders category included 35 participants who reported a primary *illness/condition* of anxiety, 34 who reported depression and 40 who reported both anxiety and depression. Comparisons of these groups indicated equivalent profiles with regard to demographic characteristics, health, and use of CTP, and were therefore aggregated for statistical analyses; $n = 502$ * = difference between proportion Health Canada Authorized and Unauthorized $p < .01$.

dispensary ($n = 63$) to *national* participants who reported BC residency and accessing CTP via dispensary ($n = 53$). Analysis indicated no differences with regard to quantity or frequency of cannabis use, and indicated substantial similarity with regard to primary medical condition; the only difference was a smaller proportion of *local* respondents reporting gastrointestinal (GI) condition as primary ($\chi^2 = 8.94 (1), p < .01$). This broad similarity between in-person confirmed users of CTP (i.e. *local*) and online respondents increased our confidence in the validity of online responses.

Demographics

Comparisons of the sample to values drawn from the Canadian 2006 Census of Population (Statistics Canada, 2006; Table 1) indicated that male, White, and Aboriginal participants were over-represented. The users of CTP were also younger, had a higher income, and were more likely to have completed high school. The regional distribution was consistent with participation in the Health Canada program (Health Canada, 2012b).

Medical conditions and symptoms

Participants were queried regarding a single primary *condition* treated with cannabis (Fig. 1). Participants also checked all applicable *symptoms* (Table 2) they treated with cannabis from a list. The mean number of symptoms patients endorsed treating was 6.74 ($n = 605$, $SD = 3.00$, Median = 6.00, Interquartile range = 4.00–8.00). Symptoms reportedly treated with CTP by fewer than 10% of the sample include high blood pressure (9%), tics (8%), regulating blood sugar (7%), seizures (6%), bladder dyscontrol (6%) and impotence (6%). Aggregate examination across *condition* indicated that pain, anxiety, and sleep problems were the most frequently endorsed

symptoms; 57% reported use to address all three symptoms, and 99% endorsed treating one or more of the three.

Symptoms treated with cannabis varied across *condition* (Table 2). Use to address pain symptoms was more prevalent among individuals whose primary conditions were pain-related (i.e., chronic spinal and non-spinal pain, arthritis). Chronic spinal pain participants were more likely to report treating muscle spasms. Participants with arthritis were more likely to report use for inflammation and ocular pressure, and less likely to report use to address anxiety and appetite. Participants who identified mood and anxiety disorders as their primary condition were more likely to use cannabis to address mental health-related symptoms (i.e., anxiety, depression, aggression, mania/psychosis), and were less likely to treat pain, inflammation, and muscle spasms. Participants who identified HIV/AIDS or GI as their primary conditions were more likely to treat symptoms of nausea and appetite, and HIV/AIDS was associated with less treatment of pain and aggression. Overall, cannabis was perceived to provide effective symptoms relief; 72% ($n = 439$) reported that CTP was *always* helpful and an additional 24% ($n = 147$) described it as *often* helpful. The proportion of participants who described CTP as *always* helpful was relatively consistent across conditions. The only difference across groups was relatively lower endorsement of *always* helpful (55%) by participants with HIV/AIDS ($\chi^2 = 10.04 (1), n = 593, p < .01$). Over half (57%, $n = 358$) of participants reported using other medications to address the symptoms they were treating with CTP. Of these, 79% ($n = 281$) described CTP as having fewer side effects than the concurrent treatment.

Use patterns

History of non-therapeutic cannabis use prior to therapeutic use was reported by 82% ($n = 441$) of participants.

^a p < .01.

Mean age was 17.30 years ($n=540$, $SD=7.08$, Median = 16, Interquartile range = 14.00–18.00) for first use and 28.35 years ($n=538$, $SD=11.25$, Median = 25, Interquartile range = 19.00–37.00) for first therapeutic use. Individuals with and without history of non-therapeutic use did not differ with regard to demographic characteristics, or conditions and symptoms. Most participants who reported prior use reported increased use with the initiation of therapeutic use; 33% reported a large increase and 32% a small increase, whereas 7% reported a large decrease and 10% a small decrease. Aggregate analyses indicated that 40% ($n=167$) of users fell into the modal quantity of use category of *more than 14 grams per week*, and that 42% ($n=226$) fell in the modal frequency of use group reporting *2–3 uses per day*. Among the group that used more than 14 grams per week, the median weekly amount used was 28 grams (Interquartile range = 21–45). Comparisons of the six medical conditions that each account for 5% or more of the sample (Table 3) indicated no difference with regard to modes of use and few differences in patterns of use; a larger proportion of individuals identifying HIV/AIDS as primary condition were among the groups with lowest quantity and frequency of use, and those who identified anxiety and/or depression as primary conditions were less likely to fall in the most frequent use group. Overall health quality was also associated with frequency of use such that participants who described their overall health as *fair* or

poor (34%, $n=161$) were overrepresented in the most frequent use group ($X^2=8.31$ (1), $n=473$, $p<.01$).

Access

Aggregate examination indicated that 32% ($n=167$) of respondents had Health Canada authorization to possess CTP. An additional 12% ($n=64$) had applications in process, and 3% ($n=13$) had applied and been rejected. The proportion of authorized individuals varied across condition (Fig. 1); individuals who identified anxiety and/or depression as primary condition were less likely to be authorized ($X^2=13.13$ (1), $n=502$, $p<.01$), whereas a greater proportion of MS ($X^2=11.08$ (1), $n=502$, $p<.01$) and GI ($X^2=8.68$ (1), $n=502$, $p<.01$) participants were authorized. Most participants reported using more than one mode of accessing CTP; the mean number of access modalities was 1.89 ($n=500$, $SD=.88$, Median = 2.00, Interquartile range = 1.00–2.00). Authorization was a determinant of access (Fig. 2); the mean number of access modalities for authorized individuals was 2.11 ($n=162$, $SD=.98$, Median = 2.00, Interquartile range = 1.00–3.00) compared to 1.78 ($n=337$, $SD=.81$, Median = 2.00, Interquartile range = 1.00–2.00) for unauthorized users ($F(1, 497)=16.26$, $p<.01$). Authorized users were more likely to access CTP via Health Canada ($X^2=11.88$ (1), $n=443$, $p<.01$), to grow for themselves ($X^2=31.42$ (1), $n=493$,

In contrast, unauthorized users were more likely to access CTP from a friend ($X^2 = 25.46$ (1), $n = 495$, $p < .01$) or from a stranger ($X^2 = 18.69$ (1), $n = 494$, $p < .01$).

Discussion

Canadians use cannabis to treat diverse conditions and symptoms in a manner that only partially overlaps with the federally authorized program. There is considerable consistency with regard to patterns of use and reported effectiveness; nearly all respondents used cannabis to treat pain, anxiety, or sleep disturbances, and over half used it to treat all three symptoms. We also observed consistency across participants with and without histories of non-therapeutic cannabis use, which suggests that, with regard to CTP, individuals who may enjoy non-therapeutic use of cannabis were not different with regard to therapeutic application of cannabis from those participants who may have been less likely to expect extra-therapeutic benefit. The substantial minority of respondents who were federally authorized to possess cannabis exhibited few differences from unauthorized users with regard to symptoms treated and patterns of use, but differed considerably with regard to mode of access.

Most respondents reported using CTP to treat conditions that are explicitly listed within the federal program; however, a large contingent also reported use for other conditions. Comparisons of symptoms treated across conditions indicated high levels of congruence (e.g., respondents with pain-related conditions were more likely to use cannabis to address pain symptoms), but also reflected substantial consistency across conditions. Specifically, use to treat sleep disturbances, and to a lesser extent anxiety and depression, was consistently high across conditions. However, despite widespread use for anxiolytic and sedative purposes, participants who reported anxiety or depression as primary reason for CTP use were less likely to have obtained federal authorization to access CTP. This may be due to the absence of these conditions among those explicitly listed by the federal program, but may also reflect accentuated stigma associated with the use of cannabis to address mental health issues. Indeed, stigma has been identified as a

substantial barrier to accessing care for mental health conditions such as depression and anxiety (Brown et al., 2010), and this may be compounded by the considerable stigma associated with use of CTP (Bottorff et al., 2013) to create a substantial barrier to accessing treatment. Research that further elucidates the appropriateness of using cannabis to treat anxiety and depression is required to guide effective treatment and help to reduce stigma.

Patterns of use were also consistent across medical conditions, with the only notable difference being slightly lower levels of use among respondents with HIV/AIDS, a difference which may be due to intermittent use to address nausea. Most participants reported initiating non-therapeutic use prior to use of CTP, and noted increased levels of use associated with the transition to therapeutic use. This reported increase is consistent with our observation that the median level of therapeutic use exceeds typical levels of non-therapeutic use (Reinarman, Cohen, & Kaal, 2004; Hazekamp et al., 2013; but see also Hazekamp & Heerdink, 2013), and suggests a potentially meaningful distinction between therapeutic and non-therapeutic use. In contrast, the relative consistency of use among CTP-users suggests that CTP regimens might transfer well across conditions, and enjoy good adherence. The most pronounced differences across respondents involved modes of access, such that unauthorized users were much less likely to access CTP from authorized, or semi-authorized (i.e. dispensaries) sources. This discrepancy contrasts with the pronounced similarity between authorized and unauthorized users on indicators of health and use of CTP, and suggests that the current system of authorization may not be discriminating among qualitatively different groups.

The primary limitations of this study are common to online medical surveys such as potential for multiple responses from a single respondent, a potentially unrepresentative sample, and lack of physician confirmation of medical conditions. In addition, response bias related to participant self-selection, and recruitment through organizations that support medical cannabis patients likely resulted in overrepresentation in our sample by individuals who respond favourably to CTP. In light of this potential bias, our characterization of the therapeutic use of cannabis should be interpreted with caution pending replication from research that employs a more systematic recruitment approach. However, these limitations are counterbalanced by several methodological

strengths including the inclusion of an in-person subsample, engagement of a community research board in the development and dissemination of the survey, and general adherence to established standards for reporting internet-based surveys (Eysenbach, 2004).

Conclusions

This was the largest and most comprehensive study to date of the therapeutic use of cannabis in Canada. We draw three primary conclusions from the data. First, reasons for use and perceived effectiveness were generally consistent across medical conditions; respondents overwhelmingly reported using cannabis to effectively address pain, sleep disturbance, and anxiety. Second, further research is required to address the substantial disconnect between the therapeutic use of cannabis and research on the risks and benefits of such use. This is particularly evident with regard to the anxiolytic and sedative use of cannabis; extrapolation from our sample to the national population of CTP users suggests levels of use for anxiolytic and sedative purposes that may be comparable to the number of Canadians who currently use benzodiazepine and other sedatives (Kassam & Patten, 2006). Such widespread use suggests a need for the systematic evaluation of the effectiveness and adverse effects of cannabis for the treatment of these conditions, as well as comparisons of cannabis with the widely-used pharmaceutical products that currently represent frontline treatments. Finally, our findings highlight the apparent discrepancy in access to cannabis across CTP users. Authorized and unauthorized users exhibit few meaningful differences with regard to medical conditions and patterns of use, but face substantial differences regarding access; many seriously ill Canadians risk increased stigma (Bottorf, Bissell, Balneaves, Oliffe, Capler & Buxton, 2013), legal sanction, and other negative outcomes associated with accessing cannabis from illegal markets. At the time of this writing the federal medical cannabis program is undergoing substantial structural changes. The present study provides a baseline for assessing the impact of these changes, the most important of which must surely involve providing a program that facilitates informed, safe, legal, and affordable access to a source of CTP for ill Canadians.

Acknowledgements

This research was supported by a grant from the UBC Institute for Healthy Living and Chronic Disease Prevention. The authors thank the people who took the time to respond to the survey. We would also like to thank Ben Atkinson, Kim Crosby and Megan Hiles for their contribution to data collection and management, and Brian Emerson for providing valuable feedback on the manuscript.

Is the medical use of cannabis a therapeutic option for children?

MJ Rieder, Canadian Paediatric Society, Drug Therapy and Hazardous Substances Committee. Is the medical use of cannabis a therapeutic option for children? *Paediatr Child Health* 2016;21(1):31-38.

Cannabis is a psychoactive compound with a long history of recreational and therapeutic use. Current considerations regarding cannabis use for medical purposes in children have been stimulated by recent case reports describing its beneficial effect with refractory epilepsy. Overall, there are insufficient data to support either the efficacy or safety of cannabis use for any indications in children, and an increasing body of data suggests possible harm, most importantly in specific conditions. The potential for cannabis as a therapeutic agent must be evaluated carefully for both efficacy and safety in treating specific paediatric health conditions. Smoking is not an acceptable mode of drug delivery for children. The use of cannabis for medical purposes in specific cases should not be construed as a justification for recreational cannabis use by adolescents. Recommendations for therapeutic use in exceptional paediatric cases are offered, always providing that this treatment course is carefully evaluated in individuals and in ongoing, well-designed research studies to determine safety and efficacy.

Key Words: *Cannabinoids; Children; Epilepsy; Medical marijuana; Nabiximols; Smoking*

Marijuana is a psychoactive substance prepared from the dried flowers and subtending leaves and stems of the female cannabis plant, usually *Cannabis sativa*, which is most commonly consumed by inhalation from smoking.(1) In contrast, cannabis refers to the various psychoactive preparations from the same plant, including marijuana but also hashish (derived from the resin of flowering somites) and cannabis oil. Cannabis has been used as a recreational drug for centuries and it is the most common illicit drug consumed in the world.(2,3)

The medical use of marijuana also goes back centuries. Marijuana was used for therapeutic purposes in China several millennia ago, with its first recorded use in a pharmacopeia appearing in 1500 BC. (4) Marijuana was customarily used to treat insomnia and as an antiemetic before the onset of specific therapies in the 1930s. Subsequently, marijuana has been labelled a drug of abuse in most countries worldwide. In Canada, marijuana was added to the restricted list under the Opium and Narcotic Drug Act by an amendment passed in 1923. Over the past two decades, there has been growing interest in the medical use of cannabis and its preparations in adults, along with increasing discussion around its potential for therapeutic use in children over the past five years.

The psychoactive properties of cannabis are primarily produced by delta-9-tetrahydrocannabinol (delta-9-THC), a cannabinoid

Le cannabis à des fins médicales est-il une option pour les enfants?

Le cannabis est une substance psychoactive utilisée depuis très longtemps dans un cadre récréatif et thérapeutique. Les considérations actuelles à l'égard de l'utilisation du cannabis à des fins médicales en pédiatrie découlent de récents rapports de cas sur son effet bénéfique lors d'une épilepsie réfractaire. Dans l'ensemble, les données sont insuffisantes pour en corroborer l'efficacité ou l'innocuité pour quelque indication que ce soit au sein de cette population, mais les données s'accumulent sur son potentiel néfaste, particulièrement pour traiter certaines affections. Il faut en évaluer soigneusement l'efficacité et l'innocuité comme agent thérapeutique contre certaines affections infantiles. L'inhalation sous forme de cigarette n'est pas un mode d'administration acceptable chez les enfants. L'utilisation de cannabis à des fins médicales dans des situations particulières ne doit pas en justifier l'utilisation à des fins récréatives chez les adolescents. Des recommandations sont formulées quant à son utilisation à des fins thérapeutiques dans des cas exceptionnels en pédiatrie, à condition d'assurer une évaluation étroite des sujets traités et de poursuivre des recherches bien conçues pour en déterminer l'innocuité et l'efficacité.

that is one of the two major neuroactive compounds found in marijuana.(5) The other major neuroactive compound, cannabidiol (CBD), lacks the psychoactive effects of delta-9-THC but does have behavioural and other central nervous system effects.(1) These compounds bind to G-protein coupled cannabinoid receptors on the membrane of cells in the central nervous system to produce their effects.(5)

NEW INFORMATION

Current status in Canada

Using marijuana for therapeutic purposes has included treatment for refractory epilepsy, described in case reports by Gowers and Reynolds from the late 19th century.(5) The development of more potent antiepileptic therapies and the trend toward marijuana prohibition reduced interest in marijuana as a therapy for refractory epilepsy. As time progressed, however, increasing knowledge of brain biology and the potent neuroactive properties of cannabinoids revived interest in its therapeutic potential. In 1996, California became the first American state to legalize the medicinal use of cannabis.(6) Several American states and the District of Columbia have subsequently legalized the use of cannabis for medical purposes, despite the United States Drug Enforcement Administration's designation of marijuana as a "schedule one"

Correspondence: Canadian Paediatric Society, 100-2305 St Laurent Boulevard, Ottawa, Ontario K1G 4J8. E-mail info@cps.ca, website www.cps.ca

drug, defined under statute as having “no currently accepted medical use and a high potential for abuse”. In Canada, medical use of marijuana was sanctioned by Health Canada in 2001, with revisions to the legislation in 2013 (www.gazette.gc.ca/rp-pr/p1/2014/2014-06-14/html/reg1-eng.php). Canadian patients can obtain access to cannabis for medical purposes by visiting a health care practitioner, who can provide documentation to present to a licensed producer, with licensure being regulated on a federal basis. The producer can then supply the patient with up to 30 days’ supply, to a maximum weight of 150 g of marijuana. A recent ruling by the Supreme Court of Canada and a subsequent response from Health Canada have effectively removed some restrictions on the form in which cannabis can be supplied to patients. These rulings should permit the therapeutic use of preparations such as specific cannabis oils.

Evidence supporting the therapeutic effect of cannabis in children with epilepsy is sparse. There are animal models demonstrating that delta-9-THC and CBD have anticonvulsant activity in animal models of epilepsy, with the caveat that some studies also demonstrated pro-convulsant activity in healthy animals.(5) In these models, tolerability was limited with respect to delta-9-THC due to psychotropic effects, while CBD was better tolerated. Overall, clinical evidence supporting the use of marijuana and other cannabis derivatives in children is very sparse. Individual case reports have been published; however, evidence tested in randomized or controlled trials is scant.(7,8) One recent Cochrane review identified four studies examining marijuana use for epilepsy.(9) A total of only 47 patients were studied, all of whom were adults. While these studies demonstrated short-term tolerance, no single study reliably demonstrated a reduction in seizure frequency. The authors concluded that the use of marijuana to treat epilepsy needed to be evaluated in properly designed and powered studies.

Much stronger data supports the limited efficacy of marijuana to treat other medical conditions. Studies investigating cannabis use to manage spasticity in adults with multiple sclerosis (MS) have shown that cannabinoids, administered orally, appear to reduce patient-reported spasticity scores, while smoked marijuana was of uncertain efficacy.(10) A similar result was obtained for central pain or painful spasms in adults with MS. There were fewer bladder complaints in adults with MS treated with nabiximols, one of three medications derived from cannabis and approved for use in Canada, although no effect was demonstrated using other oral cannabinoids. Cannabinoids also appeared to be ineffective for controlling tremors in adults with MS, chorea in adults with Huntington’s disease, levodopa-associated dyskinesia in adults with Parkinson’s disease or tics in adults with Tourette’s syndrome.(10)

Cannabis continues to be considered as a potential therapy in conditions for which there are, essentially, no data supporting its use. There have been no studies demonstrating the efficacy and safety of marijuana use to control children’s pain or nausea.(11)

Potent medications can be accompanied by significant, potentially adverse side effects. It is well recognized, for example, that many drugs commonly used for seizure therapy in children are also associated with negative effects on behaviour and learning. The most predictable side effects associated with marijuana use are red eyes, dry mouth, delayed motor skills and tachycardia;(12) however, reviews of the medical use of cannabis have also identified adverse events. A review of studies investigating marijuana use for selected neurological disorders demonstrated that 6.9% of 1619 patients treated with a cannabinoid for <6 months stopped use due to adverse events, compared with 2.2% of 1118 subjects in the control group.(10) While these effects were not well characterized,

they included nausea, weakness, mood changes and anxiety. Studies focused on cognitive impairment appeared to show twice the degree of cognitive impairment among patients treated with marijuana compared with controls.(10,13) Cannabinoid use in one randomized clinical trial involving patients with MS was associated with a higher suicide risk compared with placebo controls.(14) All of these studies involved adult patients. There is ongoing controversy regarding cannabis use being associated with a risk for serious mental health disorders such as psychosis. The data linking marijuana use with a higher risk for psychosis were highlighted in a recent study which demonstrated that up to one-quarter of cases of new-onset psychosis were associated with the recreational use of high-potency cannabis.(15,16)

There is a small body of literature suggesting that the magnitude of cognitive effects of cannabis may be age dependent. One small study focused on adolescents with attention deficit hyperactivity disorder who used marijuana regularly, and found an association with impaired executive function and, potentially, for impaired cognitive function when marijuana use was initiated before 16 years of age. When regular marijuana use was not started until after 16 years of age, there was no apparent aggravation of cognitive deficits associated with attention deficit hyperactivity disorder.(17) One neuroimaging study examining young adult recreational marijuana users showed differences in grey matter density, volume and shape compared with controls.(18) Chronic marijuana exposure is associated with adverse effects on the functional integrated relationship among spatially separated brain regions that may be exaggerated when exposure begins during adolescence.(12,19-21) While there are no data regarding the impact of cannabis use on the brains of younger children, it is probable that effects would be similar. Even these limited findings have implications for the medical use of cannabis in children.

In the context of recreational use, there are usually periods when the concentration of cannabinoids in the blood is low or minimal. In contrast, in a therapeutic context, such as using cannabis to manage intractable epilepsy, one goal would be to maintain a relatively constant concentration of cannabinoids in the bloodstream over time. Therefore, future research investigating cannabis use for medical purposes in children must include longitudinal developmental assessments, ideally with neuroimaging, and discussions about informed consent to participate in these studies need to include such considerations of effect. In conditions for which cannabis is used as a therapy of last resort, there should be a robust and complete discussion with the patient (when possible) and the family regarding the potential risks and benefits. The therapeutic course must be monitored closely for evidence of both efficacy and toxicity.

In common with many other potent psychotropic agents, marijuana use is associated with risk for dependence.(22) Risk levels range between 9% and 50% among recreational marijuana users and appear to be higher when marijuana use begins in adolescence and occurs on a daily basis.(21) Discontinuation of cannabis among chronic users is commonly associated with withdrawal symptoms including headaches, sleep disruption, irritability and anxiety.(23)

One issue germane to marijuana use for treating children is that it is usually smoked. There are several compelling reasons why smoking is an unacceptable drug delivery system for younger populations. Combustion produces tars and other by-products known to be associated with long-term harmful effects, most notably carcinogenesis. The delivery of drugs by smoking also makes it difficult to control or adjust dosage. This difficulty is especially relevant in that the THC content of marijuana available today is two to four times higher than from typical plants used decades ago.(21,24) There is

also considerable variability in THC content batch-to-batch.(21) Should cannabis be demonstrated to be an effective and safe therapy for selected health conditions in children, a more appropriate and stable dosing form other than smoking should be used. Recent rulings governing the availability of cannabis for medical purposes in Canada could open the way for other formulations.

As with other psychoactive agents, being able to demonstrate the efficacy and safety of cannabis use for medical purposes in thoughtfully designed, carefully monitored therapies for selected conditions in children is neither a rationale for, nor supportive of, the recreational use of marijuana by children or adolescents. One recent study from the United States that compared marijuana use in adolescents in states where cannabis for medical purposes was available with states where it was not, found there was no increase in recreational use where it was legal.(25) In contrast, a study in Colorado – where cannabis use for medical purposes is available – tracked attitudes toward and trends in marijuana use among adolescents, and demonstrated both lower risk-perception and a higher rate of marijuana use among 12- to 17-year-olds, compared with states where it was not available.(26) The same research group described a significant increase in motor vehicle fatalities where marijuana use was a factor following the legalization of marijuana for medical purposes in Colorado.(27)

If and when cannabis is proven to be therapeutically efficacious and safe, it must be regulated with the same care and precision as other psychoactive therapeutic agents.(28,29) The “medical marijuana” industry must also be subject to the same regulatory standards, legislative controls and degree of oversight as the pharmaceutical industry. Consideration of the particular safety issues germane to children must remain front and centre in the decision to treat exceptional paediatric cases.(30)

RECOMMENDATIONS

- While anecdotal evidence and biological plausibility suggest that cannabis and its derivatives may be an effective treatment for refractory epilepsy in children, its efficacy in this population should be carefully evaluated over the long-term, using appropriately supported and well-designed research into developmental effects, including neuroimaging (level of evidence: 4).(31)
- Medical evidence and biological plausibility suggest that therapeutic use of cannabis may have significant adverse effects in children. Risks should be carefully evaluated over the long-term, using appropriately supported and well-designed research into the safety issues specific to children,

including development and neuroimaging studies (level of evidence: 3).

- Smoking as the customary mode of delivery for marijuana is unacceptable in children for several reasons. Studies investigating cannabis use for medical purposes in children should explore alternative delivery systems to provide safe and consistent drug concentrations (level of evidence: 3).
- While research is ongoing, the use of cannabis for medical purposes in children should be evaluated on a case-by-case basis, and always with a comprehensive discussion of potential benefits and risks. Treatment plans that include cannabis should be constructed with careful attention to dose-finding, evaluation of efficacy and safety monitoring, and should only be conducted by clinicians or health teams with condition-specific expertise and the ability to assess for, and evaluate, both efficacy and toxicity (level of evidence: 4).
- Using cannabis to treat neurological conditions in children should be evaluated in accordance with a careful research strategy. The decision to study cannabis use for a specific condition should always be based on the biological plausibility of efficacy and on evidence determined by well-designed clinical trials (level of evidence: 4).
- Clinicians who treat children with cannabis should have specific expertise and training in the use of potent psychoactive drugs in this population. Treatment should be predicated by robust discussions with the patient (if possible) and family concerning the goals and potential risks of this choice, with a strong monitoring strategy in place to test for efficacy and adverse effects.
- There is biological plausibility that cannabis may produce harm if used to treat certain conditions in children, especially when started at an early age (level of evidence: 4).
- The selective use of cannabis for medical purposes in children must not be confused with condoning its recreational use by adolescents. Strategies to discourage its recreational use among adolescents should be developed on models underway to discourage alcohol and tobacco use in this age group (level of evidence: 3).

Abstract

Background: Cannabis, in herbal form, is widely used as self-medication by patients with diseases such as HIV/AIDS and multiple sclerosis suffering from symptoms including pain, muscle spasticity, stress and insomnia. Valid clinical studies of herbal cannabis require a product which is acceptable to patients in order to maximize adherence to study protocols.

Methods: We conducted a randomized controlled crossover trial of 4 different herbal cannabis preparations among 8 experienced and authorized cannabis users with chronic pain. Preparations were varied with respect to grind size, THC content and humidity. Subjects received each preparation on a separate day and prepared the drug in their usual way in a dedicated and licensed clinical facility. They were asked to evaluate the products based on appearance (smell, colour, humidity, grind size, ease of preparation and overall appearance) and smoking characteristics (burn rate, hotness, harshness and taste). Five-point Likert scores were assigned to each characteristic. Scores were compared between preparations using ANOVA.

Results: Seven subjects completed the study, and the product with highest THC content (12%), highest humidity (14%) and largest grind size (10 mm) was rated highest overall. Significant differences were noted between preparations on overall appearance and colour ($p = 0.003$).

Discussion: While the small size of the study precludes broad conclusions, the study shows that medical cannabis users can appreciate differences in herbal product. A more acceptable cannabis product may increase recruitment and retention in clinical studies of medical cannabis.

Background

It is now well-recognized that *Cannabis sativa* (marijuana, weed, pot) is being used by patients with chronic debilitating diseases such as HIV/AIDS [1], chronic non-cancer pain [2], epilepsy [3], multiple sclerosis [4] and amyotrophic lateral sclerosis [5] for the management of symptoms such as pain, nausea, poor sleep, anxiety and stress. Since 2002, cannabis for medical use has been produced

by Prairie Plant Systems Inc (PPS) under license to Health Canada [6]. Cannabis is cultivated for use in clinical trials, open-label safety studies [7], and for distribution to persons authorized under the Medical Marijuana Access Regulations (MMAR) to use marijuana for medical purposes [8]. A number of authorized persons using this product initially reported concerns about the product, include the dryness, grind size (defined as the size of the particles after

grinding raw herbal material), and tetrahydrocannabinol (THC) content of the cannabis material [9].

To improve the acceptability of the cannabis product provided to patients and to facilitate recruitment and retention of research subjects in clinical trials, Health Canada and PPS explored mechanisms to vary herbal cannabis products with varying levels of humidity, THC content, and grind size. This study was conducted to evaluate several herbal cannabis presentations in which dryness, grind size and THC content were varied. The aims of the study were to determine experienced users' preference for cannabis products, and to determine whether there was any consistent pattern towards a preferred product.

Methods

A randomized, double-blind study of cannabis products was undertaken over a six week period in June-July 2004. Subjects were all current holders of valid authorizations to possess cannabis under the Medical Marijuana Access Regulations, and were currently using cannabis for medical purposes. Subjects agreed not to drive to or from their scheduled appointments.

Four (4) different PPS preparations of *Cannabis sativa* were evaluated; an identical species was used for all preparations. THC content was varied by blending the flowering heads with leaves from lower down the plant. The product was milled using a dry conical mill (Quadro® Comill®, Waterloo, Ontario), with particle size varied using screens with circular holes of 5 or 10 mm diameter. Cannabis preparations were packaged at PPS in 30 gram bags and labeled as Presentation # 1 to Presentation # 4 prior to shipment to the site pharmacy. The site pharmacist weighed 1 g quantities of each preparation (LP 3200D scale, Sartorius, Canada). The drug was repackaged in plastic vials closed with a soft plastic/rubber top, which were then dispensed to the study nurse as needed on the days of use. The product was weighed and transferred from the original package to the dispensing container within 5 minutes, and the ambient temperature and humidity conditions in the pharmacy were recorded at the time of preparation (Digital Hygrometer DHM-010, Davidoff, Canada). The original package was resealed immediately after weighing the required amount of product.

The characteristics of the products were determined using a specially designed questionnaire. Items consisted of 5-point Likert scales and included physical characteristics (smell (0: very unpleasant; 4: very pleasant), humidity (0: unacceptably dry; 4: optimum humidity), appearance (0: looks very bad; 4: looks excellent), particle size (0: very poor, 4: excellent), colour (0: very poor, 4: excellent) and ease of preparation (0: very hard to use; 4: very easy to use) and smoking characteristics (hotness (0: very hot; 4:

very cool), harshness (0: very harsh; 4: very smooth), burn rate (0: burns too fast; 4: burns just right), and taste (0: worse possible taste; 4: best possible taste). An overall comparison to usual cannabis was made (0: much worse than usual cannabis; 4: much better than usual cannabis). A global assessment was performed on the final day at which subjects were asked to rank the products assessed in order of preference (0: worse; 4: best). Subjects were not asked about clinical parameters such as efficacy.

Eligible subjects were given a scheduled series of 4 appointments. Informed consent was signed at the first appointment. The subjects were randomly assigned to test one cannabis preparation per day over the four days. They were asked to assess physical characteristics of the drug prior to use. They were asked to prepare and use the cannabis in the manner to which they were accustomed. Within five minutes of use they were asked to comment on the harshness, hotness, burn rate and comparison with usual cannabis. Subjects remained in the cannabis laboratory for one hour after use before being allowed to return home by taxi. On the evening after each clinic visit the subjects were contacted at home by the research nurse to determine if they had additional comments or concerns regarding the product they evaluated that day.

It was estimated that recruiting 8 subjects would allow a basic and preliminary assessment of trends in perceptions of differences between product characteristics. This number of subjects was also feasible to recruit within the time period of the study. The data were double entered and validated in a dedicated and secure database. Data were entered without identifiers to protect confidentiality. Cannabis preparations were ranked according to user preferences on each item. All items were rated equally. A total rank score for each preparation was assigned. Ranks according to individual physical and smoking characteristics were examined. All statistical analyses were done using SAS (SAS Institute, North Carolina). Means, frequencies and a multiple analysis of variance (ANOVA) for cross-over design (proc mixed) were calculated to assess the comparison between products. Period effect was analyzed independently. Due to the small sample-size, no adjustments were made for multiple comparisons.

The study was conducted at a dedicated cannabis research laboratory at the Montreal General Hospital in the McGill University Health Centre (MUHC). The study was approved by the Research Ethics Committee of the McGill University Health Centre.

Results

Eight subjects were recruited for the study. No subject refused to participate, but one subject did not attend for the final visit and was excluded from the final analysis.

Therefore the final report is based on seven subjects who completed the study. Inclusion of the eighth subject in a limited analysis did not alter the overall direction of the results. The period effect could not be assessed in the main model because one subject missed one visit; however no overall differences were found on overall comparison of the four time periods.

There were 5 males and 2 females, and the mean age was 47 years (range 40–54 y). Diagnoses were varied and included peripheral neuropathic pain (4 subjects), multiple sclerosis (2 subjects), and HIV/AIDS (1 subject).

The overall results based on the Likert scores for each characteristic and the overall scores are shown in Table 1. Product 1 (10.6% THC, 14.4% humidity, 10 mm grind size) was the most well rated product, and significant differences were noted between products overall ($p = 0.03$), and for physical characteristics including general appearance ($p = 0.03$) and colour ($p = 0.03$).

Of the 28 different assessments (7 subjects using 4 products), 18 were performed using joints and 10 using pipes. Most assessments (93%) were done with subjects reporting using the same amount of cannabis as usual, and 16/18 stated no problems in preparing their joints. Product 4 received a poor rating in terms of problems rolling it by 2 subjects.

Physical characteristics

Product 2 was treated as having the best smell with 6 subjects rating it pleasant or very pleasant. Product 2 was also rated as the best humidity with 6 subjects rating it acceptable. In general appearance, product 1 was superior; 4 subjects rated product 3 as 'looks bad'. Products 1, 2 and 3 were rated similar in terms of ease of preparation, although all 7 subjects rated products 1 and 2 as easy or very easy to use. Products 1 and 2 were rated equally in terms of colour. Product 1 was rated best in terms of particle size with 5 subjects rating particle size as good or excellent.

Smoking characteristics

Product 3 was rated most 'cool' overall. Product 2 was rated highest in terms of harshness with 6 subjects rating it as moderate or smooth. Product 1 was rated as having the best burn rate (1 subject stated it 'burned just right'), while each of products 2, 3 and 4 were rated by one subject each as burning too fast. Product 2 was rated as having the best overall taste.

Global assessments

Fourteen out of 28 (50%) subjects rated products 1, 3 and 4 as 'worse than their usual cannabis', 11 assessments were the 'same as usual cannabis' (4 of which were for product 2). Only 3 assessments were 'better than usual cannabis' (products 1, 2 and 4). Globally, product 1

Table 1: Evaluation of four cannabis preparations by physical and smoking characteristics*

Characteristic	Product				p-value	Contrasts
	1	2	3	4		
<i>Cannabis preparation</i>						
THC (g%)	10.6	10.6	6.6	9.6		
Humidity (%)	14.4	12	11	11		
Drying time (days)	2	4	4	4		
Grind size (mm)	10	5	5	10		
<i>Physical</i>						
Smell	2.71	3.00	2.57	2.43	0.21	
Humidity	1.71	1.86	1.71	1.14	0.28	
General appearance	2.71	2.29	1.43	1.86	0.03	1>3,4
Ease of preparation	3.29	3.14	3.29	2.86	0.55	
Colour	2.71	2.71	2.00	2.43	0.03	1,2>3
Particle size	2.86	2.43	1.57	1.86	0.06	
<i>Smoking</i>						
Hotness	1.86	1.86	2.14	1.86	0.81	
Harshness	2.14	2.14	1.43	1.71	0.53	
Burn rate	2.57	2.29	1.86	2.00	0.55	
Taste	2.00	2.14	1.29	2.00	0.41	
TOTAL SCORE	24.57	23.86	19.29	20.14	0.03	1,2>3,4

*Characteristic scores based on 5-point Likert scales (0–4). Higher scores reflect better ratings for each characteristic. See text for details.

received the highest score in terms of all the product characteristics measured (Table 2). In this overall analysis, product 1 was superior to products 3 and 4, and product 2 was superior to product 3.

Of the products tested, over half (4/7) of those using products 1 and 2 would use it on a regular basis, and over half would not use products 3 (5/7) and 4 (5/6) on a regular basis. In terms of overall satisfaction, 3 subjects rated product 1 as good or excellent and 2 subjects rated the other products as good or excellent. Five subjects rated product 3 as poor, and one rated product 2 as very poor.

Ambient humidity and temperature

The drug samples were prepared the day before the visit for the first 5 patients, resulting in the drug being in the new container for 16 to 20 hours. For the last 3 patients, the drug spent from 6 to 17 days in the new container. Temperature and humidity measurements were taken in the pharmacy on 14 days over the 28 day period. Over this period, the mean room temperature was 22.4°C (SD 0.23), and the mean ambient humidity was 46% (SD 4.4).

Discussion

To our knowledge, this is the first ever evaluation of medical cannabis products for physical and smoking characteristics by authorized patients. We have shown that subjects may appreciate differences between cannabis preparations on the basis of physical characteristics of the herbal material, specifically general appearance and colour. We did not show differences in individual smoking characteristics, but overall impressions confirmed that subjects favoured higher THC content, higher humidity and larger grind size.

The results of this study must be interpreted with considerable caution as there are many limitations to the data obtained. The small sample size reduces the power of the study to reach definitive conclusions about patient preference. The detected differences between products could have arisen by chance, or may have been influenced by other factors such as the use of different modes of administration (pipes and joints). Further study should limit the modes of administration to reduce confounding by these factors.

The effect of room air on the humidity levels of the product is a factor which may affect the validity of the final results. The average ambient humidity at the time of product preparation was well above that of the original product specifications (46% versus 10–15%), and could have raised the humidity of the product during the storage period prior to use. This would have the effect of reducing or eliminating the potential differences between products on humidity-based assessments. This may partially

explain why differences in physical characteristics such as colour, particle size and general appearance were detected (Table 2), while the hotness, harshness and burn rate appeared to be rated similarly between products.

Subjects' evaluations of smoking characteristics of the samples immediately after use may have been influenced by the psychoactive effects of cannabis. This study recruited experienced medicinal cannabis users who would likely evaluate any cannabis product under similar conditions ('try it and see') so we feel our approach is pragmatic and relevant.

The subjects and investigators were initially blind to the characteristics of the allocated products, but the ability of the subjects to differentiate the products suggests that the blinded condition was compromised. The investigators (study nurse or physician) did not evaluate their own ability to differentiate the products

In spite of these potential limitations, this randomized double-blind study has found that two of these products (products 1 and 2) could be appreciated differently from the other two, in terms of their physical and smoking characteristics. Product 3, which was a 10% THC blend (expiry date June 2004) which had been originally shipped by Health Canada to authorized patients was rated poorly by the subjects in this study, suggesting that the product could be improved by changing physical characteristics such as blending, particle size and humidity. These changes may result in improved patient satisfaction with the product, which may in turn increase the number of patients willing to use the Health Canada product and improve compliance in long term studies using the product. The study results support a decision by Health Canada, made prior to the study in May 2004, to distribute a product made only of flowering head material, taking into account preliminary reports from authorized users, with larger grind size, higher humidity and higher THC content. A review of Health Canada statistics [10] suggests that use of the Health Canada product increased since the new product was shipped in the summer of 2004 (Figure 1). An initial delay in uptake may have been due to media reports from disgruntled users about the poor quality of the product [11].

This study should ideally be repeated with larger numbers to validate differences between products. The reliability of the subjects' reports may also be validated by repeating the test with the same subjects and products to see if there is reliability between their assessments over time. Future studies of the effect of humidity could be done with subjects removing cannabis directly from an unopened original package prior to use rather than going through pharmacy dispensing. Methods of rehumidification of

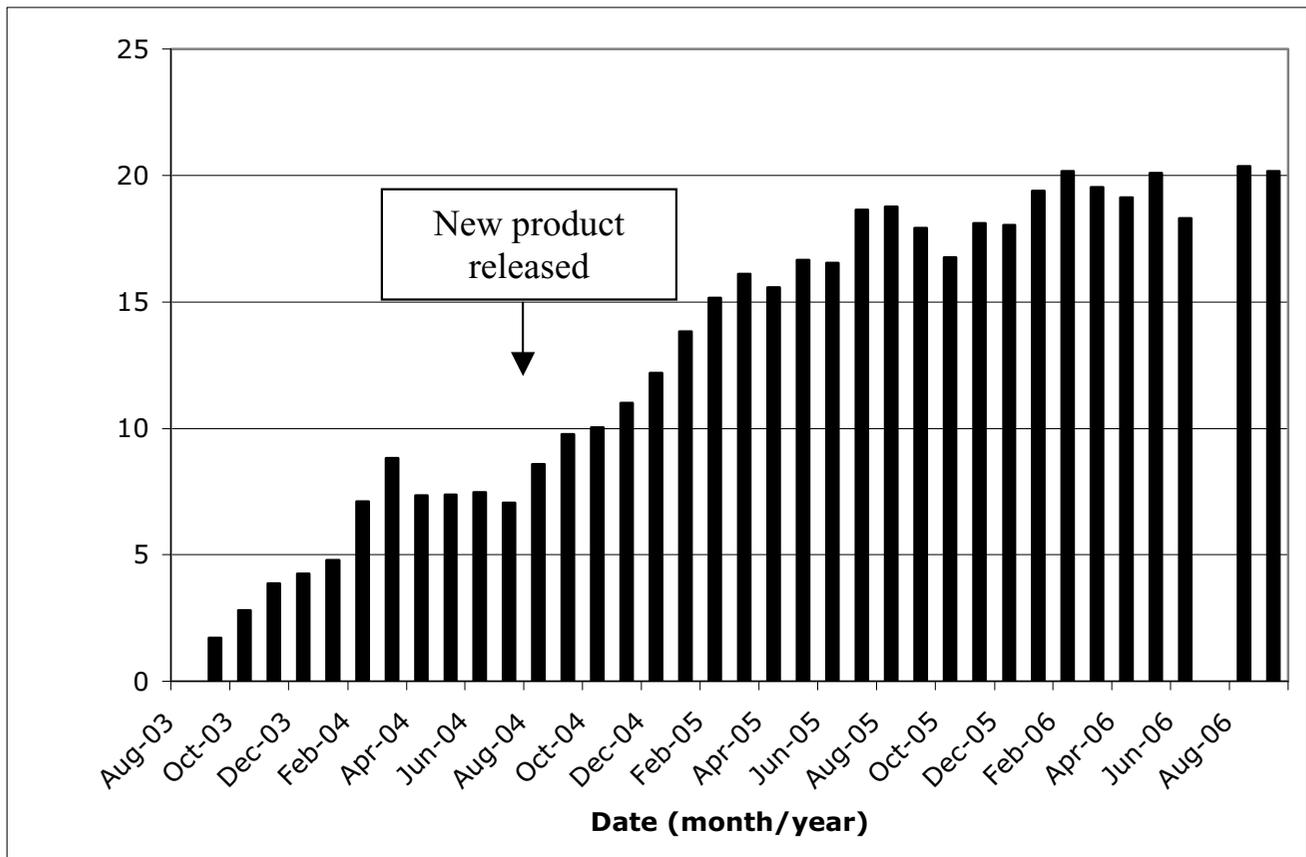

Figure 1
Percentage of authorized users obtaining herbal cannabis from Health Canada (data to Sept 2006)¹⁰.

herbal material should be explored. Finally, this study design may also be used to detect differences between cannabis products with different cannabinoid profiles or phenotypic characteristics.

Conclusion

We have shown that medical cannabis users may discriminate between cannabis preparations based on physical characteristics such as humidity, grind size, and smoking characteristics. The supply of a standardized herbal cannabis product within a legal medical access program needs to be guided by user's feedback to ensure compliance. Further work is required on other characteristics such as the profile of cannabinoids and other constituents.

Authors' contributions

The study was designed and supervised by Dr. Mark Ware, who prepared the final report and who is responsible for the work. Study management, including coordination, data collection, data entry and statistical analysis, was provided under subcontract to Boreal Primum Inc.

Competing interests

Dr Ware has received speakers fees, honoraria and grant support from companies developing cannabinoid products (AstraZeneca, Bayer, Cannasat, GW Pharma, Solvay and Valeant).

Acknowledgements

The study authors wish to thank the patients for participating in the study and providing their valuable time and interest in the project, the study nurses and pharmacists for their enthusiastic participation. We acknowledge the support of the Office of Controlled Substances and the Office of Cannabis Medical Access, Health Canada. The study was funded through a research contract agreement between the MUHC Research Institute and Health Canada. We are grateful to Suzanne Desjardins for her critical review of the manuscript.

ABSTRACT

Background: While neuropsychological deficits have been reported in healthy individuals who use street cannabis, data in patients with multiple sclerosis (MS) are lacking. Given that MS is associated with cognitive deterioration, the aim of this study was to determine the neuropsychological effects of cannabis use in this population.

Methods: Two groups, each of 25 patients with MS (cannabis users and nonusers), were administered the Minimal Assessment of Cognitive Function in MS battery of neuropsychological tests, the Hospital Anxiety and Depression Scale (HADS), and the Structured Clinical Interview for the DSM-IV Axis I Disorders (SCID-I). Group-matching and regression analysis were used to control for the effects of age, sex, education, premorbid intelligence, disability, and disease course and duration on cognitive function.

Results: Cannabis users performed significantly more poorly than nonusers on measures of information processing speed, working memory, executive functions, and visuospatial perception. They were also twice as likely as nonusers to be classified as globally cognitively impaired. There were no between-group differences on the HADS measures of depression and anxiety or lifetime SCID-I psychiatric diagnoses.

Conclusion: This cross-sectional study provides empirical evidence that prolonged use of inhaled or ingested street cannabis in patients with MS is associated with poorer performance on cognitive domains commonly affected in this population. Whatever subjective benefits patients may derive from using street cannabis (e.g., pain and spasticity relief) should be weighed against the associated cognitive side effects. *Neurology*® 2011;76:1153-1160

GLOSSARY

ANART = American National Adult Reading Test; **BVMT-R** = Brief Visuospatial Memory Test-Revised; **COWAT** = Controlled Oral Word Association Test; **CVLT-II** = California Verbal Learning Test-Revised; **D-KEFS** = Delis-Kaplan Executive Function System; **EDSS** = Expanded Disability Status Scale; **HADS** = Hospital Anxiety and Depression Scale; **JLO** = Judgment of Line Orientation; **MACFIMS** = Minimal Assessment of Cognitive Function in MS; **MFIS** = Modified Fatigue Impact Scale; **MS** = multiple sclerosis; **PASAT** = Paced Auditory Serial Addition Test; **SDMT** = Symbol Digit Modalities Test; **SCID-I** = Structured Clinical Interview for the DSM-IV Axis I Disorders.

Cannabis research in patients with multiple sclerosis (MS) has largely focused on synthetic derivatives of the drug. The clinical trials literature is small and suggests treatment may have some mildly beneficial effects particularly in alleviating pain¹ and bladder dysfunction,² but equivocal benefits for spasticity.³ The only clinical trial specifically focused on cognition as the primary outcome measure failed to find any cognitive deficits associated with use of a cannabis-based extract.⁴

Even less attention has focused on inhaled “street” cannabis. Data show that 36%–43% of patients with MS have at some time smoked cannabis.^{5,6} The figure for current use, 14%–18%, is more modest, but indicates that a substantial minority of patients with MS find cannabis helpful for relief from pain, spasticity, insomnia, bladder problems, tremors, and emotional distress.^{5,6}

Study funding: Supported by the Multiple Sclerosis Society of Canada.

Disclosure: Author disclosures are provided at the end of the article.

The benefits reported above are, however, subjective, and whether they are offset by potentially adverse cognitive effects has yet to be determined. A single pilot study suggested that MS cannabis smokers had further compromise with respect to information processing speed compared to nonusers.⁷ Given that approximately 40%–60% of patients with MS are cognitively impaired to begin with,^{8,9} any drug that may add to this burden gives cause for concern. The purpose of our study, therefore, was to examine the neuropsychological effects of inhaled or ingested cannabis on cognition in patients with MS.

METHODS **Sample selection.** Patients between the ages of 18 and 65 with confirmed MS¹⁰ were recruited from tertiary care MS clinics affiliated with the University of Toronto. Exclusion criteria included history of traumatic brain injury, psychotic illness, concurrent neurologic diseases, and poor visual acuity (less than 20/70 corrected, both eyes). Those who had undergone neuropsychological testing within the last year were also excluded in order to avoid possible practice effects.

Cannabis sample. Subjects who used cannabis recently and whose urine tested positive for cannabinoids only (i.e., no other illicit drugs were permissible) on the day of assessment were included. Subjects who reported cannabis use less than 12 hours prior to testing were excluded.

In addition, a history of cannabis use including age at onset, duration, and frequency of cannabis use was recorded for all subjects. The reasons for smoking cannabis were divided into 3 categories: medical, recreational, or a combination.

Control sample. MS cannabis users were group-matched (on age, sex, Expanded Disability Status Scale [EDSS], disease course and duration, level of education, and premorbid IQ based on the American National Adult Reading Test [ANART]) to a control group of 25 noncannabis-using patients with MS derived from a larger control sample of 38 cannabis-naïve subjects with MS. The control group was made up of subjects with MS who reported no recent history of cannabis use and had urine that tested negative for cannabinoids and other illicit drugs. A remote history of occasional teenage use was not an exclusionary factor.

Urinalysis. A broad-spectrum analysis was conducted to determine the presence of the following substances: cannabis, cocaine, opiates, amphetamines, and phencyclidine. The cannabinoid assay detects 11-nor- Δ -9-tetrahydrocannabinol-9-carboxylic acid-B glucuronide (THC-COOH glucuronide) and 11-nor- Δ -9-tetrahydrocannabinol-9-carboxylic acid (THC-COOH) in urine. These levels are combined to provide a composite score.

Demographic and neurologic data. Demographic and disease-related variables, namely age, sex, education, marital or partner status, employment status, disease course, disease duration, and current medications were collected from each patient and their medical charts. Neurologic disability according to the EDSS¹¹ was recorded from patient files. Alcohol consumption referred to the total number of drinks (a glass of wine, shot of spirits, or standard bottle [330 mL] of beer) consumed weekly. Visual acuity was assessed using the Rosenbaum Pocket Screener.

Psychiatric assessment. The presence of lifetime psychiatric disorders was established using the Structured Clinical Interview for DSM-IV Axis I Disorders (SCID-I), Mood and Anxiety Disorder sections.¹² In addition, all subjects completed the Hospital Anxiety and Depression Scale (HADS), validated for use with patients with MS.¹³ Fatigue was measured using the Modified Fatigue Impact Scale (MFIS).¹⁴

Neuropsychological assessment. Premorbid intellectual functioning was assessed with the ANART.¹⁵ Thereafter, patients were administered the Minimal Assessment of Cognitive Function in MS (MACFIMS), a comprehensive battery of 7 tests measuring 11 cognitive indices considered optimum for teasing out deficits in this population.¹⁶ The MACFIMS is regarded as the gold standard for cognitive assessment in MS and was put together by consensus following a meeting of leading neuropsychologists involved in MS research.¹⁷ The battery includes the following tests: verbal learning and memory: The California Verbal Learning Test–Revised (CVLT-II)¹⁸; visuospatial memory and learning: Brief Visuospatial Memory Test–Revised (BVRT)¹⁹; visual perception/spatial processing: the Judgment of Line Orientation (JLO)²⁰; verbal fluency/word retrieval: the Controlled Oral Word Association Test (COWAT)²¹; executive functions: the Delis-Kaplan Executive Function System (D-KEFS) Sorting Test²²; information processing speed and working memory: the Paced Auditory Serial Addition Test (PASAT)^{8,23} with 3.0- and 2.0-second interstimulus intervals; information processing speed: the Symbol Digit Modalities Test (SDMT).²⁴

As specified in the MACFIMS validation data,¹⁷ global cognitive impairment represents failure on 2 or more of 11 cognitive indices. Impairment on a single test is defined as a z score of 1.5 or more below norms derived from age-, sex-, and education-matched healthy control subjects. These normative data are provided in the test manuals.

Statistical analyses. Primary analysis included between-group comparisons with t tests and χ^2 analyses. The Mann-Whitney U test was used for non-normally distributed variables.

Further cognitive comparisons between cannabis users and nonusers were performed with a series of linear regression analyses, with each of the 11 cognitive indices as the dependent variable and cannabis use as the independent variable. Age, sex, education, EDSS, alcohol consumption, depression, anxiety, and fatigue were entered sequentially into the analysis as covariates. These variables were selected due to their potential effects on cognition. Only covariates that changed the group coefficient by 10% or more were retained in the final model for each cognitive measure.

Similarly, binary logistic regression analysis was conducted to investigate the effect of cannabis use on global cognitive impairment after controlling for the potential confounds mentioned above. As before, only covariates that changed the group coefficient by 10% or more were retained in the final model.

Pearson correlations were conducted to determine the association between age at onset of cannabis use, duration of cannabis use, and urine cannabinoid levels on the one hand and global cognitive impairment on the other. χ^2 Analysis was used to determine the association between duration of abstinence (12–24 hours vs greater than 24 hours) and global cognitive impairment.

Standard protocol approvals, registrations, and patient consents. Ethics approval for the study was obtained from Research Ethics Boards at Sunnybrook Health Sciences Centre and St. Michael's Hospital, both affiliated with the University of To-

Table 1 Demographic and neurologic variables for MS cannabis users and nonusers

Sample characteristics	Cannabis users	Nonusers	t or χ^2	p
Age, y, mean (SD)	43.6 (11.7)	43.6 (9.8)	t = 0.000	1.000
F/M	11/14	12/13	$\chi^2 = 0.081$	0.777
Education, y, mean (SD)	13.5 (2.8)	14.6 (2.8)	t = -1.482	0.145
ANART, mean (SD)	108.6 (9.7)	112.5 (7.1)	t = -1.581	0.120
Employment status, n (%) currently employed	7 (28.0)	14 (56.0)	$\chi^2 = 4.023$	0.045

ronto. All participants provided written informed consent prior to participating in the study. Patients were clearly informed of the aim of the study, namely to examine the effect of cannabis use on neuropsychiatric functioning in MS.

RESULTS Demographics and neurologic variables.

Entire sample. The sample consisted of 25 cannabis users (11 women) and 25 nonusers (12 women). The mean age of the entire sample was 43.60 (SD 10.7). Thirty-three patients (66.0%) were married or cohabitating and 21 (42.0%) were employed. Patients had received an average of 14.0 years (SD 2.8) of education. Average disease duration was 12.1 years (SD 9.4). The breakdown of disease course was as follows: relapsing-remitting 72.0%; secondary progressive 18.0%; primary progressive 10.0%. The median EDSS score was 3.0 (mean 3.32, SD 2.39, range 0-8.5). Twenty patients (40.0%) were taking

Table 2 Comparison of MS cannabis users and nonusers on psychiatric measures

Variable	Cannabis users, mean (SD)	Nonusers, mean (SD)	t or χ^2	p
SCID-I major depression, lifetime, n (%)	15 (60.0)	13 (52.0)	$\chi^2 = 0.325$	0.569
SCID-I anxiety disorder, lifetime, n (%)	10 (40.0)	8 (32.0)	$\chi^2 = 0.347$	0.556
Antidepressants, n (%) taking	10 (40.0)	12 (48.0)	$\chi^2 = 0.325$	0.569
HADS depression subscore	7.0 (4.4)	6.7 (4.9)	t = 0.182	0.856
HADS anxiety subscore	8.8 (4.7)	7.00 (5.7)	t = 1.225	0.227
Modified Fatigue Impact Scale	46.3 (16.2)	40.4 (24.2)	t = 1.022	0.322

Abbreviations: HADS = Hospital Anxiety and Depression Scale; MS = multiple sclerosis; SCID-I = Structured Clinical Interview for the DSM-IV axis I disorders.

disease-modifying drugs. Patients consumed a median of 2.0 alcoholic beverages per week (mean 3.0, SD 3.3, range 0-12). Four subjects had taken steroids within the last 3 months.

Comparison between cannabis users and nonusers. Comparisons between cannabis users and nonusers on demographic and disease-related variables are presented in table 1. There were no statistically significant group differences for age, sex, years of education, marital status, EDSS, disease course, duration of MS, and use of disease-modifying drugs. Cannabis users were significantly more likely to be unemployed. Cannabis users also reported slightly higher alcohol consumption compared to nonusers, although this difference did not reach statistical significance.

Cannabis use. The average age at onset of cannabis use was 17.0 years (median 15.0, SD 6.6, range 13-47) and the average duration of cannabis use was 26.6 years (median 31.0, SD 12.1, range 1-41). Eighteen subjects (72.0%) used cannabis on a daily basis, 6 (24.0%) reported weekly use, and one reported biweekly use. Most cannabis users (n = 24) reported inhalation (smoking or vaporization) whereas one reported consumption of food products containing cannabis. Eight subjects (32.0%) reported using cannabis for medicinal reasons, 3 (12.0%) for recreational reasons, and 14 (56.0%) for a combination.

Mean level of urine cannabinoid metabolites was 174.4 $\mu\text{g/L}$ (SD 40.8, range 61- ≥ 200) and the broad-spectrum drug screen indicated that no subject had used any illicit drugs other than cannabis. The period of abstinence from cannabis use ranged from 12 hours to 14 days prior to testing with most patients (n = 18) reporting their last use on the evening prior to testing. The remaining 7 subjects had not used cannabis for more than 24 hours.

Urine drug screening indicated that none of the noncannabis users tested positive for cannabinoids or any other nonmedicinal substances.

Psychiatric assessment. The lifetime prevalence of major depression for the entire sample was 56.0%. Lifetime prevalences for anxiety disorders were as follows: generalized anxiety disorder 26.0%; panic disorder 20.0%; phobia 4.0%; obsessive compulsive disorder 2.0%; and post-traumatic stress disorder 4.0%. Lifetime prevalence for any of the anxiety disorders was 36.0%.

Psychiatric comparison between cannabis users and nonusers is presented in table 2. There were no significant differences between groups in the lifetime prevalences of psychiatric disorders and use of antidepressant medication. Similarly, scores on HADS

Cognitive domain	Cognitive test	Cannabis users, mean (SD)/n (%) impaired	Nonusers, mean (SD)/n (%) impaired	t or χ^2	p
Learning and memory	CVLT-II immediate recall	49.5 (10.9)	52.5 (11.2)	t = -0.969	0.337
	CVLT-II long delay recall	10.6 (3.6)	11.2 (2.7)	t = -0.681	0.499
	BVMT-R total recall	22.1 (8.3)	22.8 (7.6)	t = -0.284	0.777
	BVMT-R delayed recall	8.2 (3.1)	8.7 (3.1)	t = 0.545	0.588
Verbal fluency	COWAT total score	31.0 (11.9)	33.7 (10.8)	t = -0.845	0.403
Visuospatial perception	JLO score ^a	23.9 (4.7)	26.7 (3.5)	t = -2.417	0.020
Executive functioning	D-KEFS sorting score	8.4 (2.4)	10.3 (2.7)	t = -2.704	0.009
	D-KEFS description score	31.4 (9.5)	37.4 (10.4)	t = -2.127	0.039
Information processing speed	PASAT 3.0	36.0 (12.0)	44.0 (11.4)	t = -2.402	0.020
	PASAT 2.0	26.1 (7.6)	35.0 (11.7)	t = -3.188	0.003
	SDMT Total	42.4 (11.4)	50.4 (12.9)	t = -2.329	0.024
Global cognitive impairment	≤1.5 SD on 2 or more of 11 cognitive tests, n (%)	16 (64.0)	8 (32.0)	$\chi^2 = 5.128$	0.024

Abbreviations: CVLT = California Verbal Learning Test; BVMT-R = Brief Visuospatial Memory Test-Revised; COWAT = Controlled Oral Word Association Test; JLO = Judgment of Line Orientation; D-KEFS = Delis-Kaplan Executive Functions Test; MS = multiple sclerosis; PASAT = Paced Auditory Serial Addition Test; SDMT = Symbol Digit Modalities Test.

^a JLO score corrected for sex and age.

Depression and Anxiety subscales and the MFIS showed no significant differences between cannabis users and nonusers (table 2).

Neuropsychological assessment. Neuropsychological comparisons between cannabis users and nonusers are presented in table 3. Cannabis users scored significantly lower on the PASAT-3, PASAT-2, JLO, SDMT, and D-KEFS Sorting Test and Description scores. There were no between-group differences on CVLT-immediate recall, CVLT-delayed recall, BVMT-immediate recall, BVMT-delayed recall, and COWAT.

Of all 50 patients, 24 (48.0%) were classified as cognitively impaired. Cannabis users were significantly more likely to be classified as globally impaired compared to nonusers ($\chi^2 = 5.13$, $p = 0.024$; table 3).

Although the cannabis users and nonusers were group-matched on demographic and disease-related variables, we further analyzed our data with the aim of exploring the effect of cannabis use on each cognitive measure independent of age, sex, education, alcohol consumption, EDSS, depression, anxiety, and fatigue. The final regression models reveal that cannabis use remained a significant independent predictor of performance on the PASAT-2, JLO, SDMT, D-KEFS Sorting Score, and global cognitive impairment, but not on CVLT-immediate recall, CVLT-delayed recall, BVMT-immediate recall, BVMT-delayed recall, COWAT, PASAT-3, and D-KEFS Description Score (table 4). Exclusion of the one

subject who indicated only ingesting cannabis in food products did not significantly alter the findings.

Global cognitive impairment was not significantly correlated with urine cannabinoid levels ($r = -0.321$, $p = 0.118$), age at cannabis use onset ($r = -0.321$, $p = 0.118$), or duration of cannabis use ($r = 0.158$, $p = 0.451$). The period of abstinence from cannabis use was not associated with global cognitive impairment ($\chi^2 = 0.198$, $p = 0.673$).

DISCUSSION The specific aim of this prospective study was to examine the effects of smoked or ingested cannabis on cognitive function in patients with MS. We found that cannabis users had greater deficits on information processing speed, working memory, executive function, and visuospatial perception compared to a sample of nonusers group-matched on age, sex, education, premorbid intelligence, EDSS, and disease course. Cannabis users were also twice as likely as nonusers to meet criteria for global cognitive impairment. Most of these between-group differences were retained after controlling for potential confounds.

Cognitive dysfunction affects approximately 40%–60% of patients with MS^{8,9} with detrimental effects on personal, social, and occupational functioning.⁸ Cognitive functioning is also a major determinant of quality of life.²⁵ Given these adverse psychosocial effects, identifying risk factors associated with further cognitive impairment is important. Although not the focus of the present investigation,

Table 4 Linear regression analyses for significant cognitive tests and cannabis use^a

Cognitive domain	Cognitive test indices	Covariates ^b	B (95% CI)	p
Learning and memory	CVLT-II immediate recall	Sex, education, EDSS, alcohol consumption, HADS anxiety	1.451 (–5.093 to 7.995)	0.657
Verbal fluency	CVLT-II long delay recall	Sex, education, EDSS, alcohol consumption, HADS anxiety, MFIS	0.399 (–1.286 to 2.084)	0.635
Visuospatial perception	BVMT-R total recall	Sex, education, EDSS, alcohol consumption, HADS anxiety, MFIS	–0.315 (–5.156 to 4.526)	0.896
Executive functioning	BVMT-R delay recall	Education, EDSS, alcohol consumption, HADS anxiety, MFIS	0.215 (–1.806 to 2.235)	0.831
Information processing speed	COWAT total score	Sex, Education, EDSS, HADS anxiety, MFIS	1.832 (–5.115 to 8.779)	0.533
Global cognitive impairment	JLO score	HADS anxiety, MFIS	2.904 (0.545 to 5.263)	0.017
	D-KEFS sorting score	Education, alcohol consumption	1.676 (0.274 to 3.077)	0.020

^a All models contained group as a predictor. Model parameters are presented for cannabis group after controlling for confounds.

^b Only variables that changed the coefficient for cannabis group by 10% or more were retained in the final model as covariates.

it is plausible that the additional cognitive deficits associated with chronic cannabis use have deleterious psychosocial ramifications. For example, our study found that cannabis users were twice as likely to be unemployed than nonusers. While the reasons for this are not clear, an association between impaired cognitive performance and unemployment in patients with MS has been reported,²⁶ thereby suggesting a putative link with our cannabis findings.

To date, the clinical trials literature on the effects of cannabis on cognition in patients with MS is sparse, largely limited to synthetic cannabis derivatives or cannabis-based extracts, with measures of cognition confined to secondary analysis. Results are equivocal, with deficits in long-term memory storage reported by one study¹ contrasting with an absence of deleterious cognitive problems associated with cannabinoids reported by others.^{4,27} The discrepancy between these negative findings and our results may be attributable to differences in pharmacokinetics between the various forms of cannabis and their routes of administration. Oral administration of cannabi-

noids has a slower onset of action, more erratic patterns of absorption, and lower peak concentration compared to inhaled cannabis, which allows for better absorption than oral THC.

The results of our study are consistent with data from an earlier pilot study that revealed that patients with MS who smoked cannabis performed significantly more poorly than cannabis-naïve patients on a test of information processing speed.⁷ While informative, the earlier study had a small sample size (10 cannabis users), a limited neuropsychological battery, and the absence of urinalysis confirming cannabis use. Our present study, by virtue of a more robust methodology, extends these earlier results and links smoked or ingested cannabis to more extensive cognitive deficits.

The paucity of cognitive data pertaining to the use of inhaled cannabis in patients with MS contrasts with a much larger literature obtained from general population studies. Results here have varied according to the timing of the neuropsychological inquiry. For example, there is a consistent body of evidence showing that individuals who are acutely intoxicated

display impaired memory, slowed information processing speed, and poor attention.^{28,29} What defines acute intoxication in the literature is somewhat arbitrary, with studies using 4 to 24 hours as the cutoff period.^{28,29} Of note, however, is that pharmacokinetic studies have shown that the acute cognitive effects of cannabis attributable to the initial rapid rise in serum THC begin tapering off 3 to 5 hours after consumption.^{30,31} Given that we did not want to test cognition in patients who were acutely intoxicated, we set a time frame for psychometric testing as greater than 12 hours following the last inhalation or ingestion of cannabis. The literature from the general population suggests, with few exceptions,³² that there are residual, adverse cognitive difficulties extending beyond this period.³³⁻³⁵ Our finding in the cannabis users replicates this picture and points toward the detrimental effects of cannabis persisting beyond intoxication. While it is likely that these persistent deficits are due to the residual effects of the drug itself, whether and to what extent withdrawal effects following a short period of abstinence contribute as well cannot be ascertained from our data. Notably, we did not find an association between cognitive performance and duration of abstinence (12–24 hours vs greater than 24 hours) in this study.

Cognitive dysfunction in our sample was not associated with the level of cannabinoid metabolites detected in the urine and the age at onset, duration of cannabis use, or abstinence. It is, however, possible that the lack of association may be an artifact of our sample selection where the overwhelming majority of our cannabis users began using the drug in adolescence and in whom urinary levels of metabolites clustered tightly at the upper limits of the range of detection. Our data also diverged from the general population finding of higher rates of psychopathology in cannabis users.³⁶ This pertained both to the lifetime prevalence of these disorders and current indices of emotional distress as captured by the HADS. This result may, in part, be attributed to the already high prevalence of depressive and anxiety disorders associated with MS itself.^{37,38}

A notable cognitive finding from our study was that twice as many cannabis users were rated as globally impaired when compared with the noncannabis users. While our methodology did not address etiologic constructs, fMRI data from patients with MS have consistently shown that in response to a cognitive challenge, ancillary brain activation occurs as a compensatory response to the presence of cerebral pathology.^{39,40} It is therefore tempting to speculate that the deleterious effects of cannabis may be linked to an inhibition of these compensatory responses. In addition, functional imaging findings from the gen-

eral psychiatry literature have demonstrated lower global and prefrontal blood flow in cannabis users even before they are challenged with a cognitive task.⁴⁰ These resting state data suggest that a degree of “background” cerebral compromise may further complicate cognitive functioning.

Our study has limitations. The cross-sectional design limits our ability to establish a cause and effect relationship between cannabis use and greater cognitive dysfunction. It is also important to emphasize that our results are derived from patients who have smoked cannabis on a regular basis, as much as several times per day, for more than 2 decades. These results do not necessarily extend to occasional cannabis use or frequent use for a brief period of time. Indeed, studies of cannabis use in healthy individuals have shown that the cognitive effects of cannabis are dose-dependent, with deficits in cognition primarily observed in heavy cannabis users^{34,35} and those who use cannabis over a long period of time.³⁵ Our study also does not address the reversibility of these cognitive deficits following long-term abstinence from the drug. Finally, our modest sample size introduces a cautionary note.

Our study demonstrates that inhaled or ingested cannabis is associated with adverse effects on cognition following prolonged use. Given the prevalence of cannabis use in patients with MS, further research is needed to replicate these findings in a larger sample and to explore the cerebral underpinnings of how these changes may come about.

Cannabis use in patients with multiple sclerosis

MS Chong^{1,4}, K Wolff², K Wise², C Tanton³, A Winstock² and E Silber¹

Introduction Little is known about the extent and patterns of cannabis use in people with multiple sclerosis (MS).

Methods MS patients attending neurology outpatient clinics at two hospitals in London and one in Kent, UK completed a questionnaire.

Results Questionnaires were completed by 254/337 (75%) MS patients. Forty-three per cent had used cannabis at some stage (ever users). Of these, 68% (75/110) had used cannabis to alleviate symptoms of MS (MS-related cannabis use). Forty-six (18%) had used cannabis in the last month (current users), of whom 12% (31/254) had used it for symptom relief. Being married or having a long-term partner, tobacco smokers and increasing disability were independent risk factors for MS-related cannabis use. Compared to patients who could walk unaided, cannabis use was more likely in those who were chair-bound (adjusted OR 2.47; 1.10–5.56) or only able to walk with an aid (adjusted OR 1.56; 0.90–3.60). Pain and spasms were common reasons for cannabis use. Seventy-one per cent of individuals who had never used cannabis said they would try the drug if it were available on prescription.

Conclusion A large proportion of MS patients had tried cannabis for symptom control, however current use was small. A subgroup with greater disability appears to derive some symptomatic benefit. *Multiple Sclerosis* 2006; 12: 646–651. www.sagepub.co.uk

Key words: addiction; cannabis; multiple sclerosis; pain; spasticity

Introduction

Multiple sclerosis (MS) is the most common cause of neurological disability affecting young adults in the UK. Drug therapies for MS include steroids for acute relapses and disease-modifying agents, however symptom control remains the cornerstone of management. Conventional drug therapies have limited benefit in alleviating symptoms, often because of adverse effects, leading a number of patients with MS to use alternative therapies. Cannabis was legally prescribed in the UK until it was reclassified as a Schedule 1 drug within the 1971 Misuse of Drugs Act. In spite of this, anecdotal evidence suggests that many patients continue to use cannabis illegally for medicinal purposes.

The medical use of cannabis is the subject of medical research and public debate [1,2]. A recent report by the House of Lords Select Committee

recommended that cannabis be reclassified as a Schedule 2 drug, enabling medical prescription. Cannabinoids have been purported to alleviate a variety of MS-related symptoms including spasticity, pain, tremor and bladder dysfunction [3]. Interest in the potential therapeutic uses in MS had resulted in The Medical Research Council funding a national placebo-controlled trial to assess the efficacy of synthetic Δ^9 tetrahydrocannabinol (THC) and cannabis extract for alleviating MS symptoms [4].

Despite limited evidence of efficacy, it was our impression that many MS patients use cannabis for medicinal purposes. There have been anecdotal reports where people with MS describe benefits from the drug and a limited number of studies have systematically tried to address the extent, reasons for and patterns of use in a variety of neurological conditions, including MS [5–11]. We

aimed to assess the extent and patterns of cannabis use amongst MS patients in South East London and surroundings. We surveyed MS patients to determine whether there are demographic, behavioural and MS-disability-related factors associated with the medicinal use of cannabis. We also report the perceived benefits and adverse effects of cannabis use.

Methods

Patients with a diagnosis of MS known to the Neurology Departments of Kings College Hospital and the Queen Elizabeth Hospitals in South London and The Medway Hospital in Kent were recruited. Patients under 18 years of age, those with severe mental health problems and those unwilling or unable to give consent were excluded. Information was collected through a self-report questionnaire, which was developed after consultation with and piloting amongst one of the local MS patient support groups. The questionnaire comprised a number of components: (a) demographic details, (b) MS history including disease duration, and disability using the Guy's Neurological Disability Scale [12], (c) current and previous cannabis and other recreational drug use, and (d) subjects were asked about current symptoms using a list derived from clinical experience and patient reports; for each symptom they were asked whether cannabis had been used to try to relieve this and its perceived efficacy.

Subjects who had used cannabis at least once were defined as 'ever users'. Those who were using cannabis at least once a month at the time of the survey were defined as 'current users'. 'MS-related cannabis use' was defined as those individuals who reported that they had (1) not used cannabis before developing MS and that they had started because of MS or (2) those who would not use cannabis if they did not have MS.

Data were entered into SPSS and analysed using STATA (Stata Corporation Texas). Those who completed questionnaires were compared to 'non-responders'. Comparison was made between MS-related users and the rest of the group (non-users and recreational users) and possible risk factors for MS-related cannabis use were determined. Odds ratios (ORs) and 95% confidence intervals (95% CIs) for MS-related cannabis use were calculated using logistic regression.

Results

A response rate of 75% (254/337) was achieved with higher completion among women (79% versus

66%; $P = 0.01$). Amongst men, there was a tendency for a lower response rate in those aged less than 50 years compared to those aged 50 or older ($P = 0.08$).

Characteristics of patients included in the study are shown in Table 1. The median age was 49 years and one-quarter were male. Sixty-five per cent were non-smokers and the majority (66%) drank alcohol within national recommended limits (21 units/week for males and 14 units for females). Nearly 70% of those who completed the questionnaire were either married or cohabiting with a partner and 40% of households had children living at home. MS was diagnosed within the last five years in 34%; between 5 and 15 years ago in 40%; and > 15 years ago in 23% of patients. In terms of lower-limb disability, 29% were able to walk independently, 45% required an aid to walk and 25% required a wheelchair for at least part of the day. When asked to rate their disability, 28% classified themselves as having no or mild disability, 59% reported moderate disability and 12% severe disability. Fifty-two per cent were unable to work or were medically retired.

One hundred and ten subjects (43%) reported having used cannabis at least once in their lifetime (ever users). Amongst 'ever users' (excluding an individual who only used cannabis in a trial), first cannabis use was split fairly evenly before and after the diagnosis of MS. Of the 59 individuals who used cannabis for the first time after diagnosis, 90% reported starting because of their MS. Forty-six (18%) subjects were using cannabis at the time of the survey (current-users, Table 2) and 12% (31/247) reported using cannabis in an attempt to alleviate MS symptoms.

Seventy-five patients (30%) reported cannabis use to attempt to alleviate MS symptoms (MS-related users). The symptoms for which cannabis was used and its perceived effect are shown in Table 3. The most commonly cited symptoms for cannabis use were pain and spasms (>80%) and the majority of persons using it for these symptoms reported benefit. Seventy-one per cent of individuals who had never used cannabis stated that they would try the drug if it were legal or available on prescription.

Comparison of MS-related cannabis users with the rest of the group (Table 1) showed that they were less likely to be single than married or cohabiting. Whether there were children living at home did not influence the risk of using cannabis. There was a strong association between smoking cigarettes and MS-related cannabis use, but no significant association with alcohol consumption or other illicit drug use. There was no significant geographical variation between the three survey sites with regard to cannabis use.

Table 1 Comparison of risk factors between MS-related cannabis users ($n=75$) and non-MS-related cannabis users ($n=179$)

Self-rated disability				0.05
None/mild	15 (20.0)	54 (32.0)	1	
Moderate/severe	60 (80.0)	115 (68.1)	1.88 (0.98–3.60)	

Non-MS-related cannabis users included non-users and recreational users. All subjects did not complete each question, thus totals do not add up to 254.

The risks of MS-related cannabis use increased with greater physical disability. Use was higher in those who rated their disability as moderate or severe and there was a significant trend to increasing use with greater lower-limb dysfunction (OR 1.56; 95%CI 1.07–2.28; $P_{\text{trend}}=0.02$). The odds of cannabis use were approximately double among those who had upper-limb problems that made them dependent upon others (OR=2.22; 95%CI 1.04–4.32) compared with those with no upper-limb disability. MS-related cannabis use did not correlate with fatigue, mood, cognitive, visual, speech or swallowing problems. There was a tendency to greater use of cannabis amongst those

reporting bowel and sexual dysfunction but these were not statistically significant. Multivariate analysis (Table 4) identified tobacco smoking and marital status as independent risk factors for MS-related cannabis use. There was a tendency to lower-limb disability as a risk factor for cannabis use however this did not reach statistical significance.

The side effects experienced by MS-related cannabis users are shown in Table 5. The most common of these were feeling 'quiet and mellow' (41%), sedated (35%), euphoric ('giggly' 27%), 'lazy' (23%) and increased appetite (29%). Three subjects reported that cannabis made them feel 'paranoid', a

further three said it exacerbated their weakness and one experienced hallucinations. The most frequently expressed concerns raised by MS-related users were that not enough research had been carried out on the medicinal use of cannabis for MS (59%), potential harm from smoking tobacco with cannabis (41%), including effects on their lungs (32%), risk of dependence (31%), interference with other treatments (27%), cognitive effects (25%), effects on mood (21%), financial costs (48%) and possible stigma (25%).

Discussion

Our results raise a number of issues including the extent of cannabis use amongst our subjects, the clinical efficacy of cannabis, the risk factors for MS-related use and possible adverse effects. Almost half of the respondents had tried cannabis at some time and of these 68% were 'MS-related users'. There was

a significant correlation between MS-related cannabis use and disability. The other independent determinants of cannabis use were being married or in a stable relationship and cigarette smoking. Possible reasons for the increased use amongst people who were married or cohabiting include the partner's ability to acquire and prepare the cannabis, particularly in those who are more disabled.

There remains debate as to the clinical efficacy of cannabinoids in the management of MS symptoms. Cannabinoids appear to have benefit in reducing pain in MS [13] and other neuropathic pain syndromes [14], however a meta-analysis has suggested that cannabinoids are not more efficacious than minor opiates in the management of pain [15]. Both the CAMS [4] and an earlier smaller study [16] found no significant improvement in spasticity. In the CAMS study, ambulant subjects on cannabinoids had a significant improvement in walking times and self-rated scores of pain and spasticity. Other controlled trials using cannabinoids in MS have reported improvement in bladder function [17], but not tremor [18].

Despite the limited evidence for clinical efficacy and the fact that the drug remains illegal, almost one-third of our patients with MS had used cannabis in an attempt to alleviate symptoms. In the previous month, 18% had used the drug and in two-thirds of these this was MS-related use. The most common symptoms for cannabis use cited by our subjects were pain and spasticity and a large proportion experienced benefit. Similarly, in a survey of 112 MS patients known to use cannabis in the UK and USA, over 90% reported alleviation of symptoms of spasticity and pain [8]. Of note is that over half of our subjects had used cannabis to treat sleep problems and that 88% found cannabis to be helpful for this symptom. The issue of sleep problems in MS has received relatively little research attention but a recent clinic-based survey in

Table 3 Symptoms experienced by MS-related cannabis users (*n* = 75) and perceived effect

Symptom	Number reporting symptom	Ever tried cannabis to help <i>n</i> (%)	Improves/relieves symptom <i>n</i> (%)

*Adjusted for other variables in the table ($n = 232$).

our unit has identified initial, middle and terminal insomnia in approximately half of patients [19]. Cannabis use for sleep was not questioned in most previous studies apart from a recent study in Nova Scotia where sleep problems were relieved in over 90% of cases [9]. Surprisingly, in our survey bladder problems were rarely cited as a reason for cannabis use.

Despite the large amount of media attention given to medicinal cannabis use, other studies have also reported relatively low rates of regular self-medication with cannabis. In a recent survey, 43% of patients had used cannabis, 16% for medical purposes [10], and in another survey 36% had ever used cannabis, and 14% continued to use it for symptom treatment [9]. These results are similar to ours and suggest that despite the largely negative results of the recent well conducted trial of cannabis use for spasticity the drug may be both bene-

ficial and tolerated in a small proportion of patients with symptoms resistant to conventional therapies.

There may be risks of self-medication with a psychoactive substance by people with a neurological illness. Recent work has raised concerns about alcohol and illicit drug use amongst people with MS [20,21]. In our subjects, MS-related cannabis use was not associated with alcohol or other illicit substance misuse, however 15% had used other illicit drugs previously. If anything, there appeared to be an inverse relationship between high levels of alcohol consumption and MS-related cannabis use. On the other hand, cigarette smoking was an independent predictor of cannabis use and a proportion of subjects expressed concern about associated tobacco use. A proportion of MS-related users expressed concerns about the costs of cannabis use. Over 70% of non-users said that they would try cannabis if it were legal or available on prescription. Medical prescribing and other formulations (such as tablets or a spray) may be helpful in addressing both the issues of smoking and the association with illicit drug use.

There is a need for careful dosage induction and monitoring when cannabis is used for therapeutic purposes. A small proportion of our cohort experienced potentially serious adverse effects, including psychiatric symptoms and increasing weakness. The long-term safety of cannabis use is uncertain and some have raised concerns about the risk of developing psychiatric disorders with prolonged cannabinoid use [22].

This study has a number of strengths and weaknesses. Like all self-reported surveys, these data are dependent on veracity and recall, a fact that is especially relevant with illegal and/or stigmatizing behaviour. In contrast to some earlier studies [8], our response rate is relatively high (75%) and may thus be more representative of our population. This study also analysed specific risks for cannabis use, in particular social factors, levels of disability and

Table 5 Side effects reported as moderate or severe experienced by MS-related cannabis users ($n = 75$)

the specific symptoms for which cannabis was used and its perceived effects.

This study complements information from controlled trials by providing details of actual cannabis use in a large spectrum of people with MS. It demonstrates a strong relationship between cannabis use and disability and raises concerns about the relationship with tobacco use. Further long-term study is needed prior to the drug being made more widely available. These include dosage, routes of delivery, interaction with other prescription drugs and alcohol as well as the possibility of psychological dependence.

ABSTRACT

Objective: Medicinal use of cannabis in chronic neurological diseases is a controversial topic of medical research and the subject of intense public debate. The aim of the study was to evaluate the prevalence of cannabis use, related factors, and degree of satisfaction in Spanish patients with multiple sclerosis (MS) prior to the establishment of medically supervised use.

Methods: Cross-sectional, questionnaire-based survey provided during routine medical visits to consecutive patients in two university-based neurology clinics.

Results: The questionnaire was returned by 175 MS patients (94.1% response rate). The prevalence of ever-use and medicinal cannabis use were 43% and 17.1%, respectively. At the time of the survey, cannabis was being used by 12.5% (5/45) of recreational and 56.7% (17/30) of medical users ($p < 0.001$). First cannabis consumption was after MS onset in 15 (50%) medicinal users. Clinical improvement was reported by 14 (46.7%) medicinal users. Smoking use, awareness of cannabis potential benefits, pain, higher disability, and lower age were independently associated with the medicinal use of cannabis. Most patients would support a future legalisation of cannabis for the control of their symptoms and were willing to receive cannabis under medical control once legalised (83.4% of never-users, 94.5% of ever-users, $p < 0.05$).

Conclusion: Almost half of our MS patients had tried cannabis at some time. However, medicinal use was low and clinical improvement after cannabis use was only reported by a subset of patients. Overall, MS patients were highly motivated for a future medically controlled use.

1. Introduction

The limited benefit of current treatments for the relief of symptoms in patients with multiple sclerosis (MS) has led to the search for alternative and untried therapies. The use of cannabis in this setting is a controversial topic of medical research with great public interest [1]. Whereas most studies have noted an improvement of some MS symptoms after cannabis use [2,3], others reported a lack of efficacy or even clinical worsening [4]. However, most authors suggest a benefit of cannabinoids in MS in at least a subset of patients with spasticity, muscle spasms, neuropathic pain, and lower urinary tract symptoms.

In 2001, a proposition to the Spanish administration by the Parliament of Catalonia, an autonomous community in northeastern Spain, in order to legalise the medical use of cannabis was denied, but opened up an intense public debate. Since 2007, an oromucosal

cannabis-based medicine can be prescribed as compassionate medicine for the treatment of spasticity and as a foreign medicine for the treatment of neuropathic pain in MS. The present study was aimed at evaluating the current prevalence and pattern of cannabis use, degree of satisfaction and expectations in MS patients of our community prior to any medically supervised cannabis use.

2. Patients and methods

The study was based on a consecutive series of adult patients with a diagnosis of MS, based on McDonald criteria. Patients were controlled in two MS University Clinics (Hospital del Mar and Hospital Clínic of Barcelona, Spain) and were invited to participate in the survey from September 2006 to May 2007. There were no exclusion criteria with the exception of moderate to severe cognitive impairment. A cross-sectional, questionnaire-based survey with fifty-six detailed questions was provided to consecutive patients during their routine visits in the outpatient clinics. Patients were assessed for the Expanded Disability Status Scale (EDSS), progression index, MSSS (Multiple Sclerosis Severity Score), and the MS form (relapsing–

Mean (SD). DMD: disease-modifying drugs. *Statistically significant.

remitting, secondary progressive, primary progressive). The questionnaire was completed at home and sent back to the Hospital in a postage-paid envelope. No personal identity data was included in the survey, so anonymity was maintained throughout the analysis. The study was approved by the local ethics committees.

Questions were designed to collect detailed information on demographic data, history of cannabis use and opinions. The questionnaire included the following sections: *Section 1, demographic and disease characteristics*: age, sex, marital status, years of education, employment status, economic incomes, smoking habit and alcohol intake, years of disease evolution, age at disease onset, self-reported MS symptoms (detailed in fourteen symptoms as present or absence), and current treatments. *Section 2, personal history of cannabis use*: previous and current consumption (last month), purpose (recreational/medicinal), age at first use, consumption pattern, frequency, type of cannabis (hashish or marijuana), and source of the drug. Medicinal use of cannabis was defined as any recurrent consumption in order to relieve symptoms related with MS. *Section 3, cannabis for medical use*: evaluation of the cannabis effect on clinical symptoms based on 100-mm visual analogue scale (VAS), reasons for cannabis withdrawal, cannabis adverse effects, and general subjective perceptions after cannabis use. *Section 4, opinion of cannabis and general comments*: awareness of the potential medicinal benefits of cannabis, reasons for non-consumption, opinions on cannabis legalisation, and expectations concerning future medically supervised use measured by VAS. A standard Hamilton rating depression scale was additionally included in the survey to assess any potential

effect of the patients' mood state on their answers. A value ≥ 18 was considered suggestive of moderate depression.

3. Statistical analysis

The sample size was calculated estimating the proportion of MS patients using cannabis for medicinal reasons (12% of MS patients, as previously reported) [5] and an estimated prevalence in our region of 3000 MS patients [6]. A sample of 163 patients was required to provide a 95% confidence interval at the 5% level. Patients were classified as cannabis non-users, recreational users, and medicinal users. Values were expressed as percentage or mean (SD). Categorical variables were analysed using the chi-square test, and parametric and non-parametric variables using *T*-test and Kruskal–Wallis test, respectively. Multivariate analysis evaluated odds ratios (OR) and the resulting 95% confidence intervals (CI) of those variables related with cannabis use reaching a $p < 0.1$ in the univariate analysis. Statistical significance was established at a 0.05 level.

4. Results

One hundred and seventy-five MS patients returned the questionnaire (94.1% response rate). The frequency of cannabis ever-use was 43% (75/175). Recreational use of cannabis was reported by 45 patients (25.7%) and medicinal use by 30 patients (17.1%). At the time of the survey, 5 patients were using cannabis for recreational purposes

(12.5% recreational users) and 17 patients for medicinal purposes (56.7% medicinal users) ($p < 0.001$).

Table 1 shows the demographic and clinical characteristics of medicinal cannabis users. These patients had a considerable degree of disability (mean EDSS 4.2 (2.1)) and more than 50% reported disabling clinical symptoms such as pain, spasticity, fatigue, depression, sphincter dysfunction and walking disturbances. Comparison of medicinal users with non-medicinal users (non-users and recreational users) (Table 1) showed a higher frequency of cigarette smoking, higher EDSS, progression index, MSSS, and Hamilton Scale score in medicinal users ($p < 0.05$). Medicinal cannabis users were also significantly more often retired, smokers, had more progressive forms of the disease, higher EDSS, progression index, MSSS and more depressive

symptoms (Hamilton Scale score 15.1 (7.5) vs. 9.4 (7.3), $p < 0.01$) when compared to recreational users (Table 2).

Medicinal users began cannabis consumption at older ages, and half of them after the onset of MS. Use of own prepared ingested or vapour inhaled cannabis were found only among MS medicinal users ($p < 0.001$), and mainly among patients with no previous history of recreational use. Both recreational and medicinal users consumed marijuana more often than hashish, and usually before evening bedtime whatever the purpose of use. Medicinal users grew their own cannabis more often than recreational users ($p < 0.001$) (Table 2). Cigarette smoking, awareness of cannabis potential benefit, pain, higher EDSS, and lower age were independently associated with medicinal use of cannabis (Table 3).

Muscle spasms	0.815	0.212–3.135	0.77

*Statistically significant.

When MS patients were asked about any symptom amelioration, 14 out of 30 medicinal users (46.7%) reported clinical improvement after cannabis use. The VAS evaluation of self-reported clinical modifications after cannabis medicinal use showed a wide range of improvement that was mainly perceived in sleep disturbances, pain, tremor, and muscle spasms (Table 4). Adverse effects, mainly dry mouth, dizziness, somnolence, and feeling “high”, were reported by 13 medicinal users (43%) and 10 recreational users (22%) ($p=0.05$) (Table 5). Cannabis therapy had to be discontinued at some time by 56.7% of medicinal users due to supply problems (9 patients), adverse effects (6 patients), and lack of efficacy (2 patients). Once suppressed, more than 50% of these patients reported some kind of worsening of MS symptoms. Current medicinal users (17 patients) compared to past medicinal users (13 patients) had significantly more tremor (41% vs. 0%), grew cannabis by their own more often (64.7% vs. 15.4%), and reported higher frequency of clinical improvement after cannabis use (52.9% vs. 15.4%).

Awareness of potential cannabis benefits for the control of MS symptoms was higher among consumers (86.7% of MS patients using cannabis for medicinal use, 68.9% of recreational users, and 52.6% of non-users, $p<0.01$). Reasons for not using cannabis despite the awareness of a potential benefit were concerns about possible adverse effects (40.6%), absence of interest (36.2%), considerations of the drug's illegality (14.5%), and unknown supplies (8.7%). Most MS patients would support a future legalisation of cannabis for the control of their symptoms and were willing to receive cannabis under medical control once legalised (83.4% of never-users of cannabis and 94.5% of ever-users, $p<0.05$) (Tables 1 and 2). Most arguments for denying a future supervised use of cannabis were considerations about the illegality of the drug and concerns about possible adverse effects. The

Table 4
Perceived effect of medicinal cannabis analyzed by visual analogue scales (VAS)

expected future benefits assessed by VAS were 62 mm (31) in never-users, 71 mm (27) in recreational users, and 62 mm (26) in medicinal users ($p=0.4$).

5. Discussion

The most common symptoms reported by our MS medicinal users of cannabis were spasticity, pain, fatigue, sleep disturbances, depression, sphincter dysfunctions, and walking disturbances. These results were not unexpected considering the high disability of these patients (mean EDSS, 4.3). However, the only disabling complaint independently associated with medicinal cannabis use was the presence of pain. In addition to the well-known association with cigarette smoking, other factors significantly related to medicinal use in the multivariate analysis were awareness of the potential benefits of cannabis, higher disability measured by the EDSS, and younger age.

A beneficial effect of cannabis on clinical complaints was perceived by 46.7% of medicinal users of cannabis, a value that was also very similar among current medicinal users (52.9%). The VAS analysis showed a wide range of clinical improvements suggesting a considerable variability in patients' response. Although the reduced number of analyzed patients limits the interpretation of our study, the percentage of clinical improvement was very similar to a recently published study assessing patients using long-term medicinal cannabis [7]. A feeling of general improvement might explain why patients continue to use cannabis even after no clinical improvement. Additionally, a placebo effect cannot be excluded in those patients consuming the drug for medicinal purposes. Recreational MS users did not perceive any positive effects on clinical complaints, although they have lower disability than medicinal users.

The prevalence of ever-users (43%) and medicinal users (17.1%) of cannabis in our MS patients was similar to other surveys in Canada, UK, USA, and The Netherlands (ranging from 36 to 43%, and from 12 to 22%, respectively) [5,8–11]. The response rate in our study was very high (95%), thus reducing any possible influence of more motivated patients. In addition, our study also directly evaluated the EDSS, progression index, and MSSS as measures of disability and disease progression. As a result, a more accurate assessment was obtained than the self-reported measurements used in previous surveys. It is noteworthy that most of our MS medicinal cannabis users were older than recreational users and started the cannabis use after disease onset. This result differs from previous reports that suggest that medicinal use usually evolves from a prior recreational use [8,11,12]. This consumption pattern would indicate an active search for the drug as an alternative therapy rather than a modification of prior recreational use.

The most usual cannabis source was by own growing or supplies from a close friend or relative. Our MS patients reported frequent discontinuation of the medicinal cannabis use, often due to difficulties in obtaining the drug. Half of these patients had some kind of clinical worsening after suppression. Current medicinal users reported greater clinical improvement and grew more their own cannabis than past

medicinal users, therefore contributing to the continuation of the therapy due to easier cannabis availability. All these facts may imply that most MS patients using cannabis on their own have a high risk of treatment discontinuation with the subsequent potential worsening of symptoms and, additionally, a higher chance of consumption of non-reliable and uncontrolled products.

The therapeutic properties of cannabinoids in MS have been assessed by several studies [1–3,13,14]. Although improvement of clinical symptoms after cannabis use has only been reported by a subset of MS patients, the potential benefits of cannabis in MS may have received too much emphasis based on the popular knowledge of this substance and patients' opinion, favouring the use of cannabis as an alternative therapy in this disease. Whatever the benefit of cannabinoids in MS and its potential long-term effects [7,15], the overall expectations for medically controlled cannabis are high. Our results suggest that once cannabinoids products are available, the majority of MS patients will be more than willing to use them under medical prescription. Further scientific studies are therefore needed to establish the indications for medically controlled cannabinoids for the management of MS symptoms and to avoid the setbacks of a non-supervised use.

Report of a parent survey of cannabidiol-enriched cannabis use in pediatric treatment-resistant epilepsy

Brenda E. Porter and

Department of Neurology, Stanford University

Catherine Jacobson

Department of Neurology, Stanford University

Abstract

Severe childhood epilepsies are characterized by frequent seizures, neurodevelopmental delays and impaired quality of life. In these treatment-resistant epilepsies, families often seek alternative treatments. This survey explored the use of cannabidiol-enriched cannabis in children with treatment-resistant epilepsy. The survey was presented to parents belonging to a Facebook group dedicated to sharing information about the use of cannabidiol-enriched cannabis to treat their child's seizures. Nineteen responses met the inclusion criteria for the study: a diagnosis of epilepsy and current use of cannabidiol-enriched cannabis. Thirteen children had Dravet syndrome, four had Doose syndrome, and one each had Lennox-Gastaut syndrome and idiopathic epilepsy. The average number of anti-epileptic drugs (AEDs) tried before using cannabidiol-enriched cannabis was 12. Sixteen (84%) of the 19 parents reported a reduction in their child's seizure frequency while taking cannabidiol-enriched cannabis. Of these, two (11%) reported complete seizure freedom, eight (42%) reported a greater than 80% reduction in seizure frequency, and six (32%) reported a 25-60% seizure reduction. Other beneficial effects included increased alertness, better mood and improved sleep. Side effects included drowsiness and fatigue. Our survey shows that parents are using cannabidiol-enriched cannabis as a treatment for children with treatment-resistant epilepsy. Because of the increasing number of states that allow access to medical cannabis, its use will likely be a growing concern for the epilepsy community. Safety and tolerability data for cannabidiol-enriched cannabis use among children is not available. Objective measurements of a standardized preparation of pure cannabidiol are needed to determine whether it is safe, well tolerated and efficacious at controlling seizures in this difficult-to-treat pediatric population.

Introduction

Childhood epilepsies beginning in the first few years of life are frequently characterized by seizures that are resistant to available treatments, including anti-epileptic drugs (AEDs), the ketogenic diet, high doses of steroids and surgery [1]. A high seizure burden in early childhood likely contributes to the severe cognitive, behavioral and motor delays common in these children [2].

When indicated treatments fail to control their child's seizures, some parents turn to alternative treatments. One of these alternative treatments is cannabidiol-enriched cannabis. The cannabis plant contains approximately 80 cannabinoids of which cannabidiol and Δ^9 -tetrahydrocannabinol (THC) are the two most abundant [3,4].

Cannabidiol and THC exert very different physiological effects. Most importantly, cannabidiol is not psychoactive. In recent years, medical uses of cannabis have focused on cannabidiol, both because of its non-psychoactive nature and because it shows promise in treating disease [5]. However, in states where medical cannabis is legal, cannabidiol is currently only available in whole plant preparations that contain all the components of the cannabis plant, including THC. This poses significant risks when administering cannabidiol-enriched cannabis to epileptic children. First, cannabis use during development has been correlated with deleterious effects on brain development and cognition, primarily due to THC [6,7]. Second, THC can be pro-convulsive in epileptic brains [8].

In contrast to THC, numerous studies conducted over the last 40 years demonstrate anticonvulsant effects of pure cannabidiol in partial and generalized seizure animal models, including acute and kindling models [9,10,11,12,13,14]. In humans, two small double blind, placebo-controlled studies examined pure cannabidiol in adults with treatment-resistant epilepsy. In 1978, Mechoulam et al. randomized nine patients to either 200mg/day of pure cannabidiol or placebo [15]. During the three-month trial, two of four patients treated with cannabidiol became seizure free, whereas seizure frequency was unchanged in the five patients receiving placebo. In a second small clinical trial, 15 adult patients suffering from treatment-resistant secondary generalized epilepsy were randomly divided to placebo or 400mg of pure cannabidiol daily for up to 18 weeks [16]. Among the eight cannabidiol patients, four had a marked reduction and three had a partial reduction in seizures. One of the seven patients on placebo experienced a partial reduction in seizures. The most often reported side effect of pure cannabidiol was drowsiness. No patients reported psychoactive effects. In contrast, an open-label study found that cannabidiol was ineffective in controlling seizures; Ames and Cridland reported that seizure frequency was unchanged in 12 institutionalized patients with uncontrolled seizures receiving 200 mg of pure cannabidiol daily [17].

With the legalization of medical cannabis in an increasing number of states, parents of children with uncontrolled seizures have opted to treat their children's seizures with cannabidiol-enriched cannabis. This trend has produced an online presence of parents describing cannabidiol-enriched cannabis use in children with epilepsy. We asked parents from a Facebook group to anonymously fill out a survey on their experience of giving

cannabidiol-enriched cannabis to their children in order to gain insights into current cannabidiol-enriched cannabis use as an alternative treatment for childhood epilepsy.

Methods

The Stanford University institutional review board judged the study exempt from requiring full review by the board. Study data were collected and managed using REDCap electronic data capture tools hosted at the Stanford Center for Clinical Informatics. REDCap (Research Electronic Data Capture) is a secure web-based application designed to support data capture for research studies [18]. The survey consisted of 24 questions that measured clinical factors, including diagnosis and seizure types, and the parental-reported effect of cannabidiol-enriched cannabis on the child's seizure frequency and side effects. The survey was presented to a Facebook group composed of approximately 150 parents supporting the use of cannabidiol-enriched cannabis to treat seizures in their children with treatment-resistant epilepsy. The survey link was posted and displayed for two weeks, then reposted to the top of the group's page for another two weeks. Twenty parents responded to the survey. Nineteen responses met the inclusion criteria – diagnosis of treatment-resistant epilepsy and cannabidiol-enriched cannabis use – and were included in the analysis. One response was excluded because the child's diagnosis did not include epilepsy.

Because the cannabidiol-enriched cannabis survey results had a large number of patients with Dravet Syndrome and reported mostly positive outcomes for both seizure control and side effects, we wanted to assess parents' response to the same survey questions with a well known and effective treatment for seizures in Dravet syndrome, stiripentol. This would allow us to see if the parents' responses to our seizure burden questions were similar to the results from a clinical trial of stiripentol. In addition, side effects across the two drugs could be compared. To this end, we administered the same survey substituting stiripentol in place of cannabidiol-enriched cannabis. The stiripentol survey was presented to a different Facebook support group composed of parents of children with Dravet Syndrome having approximately 800 members. The stiripentol survey link was also initially posted for two weeks, and reposted to the top of the group's page for two additional weeks. Twenty-two parents responded to the stiripentol survey and all responses were included in analysis. Responses from both surveys were descriptively analyzed.

Results

The results from the cannabidiol-enriched cannabis survey are summarized in Table 1. The children ranged in age from 2 to 16 years. Thirteen children had Dravet syndrome (one of whom had epilepsy in female with mental retardation, EMFR), four children had Doose syndrome, and one each had Lennox-Gastaut syndrome and idiopathic early-onset epilepsy. The children experienced a variety of seizure types including focal, tonic-clonic, myoclonic, atonic and infantile spasms. In all cases, except patient 14 (age 2 years), the children experienced treatment-resistant epilepsy for more than 3 years before trying cannabidiol-enriched cannabis. The 2 year old had experienced intractable seizures for 16 months before trying cannabidiol-enriched cannabis. The children had unsuccessfully tried an average of 12 other AEDs before their parents began cannabidiol-enriched cannabis treatment. The

doses of cannabidiol the parents reported providing ranged from less than 0.5 mg/kg/day to 28.6 mg/kg/day. The doses of THC contained within those samples were reported to range from 0 to 0.8mg/kg/day. To obtain dosage information, parents reported having their preparations tested at commercial medical cannabis testing facilities. Seizure frequency before administering cannabidiol-enriched cannabis ranged from 2 per week to 250 per day. The duration of cannabidiol-enriched cannabis administration ranged from two weeks to over one year. Sixteen (84%) of the 19 parents reported a reduction in their child's seizure frequency. Two parents reported that their child became seizure-free after more than 4 months of cannabidiol-enriched cannabis use. Of the remaining 14 parents reporting a change in seizure frequency, 8 reported a greater than 80% reduction in seizure frequency, three reported a greater than 50% seizure frequency reduction and three reported a greater than 25% seizure frequency reduction. Three parents reported no change. Twelve parents weaned their child from another AED after starting cannabidiol-enriched cannabis treatment (see Table 1).

Beneficial effects of cannabidiol-enriched cannabis other than reduced seizures included better mood (15/19, 79%), increased alertness (14/19, 74%), better sleep (13/19, 68%) and decreased self-stimulation (6/19, 32%). Negative side effects included drowsiness (7/19, 37%) and fatigue (3/19, 16%) (Table 2). Side effects reported while taking other AEDs included rash, vomiting, irritability, dizziness, confusion and aggressive behavior; none were reported with the use of cannabidiol-enriched cannabis.

To understand if our questions might produce results similar to clinical trial results, we asked for responses to an identical survey replacing cannabidiol-enriched cannabis with another AED in use for Dravet syndrome. We surveyed parents on a Facebook group about stiripentol, which is approved only in Europe (though Americans can obtain it). We asked these parents to report how stiripentol affects their child's seizure frequency as well as which side effects were evident on the drug. Fifteen of the 22 (68%) parents reported that stiripentol reduced their child's seizure frequency. Four parents reported a substantial increase in seizure frequency, while three parents reported no change. Common negative side effects reported on stiripentol included appetite decrease (5/22, 23%), weight loss (6/22, 27%), insomnia (4/22, 18%) and increased self-stimulation (3/22, 14%). The reports in response to our survey are consistent with published data on the effects of stiripentol in children with Dravet syndrome [19], and support that our survey questions identify seizure and side effects similar to clinical trial results.

Discussion

Summary

We found that parents of children with severe treatment-resistant epilepsies are using cannabidiol-enriched cannabis to treat their child's epilepsy. Parents report a high rate of success in reducing seizure frequency with this treatment. Cannabidiol-enriched cannabis appears to be behaviorally well tolerated with some positive side effects not commonly associated with other AEDs. There are, of course, multiple limitations of an anonymous parental survey. We cannot verify the doses or the children's response to the cannabidiol-enriched cannabis. We approached a group of parents who have an ongoing interest in using

cannabidiol-enriched cannabis for their children's seizures which likely selected for positive outcomes. Nonetheless, the overall positive results on seizure control in a medically refractory group of childhood epilepsies suggest further studies of cannabidiol are warranted.

Parents report reduced seizures

The report of reduced seizure burden in the population that we surveyed is surprising. The children comprised a highly refractory epilepsy population with the majority having Dravet syndrome, a severe form of childhood epilepsy that often does not respond to available treatments, including AEDs, the ketogenic diet and the vagus nerve stimulator [1]. The children had failed to respond to an average of 12 AEDs prior to the use of cannabidiol-enriched cannabis. The children experienced various seizure types and the parental reports suggest that cannabidiol-enriched cannabis may have efficacy for diverse seizures. The limited size of our survey and small representation of syndromes other than Dravet does not provide additional guidance on what epilepsy types to move forward with in clinical trials. It is important to note, however, that the diagnoses and seizure types reported in this anonymous survey could not be validated by an experienced clinician.

Parents report favorable side effects profile

Quality of life surveys show that adverse effects of AEDs have as much of an impact on the patient's ability to enjoy life as the seizures themselves [20]. Our survey reports that cannabidiol-enriched cannabis is behaviorally well tolerated and may have beneficial effects on cognition and mood. Many parents reported that their children experienced better sleep, increased alertness, and better mood while taking cannabidiol-enriched cannabis. These beneficial side effects are rarely reported with pediatric use of other AEDs [21]. Additionally, many negative side effects commonly associated with AEDs, such as irritability, insomnia and aggressive behavior were notably absent from the parent reports on cannabidiol-enriched cannabis. Because of the apparent efficacy of cannabidiol-enriched cannabis, 12 parents reported weaning their child from other AEDs, thereby further increasing the child's quality of life by removing negative side effects associated with those other AEDs.

Bias Issues

We recognize that this survey has multiple biases that prevent us from making strong conclusions about the overall efficacy of cannabidiol-enriched cannabis in pediatric epilepsy. The positive reports on seizure control and side effects prompted us to investigate whether the wording of the questions produced a strong positive bias. We conducted an additional survey, using the same questions, of parents using stiripentol, a drug that is approved for treatment of Dravet syndrome in Europe. Our results from the stiripentol survey are consistent with published studies on the efficacy and tolerability of stiripentol [19]. Because the answers to the stiripentol survey match the published data on stiripentol's effects, it is unlikely that the wording of the survey questions was inherently biased. Still, there remains the bias of subject selection, in that the parents involved in the Facebook group were proponents of using cannabidiol-enriched cannabis for their children.

Use of medical cannabis poses risks

The new trend of medical cannabis use in children poses risks due to a lack of standardization and regulation, imprecise dosing and possible adverse side effects and medication interactions. A lack of regulation and standardization in the medical cannabis industry results in products that are of questionable quality and composition. Most parents reported using cannabis extracts, either purchased from a dispensary, or directly from a medical cannabis grower. Cannabis extracts are often inaccurately labeled and can contain highly variable levels of cannabidiol and THC. These extracts could also contain contaminants, such as fungus and pesticides, which may cause long-term organ damage. Further, while published reports on pure cannabidiol in animal models, as well as in humans with epilepsy, have demonstrated an anticonvulsant effect of cannabidiol, the data on THC's role in epilepsy is conflicting. In some cases, THC has been shown to be pro-convulsive [22]. Furthermore, animal studies have demonstrated that removal of THC from epileptic animals treated with THC can lead to hyperexcitability [8,22].

Future Directions

Because parents are increasingly using artisanal preparations of cannabidiol-enriched cannabis in an attempt to reduce the child's seizure burden, it is critical to obtain more data about the safety and efficacy of cannabidiol. These poorly regulated preparations may not represent the potential benefits and risks of pure cannabidiol. Formal studies to determine safety, optimal dosing, tolerability and efficacy of a standardized cannabidiol preparation in different populations of children and adults with epilepsy will provide the data necessary to determine whether cannabidiol has a place in epilepsy treatment.

Acknowledgments

The project described was supported by the Stanford University Institutional Epilepsy Training grant 5TSNS007280-27 and by the National Center for Research Resources and the National Center for Advancing Translational Sciences, National Institutes of Health, through grant UL1 RR025744. As of July 1st, 2013, Dr. Jacobson is a postdoctoral scholar at UCSF supported by GW Pharma. We would like to thank the Pediatric Cannabis Therapy and Dravet Syndrome Facebook groups for their participation in the surveys. We would also like to thank Dr. Orrin Devinsky for help in editing the manuscript.

Medicinal Cannabis: History, Pharmacology, And Implications for the Acute Care Setting

Mary Barna Bridgeman, PharmD, BCPS, BCGP; and Daniel T. Abazia, PharmD, BCPS, CPE

INTRODUCTION

Medicinal cannabis, or medicinal marijuana, is a therapy that has garnered much national attention in recent years. Controversies surrounding legal, ethical, and societal implications associated with use; safe administration, packaging, and dispensing; adverse health consequences and deaths attributed to marijuana intoxication; and therapeutic indications based on limited clinical data represent some of the complexities associated with this treatment. Marijuana is currently recognized by the U.S. Drug Enforcement Agency's (DEA's) Comprehensive Drug Abuse Prevention and Control Act (Controlled Substances Act) of 1970 as a Schedule I controlled substance, defined as having a high potential for abuse, no currently accepted medicinal use in treatment in the United States, and a lack of accepted safety data for use of the treatment under medical supervision.¹

Cannabis is the most commonly cultivated, trafficked, and abused illicit drug worldwide; according to the World Health Organization (WHO), marijuana consumption has an annual prevalence rate of approximately 147 million individuals or nearly 2.5% of the global population.² In 2014, approximately 22.2 million Americans 12 years of age or older reported current cannabis use, with 8.4% of this population reporting use within the previous month.^{3,4} General cannabis use, both for recreational and medicinal purposes, has garnered increasing acceptance across the country as evidenced by legislative actions, ballot measures, and public opinion polls; an October 2016 Gallup poll on American's views on legalizing cannabis indicated that 60% of the population surveyed believed the substance should be legalized.⁵ Further, a recent Quinnipiac University poll concluded 54% of American voters surveyed would favor the legalization of cannabis without additional constraints, while 81% of respondents favored legalization of cannabis for medicinal purposes.⁶ Limited data suggest that health care providers also may consider this therapy in certain circumstances.⁷⁻⁹ In the United States, cannabis is approved for medicinal use in 28 states, the District of Columbia, Guam, and Puerto Rico as of January 2017.¹⁰

The use and acceptance of medicinal cannabis continues to evolve, as shown by the growing number of states now permitting use for specific medical indications. The Food and Drug Administration (FDA) has considered how it might support the scientific rigor of medicinal cannabis claims, and the review of public data regarding safety and abuse potential

is ongoing.^{11,12} The purpose of this article is to review the historical significance of the use of medicinal cannabis and to discuss its pharmacology, pharmacokinetics, and select evidence on medicinal uses, as well as to describe the implications of evolving medicinal cannabis regulations and their effects on the acute care hospital setting.

HISTORICAL SIGNIFICANCE

Cannabis is a plant-based, or botanical, product with origins tracing back to the ancient world. Evidence suggesting its use more than 5,000 years ago in what is now Romania has been described extensively.¹³ There is only one direct source of evidence (Δ^6 -tetrahydrocannabinol [Δ^6 -THC] in ashes) that cannabis was first used medicinally around 400 AD.¹⁴ In the U.S., cannabis was widely utilized as a patent medicine during the 19th and early 20th centuries, described in the *United States Pharmacopoeia* for the first time in 1850. Federal restriction of cannabis use and cannabis sale first occurred in 1937 with the passage of the Marihuana Tax Act.^{15,16} Subsequent to the act of 1937, cannabis was dropped from the *United States Pharmacopoeia* in 1942, with legal penalties for possession increasing in 1951 and 1956 with the enactment of the Boggs and Narcotic Control Acts, respectively, and prohibition under federal law occurring with the Controlled Substances Act of 1970.^{1,17,18} Beyond criminalization, these legislative actions contributed to creating limitations on research by restricting procurement of cannabis for academic purposes.

In 1996, California became the first state to permit legal access to and use of botanical cannabis for medicinal purposes under physician supervision with the enactment of the Compassionate Use Act. As previously stated, as of January 1, 2017, 28 states as well as Washington, D.C., Guam, and Puerto Rico will have enacted legislation governing medicinal cannabis sale and distribution; 21 states and the District of Columbia will have decriminalized marijuana and eliminated prohibition for possession of small amounts, while eight states, including Alaska, California, Colorado, Maine, Massachusetts, Nevada, Oregon, and Washington, as well as the District of Columbia, will have legalized use of marijuana for adult recreation.^{10,19}

THE MEDICINAL CANNABIS DEBATE

As a Schedule I controlled substance with no accepted medicinal use, high abuse potential, concerns for dependence, and lack of accepted safety for use under medical supervision—along with a national stigma surrounding the potential harms and implication of cannabis use as a gateway drug to other substances—transitioning from a vilified substance to one with therapeutic merits has been controversial. The *United States Pharmacopoeia* and the FDA have considered the complexities

Medicinal Cannabis: History, Pharmacology, and Implications for the Acute Care Setting

of regulating this plant-based therapy, including the numerous compounds and complex interactions between substances in this product, and how it might fit into the current regulatory framework of drugs in United States.^{11,12,17}

The emergence of interest in botanical medicinal cannabis is thought by many to be a collateral effect of the opioid abuse epidemic; public perception surrounding the use of medicinal cannabis suggests that this plant-based therapy is viewed as not much different than a botanical drug product or supplement used for health or relief of symptoms if disease persists. Like some herbal preparations or supplements, however, medicinal cannabis may similarly pose health risks associated with its use, including psychoactive, intoxicating, and impairing effects, which have not been completely elucidated through clinical trials. Proponents argue that there is evidence to support botanical medicinal cannabis in the treatment of a variety of conditions, particularly when symptoms are refractory to other therapies; that beneficial cannabinoids exist, as evidenced by single-entity agents derived from cannabis containing the compounds THC and cannabidiol (CBD); that cannabis is relatively safe, with few deaths reported from use; that therapy is self-titratable by the patient; and that therapy is relatively inexpensive compared with pharmaceutical agents.^{20–22} Opponents of medicinal cannabis use argue, in part, that well-designed randomized trials to confirm benefits and harms are lacking; that it has not been subject to the rigors of the FDA approval process; that standardization in potency or quantity of pharmacologically active constituents is absent; that adverse health effects relate not only to smoking cannabis but to unmasking mental health disorders, impairing coordination, and affecting judgment; that standardization does not exist for product packaging and controls to prevent inadvertent use by minors or pets; that there is a potential for dependence, addiction, and abuse; and that costs pose a potential burden.^{23–25}

Regardless of personal views and perceptions, to deny or disregard the implications of use of this substance on patient health and the infrastructure of the health care system is irresponsible; clinicians must be aware of these implications and informed about how this therapy may influence practice in a variety of health care settings, including acute care.

PHARMACOLOGY

Endocannabinoids (eCBs) and their receptors are found throughout the human body: nervous system, internal organs, connective tissues, glands, and immune cells. The eCB system has a homeostatic role, having been characterized as “eat, sleep, relax, forget, and protect.”²⁶ It is known that eCBs have a role in the pathology of many disorders while also serving a protective function in certain medical conditions.²⁷ It has been proposed that migraine, fibromyalgia, irritable bowel syndrome, and related conditions represent clinical eCB deficiency syndromes (CEDs). Deficiencies in eCB signaling could be also involved in the pathogenesis of depression. In human studies, eCB system deficiencies have been implicated in schizophrenia, multiple sclerosis (MS), Huntington’s disease, Parkinson’s disease, anorexia, chronic motion sickness, and failure to thrive in infants.²⁸

The eCB system represents a microcosm of psychoneuroimmunology or “mind–body” medicine. The eCB system consists of receptors, endogenous ligands, and ligand metabolic

enzymes. A variety of physiological processes occur when cannabinoid receptors are stimulated. Cannabinoid receptor type 1 (CB₁) is the most abundant G-protein–coupled receptor. It is expressed in the central nervous system, with particularly dense expression in (ranked in order): the substantia nigra, globus pallidus, hippocampus, cerebral cortex, putamen, caudate, cerebellum, and amygdala. CB₁ is also expressed in non-neuronal cells, such as adipocytes and hepatocytes, connective and musculoskeletal tissues, and the gonads. CB₂ is principally associated with cells governing immune function, although it may also be expressed in the central nervous system.

The most well-known eCB ligands are N-arachidonylethanolamide (anandamide or AEA) and sn-2-arachidonoylglycerol (2-AG). AEA and 2-AG are released upon demand from cell membrane phospholipid precursors. This “classic” eCB system has expanded with the discovery of secondary receptors, ligands, and ligand metabolic enzymes. For example, AEA, 2-AG, N-arachidonoyl glycine (NAGly), and the phytocannabinoids Δ^9 -THC and CBD may also serve, to different extents, as ligands at GPR55, GPR18, GPR119, and several transient receptor potential ion channels (e.g., TRPV1, TRPV2, TRPA1, TRPM8) that have actions similar to capsaicin.²⁸ The effects of AEA and 2-AG can be enhanced by “entourage compounds” that inhibit their hydrolysis via substrate competition, and thereby prolong their action through synergy and augmentation. Entourage compounds include N-palmitylethanolamide (PEA), N-oleoylethanolamide (SEA), and cis-9-octadecenoamide (OEA or oleamide) and may represent a novel route for molecular regulation of endogenous cannabinoid activity.²⁹

Additional noncannabinoid targets are also linked to cannabis. G-protein–coupled receptors provide noncompetitive inhibition at mu and delta opioid receptors as well as norepinephrine, dopamine, and serotonin. Ligand-gated ion channels create allosteric antagonism at serotonin and nicotinic receptors, and enhance activation of glycine receptors. Inhibition of calcium, potassium, and sodium channels by noncompetitive antagonism occurs at nonspecific ion channels and activation of PPAR α and PPAR γ at the peroxisome proliferator-activated receptors is influenced by AEA.³⁰

THC is known to be the major psychoactive component of cannabis mediated by activation of the CB₁ receptors in the central nervous system; however, this very mechanism limits its use due to untoward adverse effects. It is now accepted that other phytocannabinoids with weak or no psychoactivity have promise as therapeutic agents in humans. The cannabinoid that has sparked the most interest as a nonpsychoactive component is CBD.³¹ Unlike THC, CBD elicits its pharmacological effects without exerting any significant intrinsic activity on CB₁ and CB₂ receptors. Several activities give CBD a high potential for therapeutic use, including antiepileptic, anxiolytic, anti-psychotic, anti-inflammatory, and neuroprotective effects. CBD in combination with THC has received regulatory approvals in several European countries and is under study in registered trials with the FDA. And, some states have passed legislation to allow for the use of majority CBD preparations of cannabis for certain pathological conditions, despite lack of standardization of CBD content and optimal route of administration for effect.³² Specific applications of CBD have recently emerged in pain (chronic and neuropathic), diabetes, cancer, and neuro-

Medicinal Cannabis: History, Pharmacology, and Implications for the Acute Care Setting

degenerative diseases, such as Huntington's disease. Animal studies indicate that a high dose of CBD inhibits the effects of lower doses of THC. Moreover, clinical studies suggest that oral or oromucosal CBD may prolong and/or intensify the effects of THC. Finally, preliminary clinical trials suggest that high-dose oral CBD (150–600 mg per day) may exert a therapeutic effect for epilepsy, insomnia, and social anxiety disorder. Nonetheless, such doses of CBD have also been shown to cause sedation.³³

PHARMACOKINETICS AND ADMINISTRATION

The three most common methods of administration are inhalation via smoking, inhalation via vaporization, and ingestion of edible products. The method of administration can impact the onset, intensity, and duration of psychoactive effects; effects on organ systems; and the addictive potential and negative consequences associated with use.³⁴

Cannabinoid pharmacokinetic research has been challenging; low analyte concentrations, rapid and extensive metabolism, and physicochemical characteristics hinder the separation of compounds of interest from biological matrices and from each other. The net effect is lower drug recovery due to adsorption of compounds of interest to multiple surfaces.³⁵ The primary psychoactive constituent of marijuana— Δ^9 -THC—is rapidly transferred from lungs to blood during smoking. In a randomized controlled trial conducted by Huestis and colleagues, THC was detected in plasma immediately after the first inhalation of marijuana smoke, attesting to the efficient absorption of THC from the lungs. THC levels rose rapidly and peaked prior to the end of smoking.³⁶ Although smoking is the most common cannabis administration route, the use of vaporization is increasing rapidly. Vaporization provides effects similar to smoking while reducing exposure to the byproducts of combustion and possible carcinogens and decreasing adverse respiratory syndromes. THC is highly lipophilic, distributing rapidly to highly perfused tissues and later to fat.³⁷ A trial of 11 healthy subjects administered Δ^9 -THC intravenously, by smoking, and by mouth demonstrated that plasma profiles of THC after smoking and intravenous injection were similar, whereas plasma levels after oral doses were low and irregular, indicating slow and erratic absorption. The time courses of plasma concentrations and clinical "high" were of the same order for intravenous injection and smoking, with prompt onset and steady decline over a four-hour period. After oral THC, the onset of clinical effects was slower and lasted longer, but effects occurred at much lower plasma concentrations than they did after the other two methods of administration.³⁸

Cannabinoids are usually inhaled or taken orally; the rectal route, sublingual administration, transdermal delivery, eye drops, and aerosols have been used in only a few studies and are of little relevance in practice today. The pharmacokinetics of THC vary as a function of its route of administration. Inhalation of THC causes a maximum plasma concentration within minutes and psychotropic effects within seconds to a few minutes. These effects reach their maximum after 15 to 30 minutes and taper off within two to three hours. Following oral ingestion, psychotropic effects manifest within 30 to 90 minutes, reach their maximum effect after two to three hours, and last for about four to 12 hours, depending on the dose.³⁹

Within the shifting legal landscape of medical cannabis, different methods of cannabis administration have important public health implications. A survey using data from Qualtrics and Facebook showed that individuals in states with medical cannabis laws had a significantly higher likelihood of ever having used the substance with a history of vaporizing marijuana (odds ratio [OR], 2.04; 99% confidence interval [CI], 1.62–2.58) and a history of oral administration of edible marijuana (OR, 1.78; 99% CI, 1.39–2.26) than those in states without such laws. Longer duration of medical cannabis status and higher dispensary density were also significantly associated with use of vaporized and edible forms of marijuana. Medical cannabis laws are related to state-level patterns of utilization of alternative methods of cannabis administration.³⁴

DRUG INTERACTIONS

Metabolic and pharmacodynamic interactions may exist between medical cannabis and other pharmaceuticals. Quantification of the *in vitro* metabolism of exogenous cannabinoids, including THC, CBD, and cannabidiol (CBN), indicates hepatic cytochrome 450 (CYP450) isoenzymes 2C9 and 3A4 play a significant role in the primary metabolism of THC and CBN, whereas 2C19 and 3A4 and may be responsible for metabolism of CBD.⁴⁰ Limited clinical trials quantifying the effect of the exogenous cannabinoids on the metabolism of other medications exist; however, drug interaction data may be gleaned from the prescribing information from cannabinoid-derived pharmaceutical products such as Sativex (GW Pharmaceuticals, United Kingdom) and dronabinol (Marinol, AbbVie [United States]).^{41,42} Concomitant administration of ketoconazole with oromucosal cannabis extract containing THC and CBD resulted in an increase in the maximum serum concentration and area under the curve for both THC and CBD by 1.2-fold to 1.8-fold and twofold, respectively; coadministration of rifampin is associated with a reduction in THC and CBD levels.^{40,41} In clinical trials, dronabinol use was not associated with clinically significant drug interactions, although additive pharmacodynamic effects are possible when it is coadministered with other agents having similar physiological effects (e.g., sedatives, alcohol, and antihistamines may increase sedation; tricyclic antidepressants, stimulants, and sympathomimetics may increase tachycardia).⁴¹ Additionally, smoking cannabis may increase theophylline metabolism, as is also seen after smoking tobacco.^{40,42}

ADVERSE EFFECTS

Much of what is known about the adverse effects of medicinal cannabis comes from studies of recreational users of marijuana.⁴³ Short-term use of cannabis has led to impaired short-term memory; impaired motor coordination; altered judgment; and paranoia or psychosis at high doses.⁴⁴ Long-term or heavy use of cannabis, especially in individuals who begin using as adolescents, has led to addiction; altered brain development; cognitive impairment; poor educational outcomes (e.g., dropping out of school); and diminished life satisfaction.⁴⁵ Long-term or heavy use of cannabis is also associated with chronic bronchitis and an increased risk of chronic psychosis-related health disorders, including schizophrenia and variants of depression, in persons with a predisposition to

Medicinal Cannabis: History, Pharmacology, and Implications for the Acute Care Setting

such disorders.^{46–48} Vascular conditions, including myocardial infarction, stroke, and transient ischemic attack, have also been associated with cannabis use.^{49–51} The use of cannabis for management of symptoms in neurodegenerative diseases, such as Parkinson's, Alzheimer's, and MS, has provided data related to impaired cognition in these individuals.^{52,53}

A systematic review of published trials on the use of medical cannabinoids over a 40-year period was conducted to quantify adverse effects of this therapy.⁵⁴ A total of 31 studies evaluating the use of medicinal cannabis, including 23 randomized controlled trials and eight observational studies, was included. In the randomized trials, the median duration of cannabinoid exposure was two weeks, with a range between eight hours and 12 months. Of patients assigned to active treatment in these trials, a total of 4,779 adverse effects were reported; 96.6% (4,615) of these were not deemed by authors to be serious. The most common serious adverse effects included relapsing MS (9.1%; 15 events), vomiting (9.8%; 16 events), and urinary tract infections (9.1%; 15 events). No significant differences in the rates of serious adverse events between individuals receiving medical cannabis and controls were identified (relative risk, 1.04; 95% CI, 0.78–1.39). The most commonly reported non-serious adverse event was dizziness, with an occurrence rate of 15.5% (714 events) among people exposed to cannabinoids.⁵⁴

Other negative adverse effects reported with acute cannabis use include hyperemesis syndrome, impaired coordination and performance, anxiety, suicidal ideations or tendencies, and psychotic symptoms, whereas chronic effects may include mood disturbances, exacerbation of psychotic disorders, cannabis use disorders, withdrawal syndrome, and neurocognitive impairments, as well as cardiovascular and respiratory conditions.⁵² Long-term studies evaluating adverse effects of chronic medicinal cannabis use are needed to conclusively evaluate the risks when used for an extended period of time.

MEDICINAL USES

Cannabis and cannabinoid agents are widely used to alleviate symptoms or treat disease, but their efficacy for specific indications is not well established. For chronic pain, the analgesic effect remains unclear. A systematic review of randomized controlled trials was conducted examining cannabinoids in the treatment of chronic noncancer pain, including smoked cannabis, oromucosal extracts of cannabis-based medicine, nabilone, dronabinol, and a novel THC analogue.⁵⁵ Pain conditions included neuropathic pain, fibromyalgia, rheumatoid arthritis, and mixed chronic pain. Fifteen of the 18 included trials demonstrated a significant analgesic effect of cannabinoids compared with placebo. Cannabinoid use was generally well tolerated; adverse effects most commonly reported were mild to moderate in severity. Overall, evidence suggests that cannabinoids are safe and moderately effective in neuropathic pain with preliminary evidence of efficacy in fibromyalgia and rheumatoid arthritis.⁵⁵

While there is not enough evidence to suggest routine use of medicinal cannabis for alleviating chemotherapy-related nausea and vomiting by national or international cancer societies, therapeutic agents based on THC (e.g., dronabinol) have been approved for use as an antiemetic in the United States for a number of years. Only recently has the efficacy and safety of

cannabis-based medicines in managing nausea and vomiting due to chemotherapy been evaluated. In a review of 23 randomized, controlled trials, patients who received cannabis-based products experienced less nausea and vomiting than subjects who received placebo.⁵⁶ The proportion of people experiencing nausea and vomiting who received cannabis-based products was similar to those receiving conventional antiemetics. Subjects using cannabis-based products experienced side effects such as “feeling high,” dizziness, sedation, and dysphoria and dropped out of the studies at a higher rate due to adverse effects compared with participants receiving either placebo or conventional antiemetics. In crossover trials in which patients received cannabis-based products and conventional antiemetics, patients preferred the cannabis-based medicines. Cannabis-based medications may be useful for treating chemotherapy-induced nausea and vomiting that responds poorly to conventional antiemetics. However, the trials produced low to moderate quality evidence and reflected chemotherapy agents and antiemetics that were available in the 1980s and 1990s.

With regard to the management of neurological disorders, including epilepsy and MS, a Cochrane review of four clinical trials that included 48 epileptic patients using CBD as an adjunct treatment to other antiepileptic medications concluded that there were no serious adverse effects associated with CBD use but that no reliable conclusions on the efficacy and safety of the therapy can be drawn from this limited evidence.⁵⁷ The American Academy of Neurology (AAN) has issued a Summary of Systematic Reviews for Clinicians that indicates oral cannabis extract is effective for reducing patient-reported spasticity scores and central pain or painful spasms when used for MS.⁵⁸ THC is probably effective for reducing patient-reported spasticity scores but is likely ineffective for reducing objective measures of spasticity at 15 weeks, the AAN found; there is limited evidence to support the use of cannabis extracts for treatment of Huntington's disease, levodopa-induced dyskinesias in patients with Parkinson's disease, or reducing tic severity in Tourette's.⁵⁸

In older patients, medical cannabinoids have shown no efficacy on dyskinesia, breathlessness, and chemotherapy-induced nausea and vomiting. Some evidence has shown that THC might be useful in treatment of anorexia and behavioral symptoms in patients with dementia. The most common adverse events reported during cannabinoid treatment in older adults were sedation-like symptoms.⁵⁹

Despite limited clinical evidence, a number of medical conditions and associated symptoms have been approved by state legislatures as qualifying conditions for medicinal cannabis use. Table 1 contains a summary of medicinal cannabis indications by state, including select disease states and qualifying debilitating medical conditions or symptoms.^{10,60,61} The most common conditions accepted by states that allow medicinal cannabis relate to relief of the symptoms of cancer, glaucoma, human immunodeficiency virus/acquired immunodeficiency syndrome, and MS. A total of 28 states, the District of Columbia, Guam, and Puerto Rico now allow comprehensive public medical marijuana and cannabis programs.¹⁰ The National Conference of State Legislatures uses the following criteria to determine if a program is comprehensive:

1. Protection from criminal penalties for using marijuana for a medical purpose;

Table adapted with permission from the Marijuana Policy Project;⁶⁰ table is not all-encompassing and other medical conditions for use may exist. The reader should refer to individual state laws regarding medicinal cannabis for specific details of approved conditions for use. In addition, states may permit the addition of approved indications; list is subject to change.

Medicinal Cannabis: History, Pharmacology, and Implications for the Acute Care Setting

2. Access to marijuana through home cultivation, dispensaries, or some other system that is likely to be implemented;
3. Allows a variety of strains, including more than those labeled as “low THC;” and
4. Allows either smoking or vaporization of some kind of marijuana products, plant material, or extract.

Some of the most common policy questions regarding medical cannabis now include how to regulate its recommendation and indications for use; dispensing, including quality and standardization of cultivars or strains, labeling, packaging, and role of the pharmacist or health care professional in education or administration; and registration of approved patients and providers.

REGULATORY IMPLICATIONS OF MEDICINAL CANNABIS

The regulation of cannabis therapy is complex and unique; possession, cultivation, and distribution of this substance, regardless of purpose, remain illegal at the federal level, while states that permit medicinal cannabis use have established individual laws and restrictions on the sale of cannabis for medical purposes. In a 2013 U.S. Department of Justice memorandum to all U.S. attorneys, Deputy Attorney General James M. Cole noted that despite the enactment of state laws authorizing marijuana production and sale having a regulatory structure that is counter to the usual joint efforts of federal authorities working together with local jurisdictions, prosecution of individuals cultivating and distributing marijuana to seriously ill individuals for medicinal purpose has not been identified as a federal priority.⁶²

There are, however, other regulatory implications to consider based on the federal restriction of cannabis. Physicians cannot legally “prescribe” medicinal cannabis therapy, given its Schedule I classification, but rather in accordance with state laws may certify or recommend patients for treatment. Medical cannabis expenses are not reimbursable through government medical assistance programs or private health insurers. As previously described, the Schedule I listing of cannabis according to federal law and DEA regulations has led to difficulties in access for research purposes; nonpractitioner researchers can register with the DEA more easily to study substances in Schedules II–V compared with Schedule I substances.⁶³ Beyond issues related to procurement of the substance for research purposes, other limitations in cannabis research also exist. For example, the Center for Medicinal Cannabis Research at the University of California–San Diego had access to funding, marijuana at different THC levels, and approval for a number of clinical research trials, and yet failed to recruit an adequate number of patients to conduct five major trials, which were subsequently canceled.⁶⁴ Unforeseen factors, including the prohibition of driving during the clinical trials, deterred patients from trial enrollment. The limited availability of clinical research to support or refute therapeutic claims and indications for use of cannabis for medicinal purposes has frequently left both state legislative authorities and clinicians to rely on anecdotal evidence, which has not been subjected to the same rigors of peer review and scrutiny as well-conducted, randomized trials, to validate the safety and efficacy of medicinal cannabis therapy. Furthermore, although individual single-entity pharmaceutical medications, such as dronabinol, have been isolated, evaluated, and approved for use

by the FDA, a plant cannot be patented and mass produced by a corporate entity.⁶⁵ Despite this limitation, some corporations, including GW Pharmaceuticals, are mass producing cannabis plants and extracting complex mixtures or single cannabinoids for clinical trials.⁶⁵ The complex pharmacology related to the numerous substances and interactions among chemicals in the cannabis plant coupled with environmental variables in cultivation further complicate regulation, standardization, purity, and potency as a botanical drug product.

RELEVANCE TO HOSPITAL PRACTITIONERS

Although the public has largely accepted medicinal cannabis therapy as having a benefit when used under a provider’s supervision, the implications of the use of this substance when patients transition into the acute care setting are additionally complex and multifaceted. The Schedule I designation of cannabis causes hospitals and other care settings that receive federal funding, either through Medicare reimbursement or other federal grants or programs, to pause to consider the potential for loss of these funds should the federal government intercede and take action if patients are permitted to use this therapy on campus. Similarly, licensed practitioners registered to certify patients for state medicinal cannabis programs may have comparable concerns regarding jeopardizing their federal DEA registrations and ability to prescribe other controlled substances as well as jeopardizing Medicare reimbursements. In 2009, U.S. Attorney General Eric Holder recommended that enforcement of federal marijuana laws not be a priority in states that have enacted medicinal cannabis programs and are enforcing the rules and regulations of such a program; despite this, concerns persist.

The argument for or against the use of medicinal cannabis in the acute care setting encompasses both legal and ethical considerations, with the argument against use perhaps seeming obvious on its surface. States adopting medical cannabis laws may advise patients to utilize the therapy only in their own residence and not to transport the substances unless absolutely necessary.⁶⁶ Further, many acute care institutions have policies prohibiting smoking on facility grounds, thus restricting the smoking of cannabis, regardless of purpose or indication. Of note, several Canadian hospitals, including Montreal’s Jewish General Hospital and Quebec’s Centre Hospitalier Universitaire de Sherbrooke, have permitted inpatient cannabis use via vaporization; the pharmacy departments of the respective institutions control and dispense cannabis much like opioids for pain. Canada has adopted national regulations to control and standardize dried cannabis for medical use.^{67,68} There are complicated logistics for self-administration of medicinal cannabis by the patient or caregiver; in particular, many hospitals have policies on self-administration of medicines that permit patients to use their own medications only after identification and labeling by pharmacy personnel. The argument can be made that an herb- or plant-based entity cannot be identified by pharmacy personnel as is commonly done for traditional medicines, although medicinal cannabis dispensed through state programs must be labeled in accordance with state laws. Dispensing and storage concerns, including an evaluation of where and how this product should be stored (e.g., within the pharmacy department and treated as a controlled substance, by security personnel, or with the patient); who should admin-

Medicinal Cannabis: History, Pharmacology, and Implications for the Acute Care Setting

ister it, and implications or violations of federal law by those administering treatment; what pharmaceutical preparations should be permitted (e.g., smoked, vaporized, edible); and how it should be charted in the medical record represent other logistical concerns. Inpatient use of medicinal cannabis also carries implications for nursing and medical staff members. The therapy cannot be prescribed, and states may require physicians authorizing patient use to be registered with local programs. In a transition into the acute care setting from the community setting, a different clinician who is not registered could be responsible for the patient's care; that clinician would be restricted in ordering continuation of therapy.

Despite the complexities in the logistics of continuing medicinal cannabis in the acute care setting, proponents of palliative care and continuity of care argue that prohibiting medicinal cannabis use disrupts treatment of chronic and debilitating medical conditions. Patients have been denied this therapy during acute care hospitalizations for reasons stated above.⁶⁹ Permission to use medicinal cannabis in the acute care setting may be dependent on state legislation and restrictions imposed by such laws. Legislation in Minnesota, as one example, has been amended to permit hospitals as facilities that can dispense and control cannabis use; similar legislative actions protecting nurses from criminal, civil, or disciplinary action when administering medical cannabis to qualified patients have been enacted in Connecticut and Maine.^{70–73} Proposed legislation to remove restrictions on the certification of patients to receive medicinal cannabis by doctors at the Department of Veterans Affairs was struck down in June; prohibitions continue on the use of this therapy even in facilities located in states permitting medicinal cannabis use.⁷⁴

CONCLUSION

Despite lingering controversy, use of botanical cannabis for medicinal purposes represents the revival of a plant with historical significance reemerging in present day health care. Legislation governing use of medicinal cannabis continues to evolve rapidly, necessitating that pharmacists and other clinicians keep abreast of new or changing state regulations and institutional implications. Ultimately, as the medicinal cannabis landscape continues to evolve, hospitals, acute care facilities, clinics, hospices, and long-term care centers need to consider the implications, address logistical concerns, and explore the feasibility of permitting patient access to this treatment. Whether national policy—particularly with a new presidential administration—will offer some clarity or further complicate regulation of this treatment remains to be seen.

Parkinson's disease (PD), a neurodegenerative disorder, is the second most common neurological illness in United States. Neurologically, it is characterized by the selective degeneration of a unique population of cells, the nigrostriatal dopamine neurons. The current treatment is symptomatic and mainly involves replacement of dopamine deficiency. This therapy improves only motor symptoms of Parkinson's disease and is associated with a number of adverse effects including dyskinesia. Therefore, there is unmet need for more comprehensive approach in the management of PD. Cannabis and related compounds have created significant research interest as a promising therapy in neurodegenerative and movement disorders. In this review we examine the potential benefits of medical marijuana and related compounds in the treatment of both motor and nonmotor symptoms as well as in slowing the progression of the disease. The potential for cannabis to enhance the quality of life of Parkinson's patients is explored.

1. Introduction

Marijuana, the crude product (dried flowers, stems, seeds, and leaves) derived from the cannabis sativa plant, consists of more than 85 phytocannabinoids [1, 2]. The term phytocannabinoids is used to differentiate these plant-derived cannabinoids from the synthetic cannabinoids and the structurally different endogenous cannabinoids (endocannabinoids). Among the phytocannabinoids, Cannabidiol (CBD) and Δ^9 -Tetrahydrocannabinol (Δ^9 -THC, THC) are the major constituents of marijuana [3]. Δ^9 -THC is a psychoactive agent with analgesic and muscle relaxant property [3, 4]. While CBD is a nonpsychoactive compound and has been shown to have hypnotic, anxiolytic, antipsychotic, antioxidant, and neuroprotective effects [5], THC is a partial agonist at the cannabinoid receptor 1 (CB1) and receptor 2 (CB2). Unlike Δ^9 -THC, CBD has antagonistic/inverse agonistic property at CB1 receptor and appears to modulate Δ^9 -THC-associated side effects including anxiety, tachycardia, and hunger [3]. CBD also appears to potentiate the effect of endocannabinoids by inhibiting their inactivation, thereby alleviating psychotic symptom [6].

Despite the placement of marijuana in the schedule 1 category under the US Federal Controlled Substance Act [7] and the US Federal Government's continued opposition on its legalization, 24 states and Washington DC have enacted laws allowing marijuana to treat certain medical conditions [8]. The range and types of disease conditions for which medical marijuana have been approved vary from state to state. The most common disease conditions approved by the states include cancer, HIV/AIDS, glaucoma, chronic and/or severe pain, seizure/epilepsy, cachexia, and multiple sclerosis. Moreover, two cannabinoids (dronabinol and nabilone) have been approved by the FDA for clinical use. The synthetically produced Δ^9 -THC, dronabinol (Marinol®), is a schedule III drug, which is indicated in the treatment of chemotherapy-induced nausea and emesis as well as anorexia associated with weight loss in AIDS patients. A synthetic cannabinoid, nabilone (Cesamet®), is a schedule II drug that is indicated for the treatment of nausea and vomiting associated with cancer chemotherapy. Another cannabinoid, Cannabidiol (Epidiolex®), is in a clinical trial for the treatment of drug-resistant epilepsy in children [9]. A phytocannabinoid preparation, nabiximols (Sativex®), has been approved for the

treatment of spasticity due to multiple sclerosis in a number of countries outside the United States. Nabiximols is an extract of *Cannabis sativa* L that consists of mainly THC and CBD [10, 11].

Although recent studies have provided strong evidence for the therapeutic benefit of medical marijuana [12–16], increasing access to cannabis and/or cannabinoids can result in side effects such as addiction, respiratory illness, and decline in cognitive processing. Cannabis use has been indicated as a potential cause, aggravator, or masker of major psychiatric symptoms, including psychotic, depressive, and anxiety disorders, particularly in young people [17–19]. Other negative effects include working memory deficits, reduced attention and processing speed, anhedonia, abnormal social behavior, and susceptibility to mood and anxiety disorders [20, 21]. While adult users seem comparatively resistant to cannabis-induced behavioral and brain morphologic changes, the individuals who start using cannabis during their early teens can have more severe and more long-lasting effects [22].

The target of medical marijuana and its constituents is the endocannabinoid system, which is involved in the modulation of a number of physiological functions. The endocannabinoid system includes the endocannabinoids, the cannabinoid receptors, and the enzymes involved in the biosynthesis and inactivation of the endocannabinoids [23]. The cannabinoid receptors are mainly expressed in the central nervous system and the immune system, but they have also been identified in a number of other parts of the body including the cardiovascular system, the peripheral nervous system, the reproductive system, and the gastrointestinal tract. Due to its wide distribution and effects on a range of biological process, the cannabinoid system has become an attractive target for the development of drugs that can potentially be used for the treatment of a number of pathological conditions including mood disorders and movement disorders such as PD [24]. Components of the endocannabinoid system are abundant in the striatum and other parts of the basal ganglia and play a crucial role in modulating dopamine activity and motor functions [25–27].

Parkinson's disease (PD) is the second most common neurodegenerative disorder following Alzheimer's disease and the 14th leading cause of death in all age groups in the United States [28]. The prevalence of PD increases with age and is shown to be higher in males than females in some age groups [29]. The number of people with PD is projected at approximately 9 million by 2030 in the 15 most populous countries in the world [30, 31]. Neurologically PD is characterized by the destruction of dopaminergic cells in the pars compacta region of the substantia nigra in the midbrain, resulting in dopamine deficiency in the nerve terminals of the striatum in the forebrain [32]. These changes cause impairments not just to the motor system but also to the cognitive and neuropsychological systems [33]. The nigrostriatal pathway is one of the dopamine pathways in the brain that regulates movement. The exact cause for the loss of neuronal cells is unknown, and the trigger of dopaminergic degeneration seems to be multifactorial including environmental factors and genetic susceptibilities

[34–36]. Clinically, PD is characterized by resting tremor, muscle rigidity, bradykinesia, and postural instability [32, 34, 37, 38] and it is also associated with a number of nonmotor symptoms including depression, anxiety, constipation, orthostatic hypotension, fatigue, and sleep disorders, as well as, in advanced disease, dementia [39–44]. Although dopamine deficiency accounts for the major motor symptoms of the disease, loss of noradrenergic and serotonergic nerve terminals in the limbic system may account for several of the nonmotor features seen in Parkinson's disease [45, 46].

Current therapy involves treatment of motor symptoms of PD through replacement of dopamine deficiency [47]. This includes (1) enhancement of the synthesis of brain dopamine by administration of levodopa, a dopamine precursor, (2) direct stimulation of dopamine receptors, (3) decreasing dopamine catabolism, and (4) stimulation of dopamine release and inhibition of dopamine reuptake from presynaptic sites. Another therapy involves restoring the normal balance of cholinergic and dopaminergic actions on the basal ganglia using anticholinergic drugs [47–49].

However these drugs treat only motor symptoms of Parkinson's disease and are associated with a number of adverse effects. Long-term use of levodopa, the mainstay therapy for PD, is associated with motor fluctuations [50] and levodopa-induced dyskinesia [51–53]. The monoamine oxidase B (MAO-B) inhibitors (selegiline and rasagiline) as well as inhibitors of catechol-o-methyltransferase, COMT (tolcapone and entacapone), are used mostly to reduce the motor fluctuations associated with levodopa therapy due to their levodopa-sparing effect [54–59]. Several dopamine agonists including pramipexole, ropinirole, rotigotine, and apomorphine are used as monotherapy in early stage of Parkinson disease or as adjunctive therapy with levodopa in patients with advanced PD in order to reduce motor fluctuations [56, 60–64]. In addition to their limited efficacy on motor symptoms and their adverse effects, drugs that are currently used for the treatment of PD do not have an effect on disease progression. Therefore, there is an urgent need for the development of safer drugs that treat both the motor and nonmotor symptoms of PD as well as drugs that slow the progression of the disease.

Medical marijuana has been demonstrated to improve motor symptoms including tremor, rigidity, and bradykinesia as well as nonmotor symptoms such as pain and sleep disorders of PD in observational studies [65]. Survey of PD patients in Colorado, USA, also indicated the beneficial effects of marijuana in alleviating nonmotor symptoms of PD [66]. Cannabidiol (CBD), one of the major constituents of marijuana, has been shown to be effective in the treatment of psychosis and sleep disorders in PD patients [67–69]. Another phytocannabinoid, Δ^9 -tetrahydrocannabinol (Δ^9 -THCV, THCV), was studied in animal disease model of PD and found to have neuroprotective and symptom-relieving effects [70]. Therefore, marijuana may provide an alternative or add-on therapy for Parkinson's disease. In addition, Parkinson's disease has been listed as one of the disease conditions for which medical marijuana is allowed in Connecticut, Illinois, Massachusetts, New Hampshire, New

Mexico, and New York. However, it may also be covered under chronic illnesses in several other states.

In this review we seek to investigate any scientific evidence that indicates the potential use of marijuana and/or its components for the treatment of Parkinson's disease. The review aims to (i) examine briefly current treatment and the unmet need of PD therapy, (ii) assess the role of the cannabinoid system in the modulation of movement and neuroprotection, (iii) look at the mechanism of action of marijuana constituents in the modulation of movement and PD-associated disorders, (iv) assess other beneficial effects of marijuana that contribute to the amelioration of PD, and (v) gather scientific evidence on the clinical benefit of marijuana and/or its constituents in PD patients.

2. Marijuana and Its Influence on the Endocannabinoid System

Cannabis has been used to treat disease since ancient times. Marijuana is derived from the *Cannabis sativa L.* plant. Marijuana contains the active chemicals known as cannabinoids. At least 85 cannabinoids have been identified as unique compounds in *Cannabis* [1]. The therapeutic potential of many of these ligands still remains largely unexplored prompting a need for further research. The chemicals responsible for the medicinal effects of marijuana are D9-Tetrahydrocannabinol (THC) and Cannabidiol (CBD) [71, 72]. THC is the major psychoactive ingredient, acting primarily upon the central nervous system where it affects brain function. CBD is the major nonpsychoactive ingredient in cannabis and produces neuroprotective and anti-inflammatory effects [73]. Both compounds, TCH and CBD, have anticonvulsant properties [74]. Cannabinoids have also potential to alleviate motor disorders by reducing motor impairments and neuron degeneration [75]. In addition, cannabinoids have been shown to be effective in preclinical studies involving excitotoxicity, oxidative stress, neuroinflammation, and motor complications associated with PD [76].

Some cannabinoids (endocannabinoids or ECBs) are found in the body. Initially, ECBs were discovered in the brain and subsequently in the periphery in humans and animals. Endocannabinoids are produced by cultured neurons [77], microglia, and astrocytes [78]. ECBs interact with the endocannabinoid system and aid in regulation of memory, pleasure, concentration, thinking, movement and coordination, sensory and time perception, appetite, and pain [24, 79, 80]. The ECBs activate two guanine nucleotide-binding protein-(G-protein-) coupled cell membrane receptors, consequently named the cannabinoid type 1 (CB1) and type 2 (CB2) receptors [81]. CB1 receptors are located primarily in the central and peripheral neurons and CB2 receptors are predominantly found in immune cells [82]. CB1 receptors are important mediators in signaling pathways and have been identified on both glutamatergic and gamma-aminobutyric (GABA) neurons [83]. It is believed that one important role of the neuronal CB1 component is to modulate neurotransmitter release in a manner that maintains homeostasis by preventing the development of excessive neuronal activity in the central

nervous system [82]. Animal models illustrate that activation of the CB1 receptor by their endogenous ligands can result in prominent neuroprotective effects and may prevent epileptic seizures [84]. Other studies suggest that activation of CB1 receptors offers neuroprotection against dopaminergic lesion and the development of L-DOPA-induced dyskinesias [85]. CB2 receptors are closely related to CB1 and are mainly expressed on T cells of the immune system, on macrophages and B cells, and in hematopoietic cells [86]. They are also expressed on peripheral nerve terminals where these receptors play a role in antinociception and the relief of pain [87]. In the brain, CB2 receptors are mainly expressed by microglial cells, where their role remains unclear [88].

The major identified ECBs are arachidonoyl ethanolamide (anandamide, AEA), 2-arachidonoyl glycerol (2-AG), O-arachidonoyl ethanolamine (virodhamine), and 2-arachidonoyl glyceryl ether (noladin ether) [89]. Both AEA and 2-AG are specific ligands of CB1 and CB2 receptors. Besides having activity on CB1 and CB2 receptors, AEA also has full agonistic activity at TRPV1 receptor [90]. AEA is localized in the brain and periphery [91]. In the brain AEA shows high distribution in the hippocampus, thalamus, striatum, and brainstem and to a lesser extent in the cerebral cortex and cerebellum [92]. Lower concentrations of AEA are found in human serum, plasma, and cerebrospinal fluid [93]. Similarly, 2-AG is observed in both the brain and periphery, although its concentration is almost 150 times higher in brain compared to that of AEA [92, 94, 95]. 2-AG has greater potency, stability, and agonistic activity at CB1 and CB2 receptors compared to that of AEA [96, 97]. Two prominent areas involved in the control of movement, such as the globus pallidus and the substantia nigra, contain not only the highest densities of CB1 receptors [88], but also the highest levels of ECBs, especially AEA [98, 99]. Tissue levels of AEA are regulated by fatty acid amide hydrolase (FAAH) [100]. It has also been shown that the basal ganglia contain the precursor of AEA [98, 99], supporting the theory of in situ synthesis for this compound. Studies have demonstrated that AEA synthesis is regulated by dopaminergic D2 receptors in the striatum, suggesting that the endocannabinoid system acts as an inhibitory feedback mechanism countering the dopamine-induced facilitation of motor activity [101].

Marijuana compound THC is CB₁ and CB₂ receptor partial agonist [82]. Due to the structural similarity of natural cannabinoid THC to the endogenous cannabinoid AEA, many therapeutic advantages of THC have been identified, such as lowering ocular pressure, inhibiting smooth muscle contractions, and increasing appetite [102]. When smoked, THC is rapidly absorbed from the lungs into the bloodstream and has an effect on the cannabinoid receptors. The central nervous system and specific areas of the brain contain the highest concentration of cannabinoid receptors. Therefore, cannabis or THC administration can create an overexcitation of the system that results in altered perceptions, pleasure, and mood [103].

Unlike THC, CBD has little affinity for CB1 and CB2 receptors but acts as an indirect antagonist of cannabinoid agonists. While this should cause CBD to reduce the effects of THC, it may potentiate THC's effects by increasing CB1

receptor density or through another CBI-related mechanism [73]. CBD is also an inverse agonist of CB2 receptors. CBD can counteract some of the functional consequences of CBI activation in the brain, possibly by indirect enhancement of adenosine A1 receptors activity through equilibrative nucleoside transporter (ENT) inhibition [73]. CBD helps to augment some of THC's beneficial effects, as it reduces the psychoactivity of THC, enhances its tolerability, and widens THC's therapeutic window [104].

Other cannabinoids can also contribute to the cannabis medicinal effects. Studies in experimental models and humans have suggested anti-inflammatory, neuroprotective, anxiolytic, and antipsychotic properties of chemicals extracted from marijuana [6, 15, 82, 105, 106].

3. Cannabinoids and Parkinson's Disease

3.1. Changes in the Cannabinoid System in Parkinson's Disease. Recent data from several studies indicate the important role of the endocannabinoid system in Parkinson's disease. The components of the endocannabinoid system are highly expressed in the neural circuit of basal ganglia, which is part of a complex neuronal system. This neuronal system coordinates activities from different cortical regions that directly or indirectly participate in the control of movement [107, 108]. In the basal ganglia, the endocannabinoid system bidirectionally interacts with dopaminergic, glutamatergic, and GABAergic signaling systems [109]. Endocannabinoids play a dominant role in controlling transmission at synapses between cortical and striatal neurons, in mediating the induction of a particular form of synaptic plasticity, and in modulating basal ganglia activity and motor functions [110]. The progressive loss of dopaminergic neurons that occurs in PD leads to lower striatal levels of dopamine. These low levels of dopamine result in the alteration of the equilibrium between the direct and the indirect basal ganglia pathways and ECB signaling [111].

The cannabinoid signaling system mentioned above experiences a biphasic pattern of changes during the progression of PD [112]. Early and presymptomatic PD stages, characterized by neuronal malfunction with little evidence of neuronal death, are associated with desensitization/down-regulation of CBI receptors and aggravation of various cytotoxic insults such as excitotoxicity, oxidative stress, and glial activation [113]. However, intermediate and advanced stages of PD, characterized by a deep nigral degeneration and manifestation of major Parkinsonian symptoms, are associated with upregulatory responses of CBI receptors and the endocannabinoid ligands [113]. This could explain the potential of CBI receptor ligands in alleviating common PD symptoms.

In the brain, CBI receptors are expressed by GABAergic neurons innervating the external and internal segments of the globus pallidus and the substantia nigra [114–116]. CBI receptors are also present in the corticostriatal glutamatergic terminals and in the excitatory projections from the subthalamic nucleus to the internal segment of the globus pallidus and the substantia nigra [114–116]. Within the striatum, CBI receptors

are expressed in parvalbumin immune-reactive interneurons, cholinergic interneurons, and nitric oxide synthase-positive neurons [117, 118]. Animal models of Parkinson's disease show an increase in the density of CBI receptors, levels of endogenous ligands, and CBI receptor binding in the basal ganglia [119–122]. Endogenous cannabinoids activate CBI receptors on presynaptic axons and reduce neurotransmitter and glutamate release, working as retrograde synaptic messengers released from postsynaptic neurons [123]. Similarly, activation of CBI receptors inhibits both glutamate release from substantia nigra afferents and GABA release from striatal afferents. At the same time, activation of presynaptic CBI receptors in the external segments of the globus pallidus can increase local GABA levels by reducing GABA reuptake from striatal afferents to the nucleus and decrease GABA release from striatal afferents of the substantia nigra [114, 116, 118]. Based on these evidences, it is thought that the function of the basal ganglia neuronal system is controlled by ECB. The presence of endocannabinoid systems in different neural structures and their interaction with dopaminergic, glutamatergic, and GABAergic neurotransmitter signaling systems make the components of endocannabinoid system ideal targets for a novel nondopaminergic treatment of PD.

Endocannabinoid signaling is also bidirectionally linked to dopaminergic signaling within the basal ganglia [118]. The CBI, D1, and D2 dopamine receptors are localized in the striatum [114, 115]. In animal models, CBI and D2 dopamine receptors share a common pool of G proteins, suggesting the link of their signal transduction mechanisms [124, 125]. In addition, D2 receptor stimulation resulted in release of ECBs in the striatum [101]. However, stimulation of CBI receptors completely inhibited D1-dopamine receptor mediated activation of adenylyl cyclase and decreased GABA release from striatal afferents of dopaminergic neurons of the substantia nigra resulting in an increased firing of these cells [114–116].

Another receptor involved in control of movement is transient receptor potential vanilloid type 1 (TRPV1), which is expressed in sensory neurons and basal ganglia circuitry of dopaminergic neurons [126, 127]. TRPV1 receptors are molecular integrators of nociceptive stimuli activated by endovanilloids [128]. TRPV1 also interacts with ECB. In particular, anandamide is one of the major endogenous activators of TRPV1 [129–131]. Studies have revealed that motor behavior can be suppressed by the activation of vanilloid receptors [98, 99], suggesting that TRPV1 receptors might play a role in the control of motor function.

3.2. Preclinical Data on the Endocannabinoid System as a Target for Parkinson's Disease Therapy. The association of cannabinoids with regulation of motor functions is well established [132–135]. The effect of the cannabinoids on motor activity depends on the impact of the endocannabinoid system on the dopaminergic, glutamatergic, and GABAergic signaling systems throughout the basal ganglia [112, 136]. The high density of cannabinoid, dopamine, and vanilloid-like receptors coupled with ECBs within the basal ganglia and cerebellum suggests a potential therapeutic role for the

cannabinoids in the control of voluntary movement and in movement disorders such as Parkinson's disease [98, 99, 121, 137]. Additional indications of an important role of the endocannabinoid system in the control of movement involve an inhibitory action of cannabinoids through fine tuning of various classical neurotransmitters activity [138], prominent changes in transmission of ECBs in the basal ganglia [139], and alteration of the CB1 binding as well as CB1 availability in the substantia nigra [85, 112, 119, 120, 140, 141]. These data support the idea that cannabinoid- based compounds act on vital pathways of endocannabinoid transmission and therefore might be of therapeutic interest due to their potential to diminish motor symptoms in extrapyramidal disorders such as Parkinson's disease [27, 76, 142].

Research with cannabinoid agonists and antagonists demonstrates that the cannabinoids can modulate motor activity and produce alterations in corresponding molecular correlates [129, 143–145]. It has been widely reported that synthetic, plant-derived, or endogenous cannabinoid agonists exert a powerful motor inhibition in laboratory species [129, 144, 146–149]. This hypokinetic effect was shown to be mediated by the activation of CB1 receptors in neurons of the basal ganglia circuitry [88, 137, 141, 150–152]. Stimulation of the CB1 receptor by a synthetic cannabinoid HU-210 decreased spontaneous glutamatergic activity and reduced the rotations induced by levodopa/carbidopa by 34% in PD rats [153, 154]. Administration of CB1 receptor agonists THC and two synthetic cannabinoids WIN 55,212-2 and CP 55,940 increased extracellular dopamine concentrations in rats [152, 155, 156]. WIN 55,212-2 and CP 55,940 also weakened contralateral rotations induced by a selective D₁/D₅ receptor partial agonist SKF38393 without developing catalepsy in PD rats [148]. In a gender study THC produced an increase in tyrosine hydroxylase activity in parkin-null male mice (a model of early stages of PD) and caused a motor inhibition that was significantly greater compared to wild-type animals [122]. Treatment with THC inhibited motor activity and produced catalepsy in rats [109, 144, 146, 147] and caused antinociception and ring immobility in mice [157]. In other studies THC diminished the motor inhibition caused by 6-hydroxydopamine [70] and potentiated the hypokinetic effect of reserpine in rats more than 20-fold [135]. However, in a primate model of Parkinson's disease THC did not affect locomotor activity but increased bradykinesia [125].

Administration of WIN 55,212-2 increased stimulation of GTPγ_s binding in the caudate nucleus, putamen, globus pallidus, and substantia nigra of marmosets, indicating an effective activation of CB1 signaling mechanisms [119, 120]. WIN 55,212-2 produced a dose-dependent reduction of the spontaneous motor activity and catalepsy in mutant Syrian hamsters, increased antidystonic efficacy of benzodiazepines [158], and significantly reduced the antikinetic effects of quinpirole in the reserpine-treated rats [159]. Treatment with WIN 55,212-2 also reduced levodopa-induced dyskinesias, attenuated axial, limb, and severe orolingual abnormal involuntary movements in 6-hydroxydopamine- (6-OHDA-) lesioned rats [160–163]. An endogenous cannabinoid agonist oleylethanolamide (OAE) produced reduction in dyskinetic contralateral rotations correlated with reduction of molecular

associates of L-DOPA-induced dyskinesia: reduced FosB striatal overexpression and phosphoacetylation of histone 3 [164]. Another synthetic agonist levonantradol decreased general and locomotor activity and increased bradykinesia in a primate model of Parkinson's disease [125]. Nabilone, a synthetic cannabinoid agonist, coadministered with levodopa significantly decreased total dyskinesia compared with levodopa alone treatment and increased the duration of antiparkinsonian action of levodopa by 76% in PD marmosets [165, 166].

Cannabinoid agonist anandamide (AEA) and its synthetic analog methanandamide increased the extracellular dopamine levels in the nucleus accumbens shell of rats by the activation of the mesolimbic dopaminergic system [167]. This dopamine increase was inhibited by the cannabinoid CB1 receptor antagonist rimonabant [167]. However, recent discoveries indicate that AEA is also able to activate vanilloid VR(1) receptors and that the activation of these receptors might also be responsible for changes in nigrostriatal dopaminergic activity and anandamide-induced hypokinesia [168–170]. AEA produced a tonic facilitation of glutamate release in the substantia nigra via stimulation of VRI receptors, indicating the involvement of this receptor in motor and cognitive functions of the dopaminergic system [171]. Preclinical data have shown that AEA decreased the activity of nigrostriatal dopaminergic neurons and produced hypokinesia that was completely reversed by an antagonist of vanilloid-like receptors, capsazepine [129]. Additional studies have demonstrated that AEA inhibited ambulation and stereotypic behavior, increased inactivity, and occluded the effects of an agonist of vanilloid VR₁ receptors, livanil, on locomotion in mice, suggesting a common mechanism of action for the two compounds [170]. Treatment with anandamide lowered motor activity with the maximal inhibition by approximately 85% and produced hypothermia and analgesia in mice, increased the inactivity time, and markedly decreased the ambulation and the frequency of spontaneous non-ambulatory activities in rats [146, 147, 172, 173]. Moreover, AEA produced a decrease in spontaneous motor activity in laboratory animals similar to the reported actions of THC [129, 145, 153, 170]. The hypokinetic actions of AEA were boosted by coadministration with a selective inhibitor of endocannabinoid uptake N-(3-furylmethyl) eicosa-5,8,11,14-tetraenamide, UCM707 [174].

Tissue concentrations of endocannabinoids are important for producing motor effects. Levels and activities of AEA and 2-AG can be manipulated by inhibition of FAAH enzyme, the action of which is reduced in experimental models of PD [153, 175]. Animal studies have shown that the FAAH enzyme inhibitor [3-(3-carbamoylphenyl) phenyl] N-cyclohexylcarbamate (URB597) magnified and prolonged a rapid, brief dopamine increase that was produced by AEA [167]. Additional studies have confirmed that FAAH inhibition remarkably increases AEA tissue levels but reduces 2-AG levels [176, 177]. To determine whether FAAH inhibition has beneficial impact on PD symptoms the effect of the FAAH inhibitor, URB597, was studied in MPTP- lesioned marmosets. Treatment with URB597 increased plasma levels

of AEA, did not modify the antiparkinsonian actions of L-DOPA, and reduced the magnitude of hyperactivity to levels equivalent to those seen in normal animals [178]. In PD mice URB597 prevented induced motor impairment [179]. Moreover, other FAAH inhibitors, JNJ1661010 and TCF2, also have anticataleptic properties [179]. These results reveal that FAAH inhibition may represent a new strategy for treatment of PD.

Overall, these results indicate that endogenous or exogenous cannabinoid agonists activate the dopaminergic system and play a very important role in modulation of motor behavior [180]. In addition to the effects on movement activity, cannabinoid agonists have demonstrated neuroprotective properties, suggesting that the cannabinoids have a promising pharmacological profile for not only improving Parkinsonian symptoms but also delaying PD progression [70, 85, 181–183].

The CB1 receptor antagonists can also influence movement syndromes of Parkinson's disease suggesting that modulation of the CB1 signaling system might be valuable in treatment of motor disorders. In a study with PD rats rimobabant (SR141716A), a selective antagonist of CB1 receptors has shown the potential to act as an antihypokinetic agent by enhancing glutamate release from excitatory afferents to the striatum [184]. Moreover, SR141716A prevented the effects of THC on dopamine release [156, 167] and also increased the locomotor activity in mice and rats preexposed to THC [170, 185]. SR141716A produced a 71% increase in motor activity in MPTP-lesioned marmosets with LID [136]. Coadministration of SR141716A with levodopa resulted in significantly less dyskinesia than administration of levodopa alone [136, 160]. SR141716A also reversed effect of the cannabinoid agonist WIN 55,212-2 and increased the locomotor activity in 6-OHDA-lesioned animals [159, 163]. Coadministration of SR141716A with a selective D₂/D₃ receptor agonist quinpirole reduced levels of AEA and 2AG by sevenfold in the globus pallidus, boosted the locomotive effects of quinpirole, and produced restoration of locomotion in animal models of Parkinson's disease [98, 99, 101, 136, 186]. In parkin-null mice SR141716A produced a decrease in tyrosine hydroxylase activity in the caudate-putamen and as result formed a hyperkinetic response [122]. However, SR141716A did not alleviate the motor deficits in a primate model of Parkinson's disease [125].

Another CB1 receptor antagonist AM251 and SR141716A produced antiparkinsonian effects in rats with very severe nigral degeneration (>95% cell loss) [187]. Local administration of these antagonists into denervated striatum, globus pallidus, and subthalamic nucleus reduced motor asymmetry in Parkinsonian rats [187, 188], which was inhibited by CB1 receptor agonist AM404 [187]. Another CB1 antagonist CE-178253 produced a 30% increase in motor behavior responses to L-DOPA in MPTP-treated rhesus monkeys but did not modify levodopa-induced dyskinesias [189]. THCV caused changes in glutamatergic transmission and attenuated the motor inhibition in PD rats [70]. Overall, these findings suggest that cannabinoid CB1 antagonists might be therapeutically effective in the control of Parkinson's disease and levodopa-induced dyskinesia [114, 190].

The activation of CB2 receptors might also contribute to some extent to the potential of cannabinoids in PD [191]. THCV, which is not only a CB1 antagonist but also a CB2 partial agonist, reduced the loss of tyrosine hydroxylase-positive neurons in the substantia nigra with preservation of these neurons in CB2 receptor-deficient mice [70]. CBD has also reduced the loss of tyrosine hydroxylase-positive neurons in the substantia nigra of PD rats. Both compounds, THCV and CBD, have acted via neuroprotective and antioxidant mechanisms [70, 182, 191]. CBD has also demonstrated significant effects in preclinical models of neurodegenerative disorders in combination with other cannabinoids [15, 70, 192]. CB2 receptor agonists display a promising pharmacological profile for delaying disease progression.

The cannabinoid pharmacologic manipulation represents a promising therapy to alleviate movement disorders and levodopa-induced dyskinesias. Thus, CB1 antagonists appear to have antiparkinsonian effects, while cannabinoid receptor agonists may be useful in the treatment of motor complications in Parkinson's disease.

3.3. Effect of Cannabinoids on Patients with Movement Disorders. Cannabis and related compounds have created significant research interest as a promising therapy in neurodegenerative and movement disorders. The successful use of tincture of *Cannabis indica* in treating PD was first described in Europe by Gowers [193]. Despite the lack of controlled studies, there is evidence that cannabinoids are of therapeutic value in the treatment of tics in Tourette syndrome, some forms of tremor and dystonia, chorea in Huntington's disease, the reduction of levodopa-induced dyskinesia in Parkinson's disease, and Parkinsonian syndromes [194–201].

A study with smoked cannabis queried 339 PD patients indicated that marijuana produced significant improvement of general PD symptoms in 46% of the patients; 31% of them reported improvement in resting tremor, 38% reported relief from rigidity, 45% defined reduced bradykinesia, and 14% of the patients reported alleviated dyskinesias [202]. High urine concentration (>50 ng/ml) of the THC primary active metabolite, 11-HO-THC, was associated with relief from PD symptoms [202]. The dose and frequency of the cannabis administrations were important in relieving PD symptoms. Smoked cannabis also produced a statistically significant improvement in tremor, rigidity, and bradykinesia as well as improvement in sleep and pain scores in 22 PD patients [65]. In another study, smoked cannabis was responsible for a significant improvement in the mean total motor Unified Parkinson's Disease Rating Scale (UPDRS) score, tremor, rigidity, and bradykinesia in 17 patients with PD [203]. One dose of smoked marijuana provided symptoms relief for up to 3 hours [203]. Moreover, both studies reported significant improvement of nonmotor symptoms of PD, such as pain and sleep [65, 203]. However, smoked marijuana did not reduce Parkinsonian symptoms in 5 patients with idiopathic Parkinson's disease and severe tremor [204]. A clinical trial in 19 PD and 6 patients with levodopa-induced dyskinesia demonstrated that oral cannabis extract was ineffective for alleviating parkinsonism or dyskinesia [205].

Few studies have evaluated the effects of CBD on PD symptoms. In a pilot study CBD lowered total UPDRS scores and significantly reduced psychotic symptoms in 6 PD patients with psychosis [67]. In another study CBD administration produced no improvement in measures of motor and general symptoms in 21 PD patients [68, 69]. However, the group treated with CBD had significantly different mean total scores in the Parkinson's Disease Questionnaire, 39 compared to the placebo group [68, 69]. Oral CBD improved dyskinesia by up to 30% without a significant worsening of the parkinsonism in PD patients [206]. CBD withdrawal caused severe generalized dystonia [206].

Clinical studies have been conducted to evaluate the effect of a synthetic cannabinoid nabilone. Oral nabilone significantly reduced dyskinesia without aggravating parkinsonism in seven PD patients with severe L-DOPA-induced dyskinesia [207]. In another study, nabilone produced a 22% reduction in levodopa-induced dyskinesia in PD patients [208]. Nabilone showed efficacy not only against LID but also against bradykinesia in PD patients [209]. Some other cannabinoid related compounds such as CE178253, OEA, and HU-210 have also been reported to be efficacious against L-DOPA-induced dyskinesia and bradykinesia in PD [199, 209]. However, SR 141716 did not improve Parkinsonian motor disability in PD patients [210]. The American Academy of Neurology (AAN) review deemed marijuana "probably ineffective" for treating L-DOPA-induced dyskinesia [211]. These conflicting results indicate the need for more research in this area.

Several clinical studies have been performed to evaluate the effect of marijuana on dystonia. Inhaled cannabis has provided a marked reduction in dystonia and complete pain relief in patients with right hemiplegic painful dystonia. Moreover, the patients have been able to completely discontinue opioid use [212]. Smoked cannabis also improved idiopathic dystonia and generalized dystonia due to Wilson's disease [213, 214]. In a preliminary study, administration of CBD resulted in a 50% improvement in spasm severity and frequency in a patient with blepharospasm- oromandibular dystonia [215] and amelioration of the dystonic movements within 2-3 hours in patients with dystonic movement disorders [201]. CBD also improved dystonia by 20-50% in dystonic patients and stopped tremor and hypokinesia in 2 patients with Parkinson's disease [200]. Another cannabis compound, THC, produced a reduction of abnormal movement patterns in a 14-year-old girl with marked dystonia [216] and decreased intensity of myoclonic movements in a 13-year-old boy with athetosis and myoclonic movements [216]. In contrast to these findings, one study found no significant reduction in dystonia following treatment with nabilone [165, 166].

Studies have looked at the potential benefits of medical marijuana and cannabinoids for the treatment of Huntington's disease (HD). Nabilone versus placebo showed a treatment difference of 0.86 for total motor score; 1.68 for chorea; 3.57 for Unified Huntington's Disease Rating Scale (UHDRS) cognition; 4.01 for UHDRS behavior; and 6.43 for the neuropsychiatric inventory in HD patients [217]. However, in previous study nabilone was found to increase

choreatic movements in patients with HD [197, 198]. AAN guideline examining the efficacy of marijuana for treating chorea in HD stated nabilone can be used for modest decreases in HD chorea [218]. Available data regarding the effect of CBD on HD symptoms are inconsistent. CBD produced improvement (20-40%) in the choreic movements in HD patients [219]. However, a latter study did not confirm the earlier finding [220]. A comparison of the effects of CBD and placebo on chorea severity in neuroleptic-free HD patients indicated no significant or clinically important differences [220].

Few studies have indicated that marijuana and THC can reduce tics and associated behavioral disorders in patients with Tourette's syndrome (TS) [221]. Cannabis inhalations produced a significant amelioration of TS symptoms [222]. Following marijuana administration 82% of TS patients ($N = 64$) reported a reduction, or complete remission of motor and vocal tics, and an amelioration of premonitory urges and obsessive-compulsive symptoms (OCB) [199]. Smoked marijuana also eliminated TS symptoms in one case study [223]. Administration of THC to a boy with TS improved tics and enhanced short-interval intracortical inhibition and the prolongation of the cortical silent period [224]. TCH significantly reduced tics and improve driving ability in a Tourette's patient [225]. Treatment with THC lowered the mean $C1$ specific over nonspecific binding ratio (V_3'') from 0.30 to 0.25 in six TS patients, although the difference was not significant. However V_3'' clearly declined in a patient with a marked clinical response [226]. To date, there have been only two controlled trials that investigated the effect of THC on TS [194], both of which reported a significant improvement of tics and OCB after THC administration [195, 196].

Considering the relevance of these data, the need for alternative treatments for PD motor and nonmotor symptoms, medical marijuana, or related compounds may provide a new approach to the treatment of Parkinson's disease.

4. Beneficial Effects of Cannabinoids in the Amelioration of Nonmotor Symptoms and Progression of Parkinson's Disease

4.1. Neuroprotective Actions of Cannabinoids. Cannabinoids have been shown to have neuroprotective effect due to their antioxidative, anti-inflammatory actions and their ability to suppress excitotoxicity. Plant-derived cannabinoids such as THC and CBD can provide neuroprotection against the in vivo and in vitro toxicity of 6-hydroxydopamine and this was thought to be due to their antioxidative property or modulation of glial cell function or a combination of both [182]. Studies found that CBD was able to recover 6-hydroxydopamine-induced dopamine depletion and also induced upregulation of Cu, Zn-superoxide dismutase, which is a key enzyme in endogenous defense against oxidative stress [70, 191, 227]. The reported data suggest that CBD also diminishes the increase in nicotinamide adenine dinucleotide phosphate (NADPH) oxidase expression and decreases the markers of oxidative stress, inflammation, and cell death in the kidneys [228]. Another study has also emphasized a role for

superoxide anion produced by microglial NADPH oxidase in augmenting the demise of dopaminergic neurons in the PD brain [229]. The mechanism by which CBD acts to reduce NADPH oxidase expression and inhibit oxidative injury within the PD brain has yet to be confirmed but it seems to act through mechanisms independent of CB1 or CB2 receptors [76]. However, data obtained from recent studies have hinted towards a direct relationship between the CB1 receptor and mitochondrial functions in the brain [230]. The phenolic ring moieties in cannabinoids display antioxidant activity guarding against glutamate-induced neurotoxicity in a cellular model [231]. CBD produced reduction of hydroperoxide-induced oxidative damage and was more protective against glutamate neurotoxicity compared to ascorbate and α -tocopherol, indicating that CBD is a potent antioxidant [232]. Taken together, these discoveries support the hypothesis that treatment with cannabinoids having antioxidant effects may modulate mitochondrial reactive oxygen species production [233] in the PD brain.

Inflammation has been shown to be a crucial pathological factor responsible for the demise of dopaminergic neurons in PD [234–236]. Glial cells appear to play a key role in neuroinflammation, since higher levels of activated microglia are reported in the substantia nigra of patients with PD compared to brains of control subjects [237, 238]. Cannabinoids demonstrate anti-inflammatory activities by suppressing toxic cytokine release and microglia activation [181–183]. Increased CB2 receptor expression in nigral cells and stimulation of these receptors protect dopaminergic neurons from microglia-induced inflammation and regulate neuronal survival [70]. The cannabinoids are known to be able to activate the CB2 receptor, which mediate the anti-inflammatory effects of the compounds and preserve cells from excessive apoptosis. Recent evidence substantiates that some cannabinoids may attenuate the neuroinflammation associated with PD [191, 239–241]. Several studies showed that CBD has anti-inflammatory properties [242–246] and can produce beneficial effect in acute inflammation and chronic neuropathic states [5, 247, 248]. THC demonstrates anti-inflammatory effect via activation of the CB1 receptor [249–251]. In addition, cannabinoids provide anti-inflammation effect by reducing the vasoconstriction and restoring blood supply to the injured area [252]. All these data support that cannabinoids are potentially effective compounds for the treatment of neuroinflammatory conditions, including neurodegenerative diseases like PD.

Marijuana may prevent brain damage by protecting against neuronal injury. There are a few mechanisms by which cannabinoids provide neuroprotection. One of the mechanisms involves an induction/upregulation of cannabinoid CB2 receptors, mainly in reactive microglia, and regulates the influence of these glial cells on homeostasis of surrounding neurons [253]. In combination with the increased antitoxic effects observed in cell cultures containing glia, this suggests that immunomodulation produced by CB2 receptor activation may play a primary role in the neuroprotective properties of cannabinoids [182]. Another mechanism of neuroprotection is activation of CB1 receptors. Loss of dopaminergic neurons and greater degree of motor impairment in

CB1 knockout mice have been reported [85]. Cannabinoids activating the CB1 receptor are antiexcitotoxic due to suppression of glutamatergic activity with a subsequent decrease in calcium ion influx and eventual nitric oxide production [254–256]. Sativex-like combination of phytocannabinoids has been demonstrated to produce neuroprotective effect via interaction with both CB1 and CB2 receptors [134, 257]. In addition, THC reduced the loss of tyrosine hydroxylase-positive neurons in the substantia nigra [70] and exhibited neuroprotective effect by activation of the PPAR γ receptors [258]. Overall, these data suggest that cannabinoids are neuroprotective in acute and chronic neurodegeneration and can delay or even stop progressive degeneration of brain dopaminergic system, a process that cannot be prevented currently.

4.2. Analgesic Effect of Cannabinoids. Pain is a relevant and often underestimated nonmotor symptom of PD [259, 260]. Pain affects more than 50% of people with this disorder and can cause extreme physical, psychological, and social disorders and worsen Parkinsonian disability [261, 262]. Different treatment options are used to treat PD pain [262–265]. However, these medications have significant side effects and do not provide universal efficacy [264, 265]. Cannabis is well known as a pain-relieving plant. The cannabinoid receptors in the central and peripheral nervous systems have been shown to modulate pain perception [266, 267].

Several clinical studies have been performed to investigate the effect of marijuana or cannabinoids on pain. Smoked cannabis significantly reduced neuropathic pain intensity as well as significantly improved mood disturbance, physical disability, and quality of life in HIV-patients [268]. Cannabis was effective at ameliorating neuropathic pain in patients with central and peripheral neuropathic pain [269]. Inhaled cannabis significantly reduced pain intensity (34%) compared to placebo in a clinical trial of painful distal symmetric polyneuropathy (DSPN) [270]. Whole plant extracts of *Cannabis sativa* produced statistically significant improvements on the mean pain severity score [271]. Cannabis-based medicine significantly decreased chronic pain intensity as well as sleep disturbance in multiple sclerosis patients [272, 273]. Oromucosal nabiximols (1:1 combination of the THC and CBD) produced a reduction in pain intensity scores in patients with neuropathic pain [274].

These findings are consistent with other discoveries supporting the efficacy of cannabis in relieving pain. The analgesic effect of cannabinoids has been reviewed [75, 211, 275–281]. The review of the literature suggests that marijuana and/or cannabinoids may be efficacious for pain relieving in various disease states including PD.

4.3. Antidepressant Effect of Cannabinoids. Depression is one of the common nonmotor symptoms of PD and the estimated rate varies widely, with an average prevalence of up to 50%. [282–284]. Despite its association with poor health outcomes and quality of life, depression in PD patients is underdiagnosed and undertreated [285–287]. Studies have indicated that the endocannabinoid system is involved in

the regulation of mood and emotional behavior, and the loss or blockade of the endocannabinoid signaling system results in depressive symptoms [288]. For example, the CB1 receptor antagonist rimonabant has been shown to induce symptoms of anxiety and depression [289–291]. In addition, polymorphism of the gene that encodes the CB1 receptor has been associated with depression in PD [292]. In animal models, low level of THC produced antidepressant activity and increased serotonergic activity via activation of the CB1 receptor [293]. Animal studies have also shown that inhibition of hydrolysis of the endocannabinoid anandamide exerts antidepressant effect [294] and resulted in an increased serotonergic and noradrenergic neuronal activity in the midbrain. Currently available antidepressant drugs act via increasing serotonin and/or noradrenaline levels. These, and many other studies, indicate that the cannabinoid system is a potential target for the development of novel antidepressant drugs. Epidemiological studies have demonstrated that people who used cannabis daily or weekly exhibit less depressed mood and more positive effect than nonusers of cannabis [295]. Other studies have shown an association between heavy cannabis use and depressive symptoms. However, it is not clear whether the increased depressive symptoms are due to cannabis use or other factors that increased the risk of both depression and heavy use of cannabis [296]. Therefore, moderate use of cannabis in PD patients may help alleviate depressive symptoms and improve quality of life.

4.4. Effect of Cannabinoids on Sleep Disorders. Sleep disorders are common in PD patients and negatively affect the quality of life. The reported prevalence ranges from 25% to 98% and this wide variation could be due to differences in study design and diagnostic tools used [297]. The causes of the sleep disturbances in PD are multifactorial and include neurodegeneration and the medications used to treat motor symptoms of PD [298]. Various sleep disorders including rapid eye movement sleep behavior disorder, insomnia, sleep fragmentation, excessive daytime sleepiness, restless legs syndrome, and obstructive sleep apnea have been described in PD patients [299, 300]. Cannabidiol, the major nonpsychotic component of marijuana, has been reported to improve rapid eye movement sleep behavior disorder in PD patients [68, 69]. Marijuana has also been shown to improve nonmotor symptoms of PD including sleep [65]. In clinical trials involving 2000 patients with various pain conditions, nabiximols has been demonstrated to improve subjective sleep parameters [301]. Thus, marijuana could be used to enhance the quality of life of PD patients by alleviating sleep disorders and pain.

5. Summary

Cannabis and related compounds have recently been studied as promising therapeutic agents in treatment of neurodegenerative and movement disorders including Parkinson's disease. In this review we have examined the potential benefits of medical marijuana and cannabinoids in the treatment of both motor and nonmotor symptoms as well as

in slowing the progression of the disease. We have looked into any scientific evidence that indicates the potential use of marijuana and/or related compounds for the treatment of PD. Current treatments of PD provide only relief of motor symptoms and are associated with adverse effects such as dyskinesia. In addition, these therapies do not slow the progression of the disease. Therefore, there is an urgent need for safer drugs that can treat both motor and nonmotor symptoms of PD as well as drugs that slow the progression of the disease.

In spite of the placement of marijuana in schedule 1 category under the US Federal Controlled Substance Act, 24 states and Washington DC have enacted laws allowing the use of marijuana to treat a range of medical conditions. Parkinson's disease has been listed as one of the disease conditions for which medical marijuana is allowed in a number of states. Research studies have provided evidence for the potential effectiveness of medical marijuana and its components in the treatment of PD as cannabinoids act on the same neurological pathway that is disrupted in Parkinson's disease. Involvement of the endocannabinoid system in the regulation of motor behavior, the localization of the cannabinoid receptors in areas that control movement, and the effect of cannabinoids on motor activity indicate that cannabinoids can be potentially used in the treatment of movement disorders. Cannabinoid agonists and antagonists have been shown to modulate the endocannabinoid system and modify motor activity. Cannabinoid receptor antagonists appear to produce antiparkinsonian effects while cannabinoid receptor agonists exert a powerful motor inhibition and may be useful in the treatment of motor complications. In addition, we have assessed the role of the cannabinoid system and marijuana constituents in neuroprotection as well as considered other beneficial effects of marijuana. Marijuana has been shown to improve nonmotor symptoms of PD such as depression, pain, sleep, and anxiety. Moreover, components of cannabis have been demonstrated to have neuroprotective effect due to their anti-inflammatory, antioxidative, and antiexcitotoxic properties. Due to combination of the above mentioned beneficial effects, cannabis may provide a viable alternative or addition to the current treatment of Parkinson's disease. However, there are concerns regarding the use of medical marijuana including lack of standardization and regulation, imprecise dosing, possible adverse effects, and medication interactions. Further studies are needed to provide more data on efficacy, safety, pharmacokinetics, and interactions of cannabinoids.

Competing Interests

The authors declare that there is no conflict of interests regarding the publication of this paper.

Abstract Cannabis has been used for centuries to treat seizures. Recent anecdotal reports, accumulating animal model data, and mechanistic insights have raised interest in cannabis-based antiepileptic therapies. In this study, we review current understanding of the endocannabinoid system, characterize the pro- and anticonvulsive effects of cannabinoids [e.g., Δ^9 -tetrahydrocannabinol and cannabidiol (CBD)], and highlight scientific evidence from pre-clinical and clinical trials of cannabinoids in epilepsy. These studies suggest that CBD avoids the psychoactive effects of the endocannabinoid system to provide a well-tolerated, promising therapeutic for the treatment of seizures, while whole-plant cannabis can both contribute to and reduce seizures. Finally, we discuss results from a new multicenter, open-label study using CBD in a population with treatment-resistant epilepsy. In all, we seek to evaluate our current understanding of cannabinoids in epilepsy and guide future basic science and clinical studies.

Introduction

Epilepsy affects 2.9 million people in the USA and 65 million people worldwide (cdc.gov/epilepsy). One in 26 people in the USA will develop epilepsy in their lifetime [1]. Characterized by recurrent seizures, epilepsy encompasses multiple disorders caused by varied etiologies, including genetic syndromes, stroke, infection, and traumatic brain injury. Many patients with epilepsy also have sensorimotor, cognitive, psychological, psychiatric, and social impairments, as well as impaired quality of life and an increased risk of premature death [1]. While epilepsy can affect patients of all ages, it most commonly affects children, the elderly, and individuals with low socioeconomic status. The estimated direct and indirect annual cost of epilepsy in the U.S. is \$15.5 billion (cdc.gov/epilepsy).

While many drugs can limit seizures, no drug can prevent the underlying cause of epilepsy or the development of epilepsy (epileptogenesis) in patients who are at risk (e.g., after head trauma). A third of patients remain pharmacoresistant, failing to achieve sustained seizure freedom after 2 or more adequately chosen, tolerated, and appropriately used antiepileptic drugs (AEDs; more accurately termed antiseizure drugs) [2–4]. Patients resistant to multiple AEDs have an increased risk for sudden unexpected death in epilepsy and other forms of epilepsy-related mortality [5, 6], as well as impairments in psychosocial, behavioral, and cognitive functions [3, 7–9]. For many patients, epilepsy is a progressive disorder associated with ongoing loss of brain tissue and function. Finally, multidrug combinations and high dosages cause more severe side effects, a particular problem in patients with treatment-resistant epilepsies. Assessing the side effects of AEDs is especially challenging in patients on long-term AEDs as any ‘baseline’ may be many years past and even intelligent adults, parents, and physicians may fail to appreciate chronic adverse

effects. The available AEDs fail to meet the clinical needs for both efficacy and safety [10], indicating a dire need for novel therapeutics that are targeted, disease-, and age-specific.

Recently, mounting anecdotal reports and media coverage have sparked intense interest among parents, patients, and the scientific community regarding the potential of medical cannabis to treat seizures. A potential alternative or supplement to current AEDs, the cannabis plant includes >100 diverse phytocannabinoids that, in part, target an endogenous endocannabinoid signaling network, as well as other networks. Two major phytocannabinoids derived from cannabis are psychoactive Δ^9 -tetrahydrocannabinol (THC) and nonpsychoactive cannabidiol (CBD). Both Δ^9 -THC and CBD can prevent seizures and reduce mortality in animal models of seizure with low toxicity and high tolerability [11]. However, a systematic analysis from the American Academy of Neurology and a Cochrane Database review both concluded that medical cannabis is of “unknown efficacy” to treat epilepsy [12, 13]. In this review, we examine the history of cannabinoids in epilepsy, discuss the effectiveness of preclinical seizure model studies with cannabinoids, and review recent clinical data, including a multicenter clinical trial of CBD for patients with treatment-resistant epilepsy.

History of Cannabis in Epilepsy

Cannabis has been used for millennia for medical, recreational, and manufacturing purposes. Around 2900 BCE, the Chinese Emperor Fu Hsi characterized cannabis as having sacred yin (weak, passive forces) and yang (strong, active forces) features, suggesting that it could restore homeostasis to an unbalanced body. Physicians in ancient India, Egypt, Persia, Rome, Arabia, and Greece used cannabis for spiritual and medicinal purposes, including menstrual fatigue, gout, rheumatism, malaria, beriberi, constipation, pain, and absentmindedness [14]. Early documented uses of cannabis to treat seizures include a Sumerian text from 2900 BCE and an Arabian document from the twelfth century [15, 16].

The 1854, the US Dispensatory listed cannabis to treat neuralgia, depression, pain, muscle spasms, insomnia, tetanus, chorea, insanity, and other disorders [17]. Cannabis was valued for its analgesic, anti-inflammatory, appetite-stimulating, and antibiotic properties. In the mid-1800s, the British surgeon William O’Shaughnessy reported cannabis therapy for the treatment of epilepsy, recounting an “alleviation of pain in most, a remarkable increase of appetite in all, unequivocal aphrodisia, and great mental cheerfulness” [14, 18]. Two of England’s most prominent mid-to-late nineteenth-century neurologists, J.R. Reynolds and W. Gowers, also noted the benefits of cannabis in epilepsy [19]. Gowers reported a man who previously failed bromides whose seizures were

controlled on 9.8 g of *Cannabis indica*, dosed 3 times daily for up to 6 months [20].

Cannabis was first regulated in the USA with the 1906 “Pure Food and Drug Act”. The follow-up 1937 Marijuana Tax Act was opposed by the American Medical Association, which considered the more severe restrictions an infringement on physician’s freedom to treat patients [17]. In 1970, the US Comprehensive Drug Abuse Prevention and Control Act categorized marijuana as a Schedule I drug with high potential for abuse and no accepted medicinal use. Legislation has been introduced to the US Senate to change marijuana to a Schedule II drug.

Over the last 50 years, the main chemical constituents of cannabis have been isolated and synthesized. Δ^9 -THC was isolated in 1964 and synthesized in 1971 [21, 22]. CBD was isolated in 1940 and synthesized in 1963 [23, 24]. The cannabinoid type 1 (CB₁R) and type 2 (CB₂R) receptors, which bind Δ^9 -THC, were cloned in the 1990s [25, 26], supporting an endogenous system for this principal cannabinoid’s pharmacological activity.

The Endocannabinoid System

The discovery of the endocannabinoid system in the early 1990s revealed the neuronal mechanisms that underlie the psychoactive effects of Δ^9 -THC in cannabis. Initial studies demonstrated that brief postsynaptic depolarization reduced neurotransmitter release from excitatory terminals onto Purkinje cells in the cerebellum and inhibitory terminals onto pyramidal neurons in the hippocampus [27, 28]. This phenomenon was termed “depolarization-induced suppression of excitation/inhibition” (DSE and DSI, respectively). Postsynaptic depolarization was postulated to trigger the release of an undiscovered substance that transiently limited presynaptic neurotransmitter release. Along with the discovery of nitric oxide (NO), this paradigm-shifting view suggested the concept of retrograde signaling in contrast to a primarily anterograde view of synaptic signaling. Application of a CB₁R agonist (or antagonist) enhanced (or prevented) DSE and DSI, suggesting that it was mediated by an endogenous cannabinoid ligand [29–31]. These endocannabinoids were identified as the hydrophobic ligands *N*-arachidonoyl ethanolamide (anandamide) [32] and 2-arachidonoyl glycerol (2-AG) [33, 34].

Anandamide and 2-AG are synthesized from postsynaptic membrane phospholipid precursors and released in an activity-dependent, “on-demand” manner, unlike traditional vesicular neurotransmitters (Fig. 1). Depolarization of the postsynaptic cell or direct activation of metabotropic glutamate receptors increases levels of intracellular calcium, which trigger second messenger cascades that promote endocannabinoid synthesis [35–39]. Anandamide is synthesized via

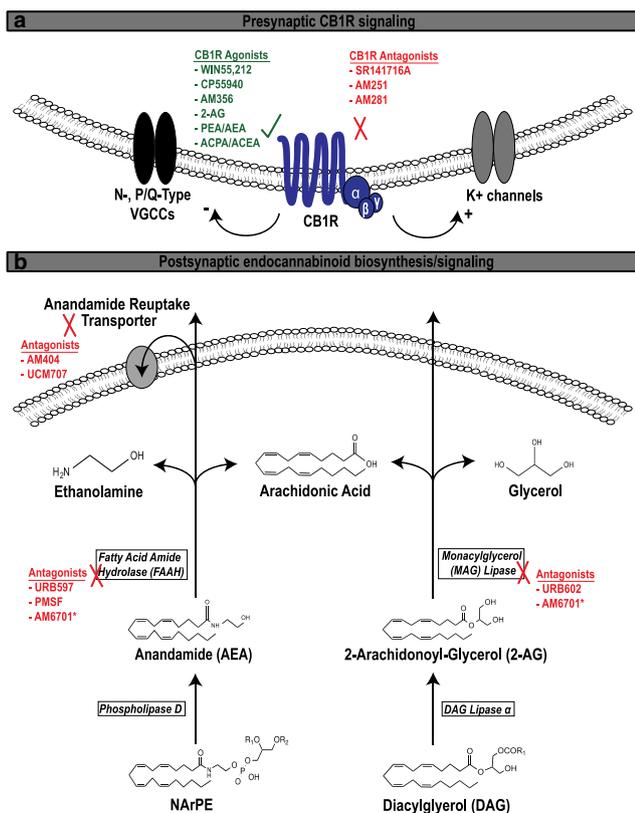

Fig. 1 Biosynthesis, degradation, and signaling of endocannabinoids. (A) Presynaptic cannabinoid type 1 receptor (CB₁R) signaling. (B) Postsynaptic endocannabinoid biosynthesis/signaling. NArPE = *N*-arachidonoyl phosphatidylethanolamine; DAG = 1-acyl, 2-arachidonoyl diacylglycerol; VGCC = voltage-gated calcium channels; PEA = palmitoylethanolamide; ACPA = arachidonylcyclopropylamide; ACEA = arachidonyl-2'-chloroethylamide; PMSF = phenylmethylsulfonyl fluoride

phospholipase D-mediated hydrolysis of *N*-arachidonoyl-phosphatidylethanolamine, and degraded by the fatty acid amide hydrolase (FAAH) into arachidonic acid and ethanolamine [40–43]. 2-AG is synthesized via diacylglycerol (DAG) lipase (DAGL) α -mediated hydrolysis of DAG, and degraded by FAAH into arachidonic acid and glycerol, or by monoacylglycerol lipase [41–44]. Chronic hyperexcitability leads to dynamic changes in the endocannabinoid pathway (see “The Endocannabinoid System: CB₁Rs”). Thus, the enzymes that regulate metabolism and cannabinoid receptors represent attractive targets to treat several neurological disorders [45]. Accordingly, the selective CB₁R blocker rimonabant was approved in >50 countries as an anorectic to treat obesity [46], and showed promise in helping smokers quit tobacco use [47], but its use was suspended when postmarketing surveillance revealed high rates of depression and suicidal ideation.

Produced in an activity-dependent manner, endocannabinoids travel to the presynaptic cell and bind to CB₁Rs. CB₁Rs are G protein-coupled receptors linked to pertussis-sensitive Gi/o α subunits. Activation of the α subunit triggers dissociation of the $\beta\gamma$ complex, which reduces adenylate cyclase production

of cyclic adenosine monophosphate [48], inhibits N- and P/Q-type voltage-gated calcium channels [31, 49–52], stimulates A-type potassium channels [53–56], activates G protein-coupled inwardly-rectifying potassium channels [57–59], and inhibits the vesicular release machinery [60]. These multiple mechanisms reduce presynaptic cell excitability and Ca²⁺, strongly diminishing presynaptic neurotransmitter release. CB₁Rs can also regulate the presynaptic release of multiple neuromodulators such as acetylcholine, dopamine, and norepinephrine [61]. Finally, endocannabinoid signaling may modulate regional-specific long-term synaptic plasticity, including long-term potentiation and long-term depression (for a review, see [62, 63]).

CB₁Rs are distributed primarily in axon terminals in the neocortex (especially cingulate, frontal, and parietal regions), hippocampus, amygdala, basal ganglia, thalamus, hypothalamus, nucleus accumbens, substantia nigra, ventral tegmental area, cerebellum, and brainstem [39]. CB₁Rs are most densely expressed at cortical and hippocampal presynaptic γ -aminobutyric acid (GABA)ergic presynaptic boutons, especially cholecystokinin-positive (CCK+) and parvalbumin-negative GABAergic interneurons [64–66]. Glutamatergic axon terminals in cortical and subcortical neurons contain fewer presynaptic CB₁ receptors than GABAergic terminals [65, 67–71].

Phytocannabinoids: Classification and Function

The cannabis plant consists contains >100 C₂₁ terpenophenolic compounds, known collectively as phytocannabinoids [72]. Most of these lipophilic cannabinoids are closely related and differ only by a single chemical functional group. Cannabinoids fall into 10 main groups, with constituents representing degradation products, precursors, or byproducts (Fig. 2, adapted from [73]). Two of the most abundant constituents are Δ 9-THC and CBD, the ratios of which vary by cannabis strain. *Cannabis sativa* contains a higher ratio of Δ 9-THC to CBD, producing more stimulating, psychotropic effects. *Cannabis indica* strains contains a higher ratio of CBD: Δ 9-THC and are typically more sedating [11, 73].

Δ 9-THC

Δ 9-THC is a partial agonist at central nervous system (CNS) CB₁Rs and CB₂Rs in the immune system. Most behavioral, cognitive, and psychotropic effects of cannabis result from the effects of Δ 9-THC at brain CB₁Rs. The subjective “high” produced by cannabis can be blocked by pretreatment with the CB₁R antagonist rimonabant [74]. Δ 9-THC impairs short-term working memory in several rodent models, which can be reversed by preapplication of a CB₁R antagonist [75–78]. Inhibition of long-term potentiation at hippocampal CA3 Schaffer Collateral/CA1 synapses may underlie this

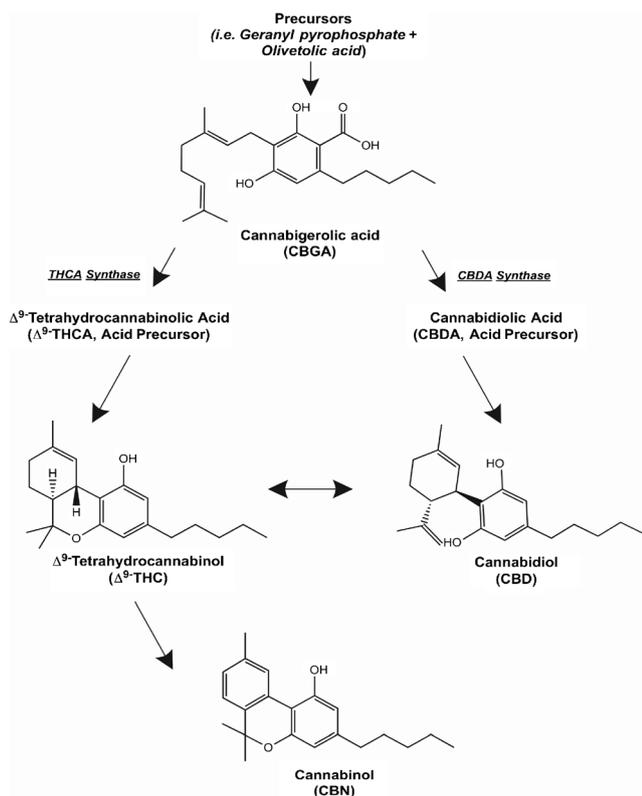

Fig. 2 Biosynthesis of phytocannabinoids [73]

effect on memory [35]. Δ⁹-THC or CB₁R agonists can increase or decrease food intake in different species [79]. Δ⁹-THC also regulates neuronal excitability during seizures (see “Preclinical Evidence”). Thus, Δ⁹-THC acts through the endocannabinoid system to regulate mood, learning and memory, neuronal excitability, and energy balance. Δ⁹-THC exerts potent anti-inflammatory functions via CB₁Rs and CB₂Rs on microglia, the primary immune cells in the CNS. Δ⁹-THC or CB₁R agonists limit neurotoxicity in *in vitro* and *in vivo* assays, including chemotoxic [80–83], low Mg²⁺ [84], and ischemic [85, 86] models. Δ⁹-THC has antioxidant effects in α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid- and *N*-methyl-D-aspartate-mediated cytotoxicity models via a CB₁R-independent mechanism [87]. Cannabinoids reduce neuronal and glial release of the proinflammatory cytokines tumor necrosis factor-α, NO, interleukin (IL)-1 and IL-6 [88–93], and increase release of anti-inflammatory cytokines IL-4, IL-10, and IL-1 receptor antagonist (IL-1a) [94, 95] via CB₁R- and CB₂R-dependent mechanisms in neurons and glia [94, 95] (reviewed in [96]). Δ⁹-THC also transiently activates and desensitizes the transient receptor potential (TRP) channels TRPA1, TRPV1, and TRPV2 [97–99]. Given the synergistic relation between seizures and inflammation [100–102], the cannabinoid system provides a novel strategy to target both segments of this feedback cycle.

CBD

CBD resembles Δ⁹-THC structurally but the 2 molecules differ significantly in pharmacology and function. CBD has very low affinity at CB₁R and CB₂R, unlike Δ⁹-THC [103–106]. The potential targets for CBD are reviewed in detail in another article in this issue (“Molecular Targets of CBD in Neurological Disorders”). CBD is an agonist at TRP channels (TRPV1, TRPV2, TRPA1) [98, 99, 104], 5-hydroxytryptamine_{1α} receptors [107], and glycine receptors [108]. CBD is an antagonist at TRP melastatin type-8 channels [97], T-type voltage-gated calcium channels [109], and G protein-coupled-receptor GPR55 (see below).

CBD exerts dynamic control over intracellular calcium stores through multiple, activity-dependent pathways [110, 111]. CBD induces a bidirectional change in intracellular calcium levels that depends on cellular excitability. Under normal physiological Ca²⁺ conditions, CBD slightly increases intracellular Ca²⁺, whereas CBD reduces intracellular Ca²⁺ under high-excitability conditions. These changes were blocked by the pretreatment with an antagonist of the mitochondrial Na⁺/Ca²⁺ exchanger, suggesting a mitochondrial site of action [111]. CBD also produces biphasic changes in intracellular calcium levels via antagonism of the mitochondrial voltage-dependent anion channel 1 [112].

CBD antagonizes GPR55, which functions as a counterpart to the canonical CB₁R/CB₂R signaling pathway [113]. GPR55 is present in the caudate, putamen, hippocampus, thalamus, pons, cerebellum, frontal cortex, and thalamus. GPR55 was initially characterized as a novel cannabinoid receptor, coupled to Gα₁₃ [114]. Activation of GPR55 in human embryonic kidney cells triggers the release of intracellular Ca²⁺ from endoplasmic reticulum stores via a pathway dependent on RhoA (Ras homolog gene family member A), phospholipase C, and inositol 1,4,5-trisphosphate receptor [115]. The endogenous membrane phospholipid L-α-lysophosphatidylinositol is a GPR55 agonist [116]. Brief application of L-α-lysophosphatidylinositol transiently increases intracellular Ca²⁺ levels and vesicular release probability at excitatory hippocampal synapses. CBD opposes this effect by reducing glutamate release, suggesting a potential antiseizure mechanism [117]. CBD also reduces epileptiform activity (burst amplitude and duration) in *in vitro* (4-aminopyridine and Mg²⁺) models through a CB₁-independent, concentration-dependent, and region-specific manner in the hippocampus. Preclinical studies demonstrate an anti-seizure effect of CBD (see “Preclinical Evidence”).

CBD also regulates several transporters, enzymes, and metabolic pathways that are common to Δ⁹-THC and endocannabinoid signaling. CBD inhibits uptake of adenosine by blocking the equilibrative nucleoside transporter [118, 119]. Increased levels of adenosine activate A₂ receptors, which regulate striatal CB₁Rs [120]. At high micromolar

levels, CBD also inhibits the uptake and enzymatic degradation of anandamide via FAAH, elevating anandamide extracellular concentrations [121]. Thus, dynamic interactions likely occur between the multiple plant cannabinoids such as CBD and Δ 9-THC (see “Entourage Effect”).

CBD limits inflammation and oxidative stress [122]. CBD reduces oxidative toxicity in an *in vitro* glutamate excitotoxicity assay [123], and raises adenosine to oppose lipopolysaccharide-induced inflammation and tumor necrosis factor- α release [118, 124]. In mice with middle cerebral artery occlusion, CBD triggered a CB₁R-independent decrease in reperfusion injury, inflammation, and death. This neuroprotective action may result from reduced myeloperoxidase activity, neutrophil migration, and microglia high-mobility group box 1 expression [125, 126]. Additionally, CBD activates peroxisome proliferator-activated receptor- γ , reduces NO and IL- β release, limits gliosis, and restricts neuroinflammation in mice injected with amyloid β [127–129]. Finally, treatment of microglial cultures with interferon- γ raised mRNA levels of the CBD receptor GPR55 [130], which regulates the inflammatory responses to neuropathic pain [131]. Taken together, these studies suggest that CBD reduces neuroinflammation in several disease-specific conditions.

The “Entourage Effect”

The “entourage effect” was a term originally coined by Ben-Shabat et al. [132] to refer to the potentiating effects of endocannabinoid metabolic byproducts on endocannabinoid function at CB₁Rs and CB₂Rs. They observed that 2 esters of the endocannabinoid 2-AG—s2-linoleoyl-glycerol and 2-palmitoyl-glycerol—were present in spleen, brain, and gut, together with 2-AG. While these esters do not bind to cannabinoid receptors or inhibit adenylyl cyclase via either CB₁ or CB₂, each ester potentiated 2-AG-induced inhibition of motor behavior, immobility on a ring, analgesia on a hot plate, and hypothermia: behavioral tests commonly referred to as the ‘tetrad’ by which CB₁-mediated effects can be detected [132]. Thus, the original concept of the entourage effect referred to a specific group of endogenous compounds, structurally similar to endocannabinoids, that potentiated the effects of endogenous cannabinoid receptor agonists at CB₁Rs and CB₂Rs.

Subsequently, the idea of the entourage effect has expanded considerably both with regard to mechanisms of interactions, as well as classes of chemical agents. The diversification of entourage effects has been promoted by scientific and lay authors, and often well beyond its original boundaries. Wagner and Ulrich-Merzenich [133] proposed 4 potential mechanisms of synergy for phytotherapeutics, using cannabis as an exemplar: 1) multitarget effects; 2) pharmacokinetic effects (e.g., improved bioavailability or solubility); 3) improved bacterial resistance; and 4) modulation of adverse events (AEs;

truly an antagonism, albeit a beneficial one) [133]. This approach thereby extended the tightly defined entourage effect to include practically any plant mixture acting through any molecular target to exert any effect.

The cannabis plant contains a complex mixture of both cannabinoids (i.e., Δ 9-THC and CBD) and terpenoids (limonene, myrcene, α -pinene, linalool, β -caryophyllene, caryophyllene oxide, nerolidol, and phytol) derived from a common precursor (geranyl pyrophosphate). Several studies posited that the “entourage” of “[whole] plants are better drugs than the natural products isolated from them”, suggesting that the clinical effects of cannabis usage may be due to complex interactions between several plant cannabinoids [134, 135]. In support of this view, CBD may potentiate the beneficial effects associated with Δ 9-THC (analgesia, antiemesis, and anti-inflammation) and reduce the negative psychoactive effects of Δ 9-THC (impaired working memory, sedation, tachycardia, and paranoia) [136–138]. Users of cannabis with a high CBD: Δ 9-THC ratio have greater tolerability and lower rates of psychosis than users of high Δ 9-THC:CBD ratios (or Δ 9-THC alone) [139]. Additional reports claim potential synergistic interactions of phytocannabinoids and phytoterpenoids that may include therapeutic effects on pain, inflammation, depression, anxiety, addiction, epilepsy, cancer, fungal, and bacterial infections [135, 140]. However, proper characterization of any “synergistic” effects of multiple plant cannabinoids requires statistically robust demonstrations of effects greater than the sum of the parts. These effects can be tested *in vitro* or *in vivo* using assays such as the isobolographic approach [141, 142]. Such a design can show if any 2 compounds, extracts, or mixtures are additive in the specific assay (e.g., models of seizure), synergistic, or antagonistic, thereby avoiding speculation about potential synergism or the confusion of additive effects with synergism. Although experimental data support the efficacy of both CBD and Δ 9-THC as individual agents in various animal models of epilepsy, we are not aware of any studies demonstrating synergy of these compounds in animal models nor any controlled trials that establish a synergistic effect in patients with epilepsy.

Collectively, several studies demonstrate functional (but not defined molecular) interactions between plant cannabinoids that extended the initial concept of the entourage effect far beyond its original intent. While such interactions may exist, further well-defined research is required to verify anecdotal claims regarding the increased antiseizure efficacy of CBD with Δ 9-THC (*vs* CBD alone) in patients with epilepsy. While natural selection may have led to combinations of phytochemicals in cannabis to resist infection or predation, there is no reason to expect “nature” to combine chemicals in a single plant to treat human epilepsy.

Animal Models of Seizures and Epilepsy

Animal models provide powerful assays to assess the potential antiseizure or antiepileptic effects of cannabinoids. Each preclinical paradigm has unique advantages and disadvantages, and many represent unique seizure etiologies, semiologies, or corresponding electroencephalography (EEG) patterns. Table 1 (adapted from [143–145]) summarizes animal models discussed in this review, grouped by relevance to human epilepsies. Acute models (e.g., kainic acid and pentylenetetrazol) allow high-throughput screening for upregulation of biomarkers, but cannot recapitulate spontaneous recurrent seizures or reduced seizure thresholds found in chronic epilepsy. Chronic models of seizure activity elicit spontaneous, recurrent seizures that can be recorded on video EEG. While technically challenging, these models better represent epileptogenesis and drug screening for humans. However chronic models are specific to the type of insult (traumatic brain injury, mouse genetic models), and may not reflect broad anatomical or functional changes in generalized epilepsy [145].

Preclinical Evidence of Cannabinoids in Epilepsy

Multiple animal models demonstrate the efficacy of cannabinoids in preventing seizures and reducing mortality in epilepsy. Animal models highlight dynamic changes in the endocannabinoid system follow chronic seizures, with both acute and chronic homeostatic regulatory components.

The Endocannabinoid System

Endocannabinoid release prevents seizure-induced neurotoxicity. Kainic acid (KA) (30 mg/kg)-induced seizures increased levels of the anandamide in wild-type mice (20 min postinjection) [146], and pilocarpine (375 mg/kg)-induced seizures increased levels of 2-AG (15 min postseizure onset) [147]. Thus, epileptiform activity triggers a neuroprotective, on-demand release of endocannabinoids (or increase endocannabinoid levels in a downstream pathway unrelated to neuroprotection). Pretreatment with an anandamide reuptake inhibitor (UCM707; 3 mg/kg) reduced KA-induced seizure severity, but not in mice with conditional CB1R deletion in principal forebrain excitatory neurons [146]. Blockade of the endocannabinoid catabolic enzyme FAAH (with AM374; 8 mg/kg) increased levels of anandamide and protected against KA (10 mg/kg)-induced hippocampal seizures and subsequent impairments in balance and coordination [148]. Inhibition of both FAAH (with AM374) and the anandamide reuptake transporter (with AM404) in rat hippocampus prevented α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid-induced excitotoxic insults (cytoskeletal damage and synaptic decline) *in vitro* and behavioral and

memory impairment *in vivo* [149]. Blockage of FAAH and DAGL α (with AM6701, 5 mg/kg) raised levels of anandamide and 2-AG, protected against KA (10 mg/kg)-induced seizures, and reduced seizure-induced cytotoxicity [150]. The endocannabinoids, methanandamide, and 2-AG reduced neuronal firing in a low Mg²⁺ *in vitro* model of status epilepticus, in a dose-dependent manner (EC₅₀ 145 ± 4.15 nM methanandamide, 1.68 ± 0.19 μ M 2-AG) [151].

CB₁Rs

Animal models demonstrate that activation of CB₁Rs reduces seizure severity. Mice with conditional deletion of CB₁Rs in principal forebrain excitatory neurons (but not interneurons) exhibited more severe KA-induced seizures (30 mg/kg) than wild-type controls. Conditional deletion of the CB₁R increased gliosis and apoptosis following KA-induced seizures and prevented activation of the protective immediate early genes (c-Fos, Zif268, brain-derived neurotrophic factor) [146]. CB₁R expression in hippocampal glutamatergic (but not GABAergic) inputs is necessary and sufficient to protect against KA-induced seizures [152]. Further, viral-induced overexpression of CB₁Rs targeted to the hippocampus reduced KA-induced seizure severity, seizure-induced CA3 pyramidal cell death, and mortality [153]. Together, these results demonstrate that CB₁Rs could limit seizure activity and protect neurons from subsequent cell death and reactive gliosis.

Seizures trigger homeostatic changes in hippocampal CB₁Rs and the endocannabinoid system (reviewed in [154]) (Fig. 3). Levels of CB₁R expression in the CA1-3 stratum oriens and radiatum (presumed excitatory inputs) and dentate gyrus steadily increased 1-week post-pilocarpine-induced seizures (Fig. 3, dark green trace) [147, 155–158]. However, sclerotic and nonsclerotic hippocampal tissue resected from patients with epilepsy displayed a reduction in DAGL α (2-AG biosynthetic enzyme), CB₁R mRNA, and CB₁R excitatory terminal immunoreactivity (Fig. 3, light green trace) [159]. Furthermore, compared with healthy controls, patients with temporal lobe epilepsy have reduced levels of anandamide in cerebrospinal fluid samples [160]. These findings suggest that seizure activity induces a homeostatic upregulation of excitatory terminal CB₁Rs, which may reduce excitatory neurotransmitter release via DSE (see “The Endocannabinoid System”). This compensatory process may be impaired in patients with prolonged treatment-resistant epilepsy or hippocampal sclerosis, leading to neuronal hyperexcitability, pharmacoresistance, and inconsistent effects of cannabis exposure. However, further research is required to verify the functional effects of this potential process in human patients, and whether CB₁R homeostasis indeed limits seizure severity or occurrence.

In contrast to effects at excitatory terminals, seizures induce a homeostatic reduction in CB₁R expression in inhibitory

Table 1 Preclinical animal models of seizures (adapted from [143–145])

Type of seizure model	Method	Mechanism	Relevant human condition	Common use
Acute	MES	Electrical stimulation	Generalized tonic-clonic seizure	Drug screening (used as a first-line screening method for AEDs)
Acute	PTZ	GABA _A R antagonist, Ca ²⁺ channels (?), Na ⁺ channels (?)	Generalized seizure	Drug screening (used as a first-line screening method for AEDs), seizure mechanism
Acute	KA	Ionotropic glutamate receptor (e.g., AMPAR, kainate receptor agonist)	Focal (temporal lobe) seizure	Drug screening, mechanism of seizures/epileptogenesis and cognitive impairments
Acute	Flurothyl	GABA _A R antagonist	Multiple acute seizures, childhood epilepsy	Development of cognitive impairments from early life seizures
Acute	Other chemoconvulsant (e.g., bicuculline, 3-MPA, picrotoxin, etc.) Hypoxia/ischemia	Various	Generalized seizures (or focal, if applied locally)	Drug screening
Acute		Anoxic depolarization, impaired Na ⁺ /K ⁺ ATPase, ↑ extracellular impairments K ⁺ /[glutamate]/[aspartate], ↑ intracellular Na ⁺ , Ca ²⁺	Hypoxic–ischemic encephalopathy	Age-specific (e.g., neonatal) drug screening, mechanisms of seizures and cognitive impairments
Acute	Hyperthermia	Activation of temperature-sensitive ion channels, release of proinflammatory cytokines	Febrile seizures	Drug screening, long-term consequences of seizures
Chronic with high propensity for induced seizures	Lithium/pilocarpine-induced chemical kindling	AChR agonist	Focal (temporal lobe) seizures	Drug screening, mechanism of seizures/epileptogenesis and cognitive impairments
Chronic with high propensity for induced seizures	Electrical (e.g., 6Hz psychomotor, limbic) kindling	Electric stimulation	Focal (temporal lobe) seizures	Drug screening, mechanism of seizures/epileptogenesis and cognitive impairments
Chronic epilepsy (SRS)	Stroke, TBI	Disease-specific models	Focal epilepsy	Drug screening, mechanism of seizures/epileptogenesis and cognitive impairments
Chronic epilepsy (SRS)	SE	Chronic treatment with KA or pilocarpine	Prolonged seizures	Drug screening
Chronic epilepsy (SRS)	Genetic (e.g., GAERs, WAG/lj mice, photosensitive baboons)	Various	Specific seizure models (e.g., absence seizures, genetic)	Drug screening

SRS = spontaneously recurring seizures; MES = maximal electroshock; PTZ = pentylenetetrazole; KA = kainic acid; 3-MPA = 3-mercaptopropionic acid; TBI = traumatic brain injury; SE = status epilepticus; GAERs = genetic absence epilepsy rats from Strouberg; GABA_AR = γ -aminobutyric acid type A receptor; AMPAR = α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor; ATPase = adenosine triphosphatase; AChR = acetylcholine receptor; AEDs = antiepileptic drugs

terminals (Fig. 3, dark red trace). Beginning 4 days following pilocarpine-induced seizures in rats, CB₁R expression progressively decreased in hippocampal CCK+ inhibitory nerve terminals [161], particularly in the CA1 stratum pyramidale and the dentate gyrus inner molecular layer, unaccounted for by CA1 neuronal cell loss alone [155, 156, 162]. By reducing CB₁R expression on inhibitory terminals (and presumed DSI), this homeostatic process may limit network disinhibition and restrain elevated excitability during prolonged epileptiform activity. In sclerotic hippocampal tissue removed from 1) 2 months post pilocarpine-induced seizures in mice [163], and 2) human patients [164], levels of CB₁R remained consistently elevated in interneuron axonal terminals (Fig. 3, light red trace). This finding suggests that patients with prolonged, pharmaco-resistant epilepsy may suffer from impaired CB₁R homeostasis on inhibitory interneuron terminals, leading to prolonged disinhibition and network excitability. Postseizure changes in CB₁R may be specific to seizure type or developmental stage, as mice with a single episode of febrile seizures induce an overall increase in DSI and CB₁R on CCK+ interneurons [165, 166].

Modulators of the Endocannabinoid System and Synthetic CB₁R Agonists/Antagonists

Figure 4 summarizes the effects of synthetic cannabinoids and phytocannabinoids in 175 pre-clinical seizure models or discrete conditions (adapted from [167]). These studies are subclassified by drug type and seizure model in corresponding tables in the Appendix (see [Supplementary Material](#)).

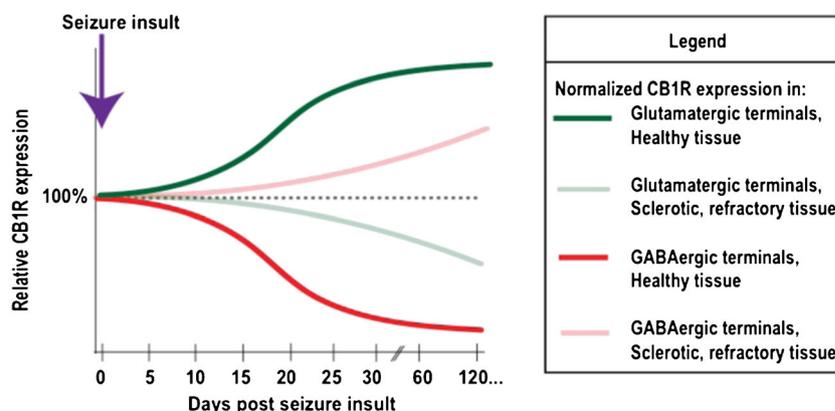

Results from 13 studies from 3 species (rat, mouse, guinea pig) demonstrate that modulation of the endocannabinoid system (via inhibition of FAAH or anandamide reuptake) provides about 46.2 % (6/13) anticonvulsant, 23.1 % (3/13) mixed effect, and 30.8 % (4/13) no significant effect in seizure models. CB₁R agonists produced an anticonvulsant effect in 68.1 % (47/69), proconvulsant effect in 2.9 % (2/69), mixed effect in 7.2 % (5/69), and no significant effect in 21.7 % (15/69) of seizure models in rats and mice. One study suggests that

CB₁R agonists may produce an anticonvulsant effect through CB₁R at low doses, but a proconvulsant effect through TRPV1 channels at high doses [168]. In addition, CB₁R agonists (WIN55, 212, ACEA) often produce an additive effect when combined with several commonly prescribed AEDs (see Fig. 4B) [169–177]. In 18 studies from mice, rats, and guinea pigs, CB₁R antagonists were proconvulsant in 38.9 % (7/18), anti-convulsant in 5.6 % (1/18), and showed no significant effect in 55.6 % (10/18) of trials. Although CB₁R agonists were anticonvulsant in 68.1 % of the studies, only 38.9 % of CB₁R antagonists were proconvulsant (most showed no effect). Thus, while activation of the endocannabinoid system may prevent long-term consequences of seizure sequelae, inhibition of the endogenous protective mechanisms may not contribute significantly to seizures. Variations in the pro- vs anticonvulsant effects in each system may reflect specific effects of the species, seizure models (acute vs chronic, focal vs generalized), dose ranges, timing, or experimental design.

Phytocannabinoids: Δ 9-THC and CBD

Evidence from 34 studies from 6 animal species demonstrate that Δ 9-THC is anticonvulsant in 61.8 % (21/34), proconvulsant in 2.9 % (1/34), mixed in 2.9 % (1/34), and shows no significant effect in 32.4 % (11/34) of seizure models. Δ 9-THC potentiated the effects of phenytoin and phenobarbital in the maximal electroshock model of generalized seizures [178, 179]. The National Toxicology Program noted a proconvulsant effect of Δ 9-THC in rats and mice [180], although species-specific differences in CB₁R expression may underlie variable responses to Δ 9-THC. CBD and its homologue cannabidiol (CBDV) were 80.5 % (33/41) anticonvulsant and 19.5 % (8/41) ineffective, at reducing seizures in mice and rats. Notably, no studies showed a proconvulsant effect for CBD or CBDV. CBDV potentiated the effects of phenobarbital, ethosuximide, and valproate in 2 seizure models [181]. These studies suggest that both Δ 9-THC and CBD provide significant protection from seizures

Fig. 3 Homeostatic changes to hippocampal cannabinoid type 1 receptors (CB₁R) in preclinical animal seizure models [147, 154–166]. GABA = γ -aminobutyric acid

in preclinical animal trials, presenting potential targets for human studies.

Tolerance and Withdrawal

Prolonged treatment with Δ 9-THC or synthetic CB1 agonists leads to a dose-dependent and region-specific desensitization, downregulation, and internalization of CB₁Rs [182–203]. These changes produce tolerance to the acute behavioral effects of Δ 9-THC in *in vivo* models, reducing cannabinoid-induced hypomotility, hypothermia, antinociception, and memory impairment with repeated usage [182, 183, 185, 197, 199, 204, 205]. In several seizure models, prolonged Δ 9-THC (but not CBD) exposure leads to tolerance to the antiepileptic activity of cannabinoids [206–210]. In humans, chronic cannabinoid usage produces tolerance towards Δ 9-THC-mediated changes in autonomic behaviors, sleep and sleep EEGs, and self-reported psychotropic high, although these changes vary in frequent users [211–216].

Withdrawal from rats chronically dosed with Δ 9-THC triggers rebound seizures and elevated anxiety-like responses in several preclinical animal studies [217–219]. Monkeys that previously self-administered intravenous Δ 9-THC demonstrate abstinent symptoms of aggressiveness, hyperirritability, and anorexia [220], as well as impaired operant behavior [221]. Results from human studies demonstrated symptoms of anxiety, aggression, dysphoria, irritability, anorexia, sleep disturbances, and sweating during abstinence from chronic Δ 9-THC usage, rescued by Δ 9-THC re-administration [222]. Withdrawal from cannabis use can trigger rebound seizures in several preclinical animal and human studies [203, 209, 210, 223–226], although other studies show no proconvulsant effect of cannabis withdrawal [178, 227].

Unlike Δ 9-THC, CBD (or nabiximols, CBD/ Δ 9-THC in a 1:1 ratio) does not seem to produce significant intoxication [228], tolerance [229–231], or withdrawal effects [232]. CBD and/or nabiximols may counteract the Δ 9-THC-dominant effects of cannabis withdrawal [233–235]. In summary, evidence suggests that while both tolerance and some withdrawal symptoms may occur with Δ 9-THC, CBD may limit the effects of cannabis tolerance and withdrawal, but more studies are needed.

Clinical Evidence of Cannabinoids in Epilepsy

Several clinical studies have examined the association between cannabis use and seizures. These include case studies, surveys and epidemiological studies, and clinical trials.

Case Studies

Case reports describe proconvulsant and anticonvulsant effect of cannabis, with the majority reporting either beneficial or

lack of effect on seizure control. Selected examples illustrate the diverse spectrum of reported responses. Cannabis used 7 times within 3 weeks was associated with multiple tonic–clonic seizures in a patient previously seizure free for 6 months on phenytoin and phenobarbital. However, seizures were not temporally correlated with immediate intoxication or withdrawal [236]. Cannabis withdrawal increased complex partial seizure frequency in a 29-year-old man with a history of alcoholism and bipolar disorder (each of which are independently associated with seizures) [226]. In another 2-part case study, a 43-year-old on carbamazepine experienced about 5–6 nightly violent seizures lasting 1 min each. When he consumed about 40 mg *C. sativa* at night, seizure frequency was reduced by 70 %, but withdrawal triggered a doubling of his baseline seizure frequency. In the same study, a 60-year-old man with a 40-year history of cannabis usage (6–8 cigarettes per day) developed status epilepticus after cannabis withdrawal [225]. Additionally, synthetic “designer” cannabinoid drugs (“spice” or “K2”) induce new-onset seizures, tachyarrhythmia, and psychosis, often with greater severity and toxicity than cannabis [237–245]. The toxicity of these synthetic agents may result from their properties as full agonists of CB₁R, while Δ 9-THC is a partial agonist.

The majority of other studies demonstrate an anticonvulsant effect of cannabis. In a 1949 trial, administration of a Δ 9-THC homolog (1,2-dimethyl heptyl) reduced the “severe anticonvulsant resistant (phenobarbital or phenytoin) grand mal epilepsy” in 2/5 children [246]. One patient whose seizures were not controlled on low-dose phenobarbital or phenytoin had fewer tonic–clonic seizures while smoking 2–5 cannabis cigarettes per day [247]. Myoclonic and other seizures were reportedly reduced in 3 adolescents on oral 0.07–0.14 mg/kg Δ 9-THC daily. Parents reported that their children were “more relaxed...more alert, more interested in her surroundings” [248]. In another study, a 45-year-old man with cerebral palsy and treatment-resistant focal epilepsy experienced a marked reduction in focal and secondary generalized seizures on daily marijuana [249]. Other recent cases also support the observation that cannabis use can reduce seizures in some patients [250, 251]. These studies suggest that cannabis can not only reduce seizure susceptibility, but also trigger rebound seizures during withdrawal. Limitations of open-label, often retrospective single case reports are compounded by the variability in epilepsy syndrome, differences in cannabis dosage, route, and composition.

Epidemiological Reports and Surveys

Recent epidemiological reports and surveys depict the incidence of medical marijuana usage for seizure control. The predicted prevalence of medical cannabis use in epileptic patients ranges from about 4 % (77=total patient population in US medical cannabis program) to about 20 % (310=total patients at a tertiary

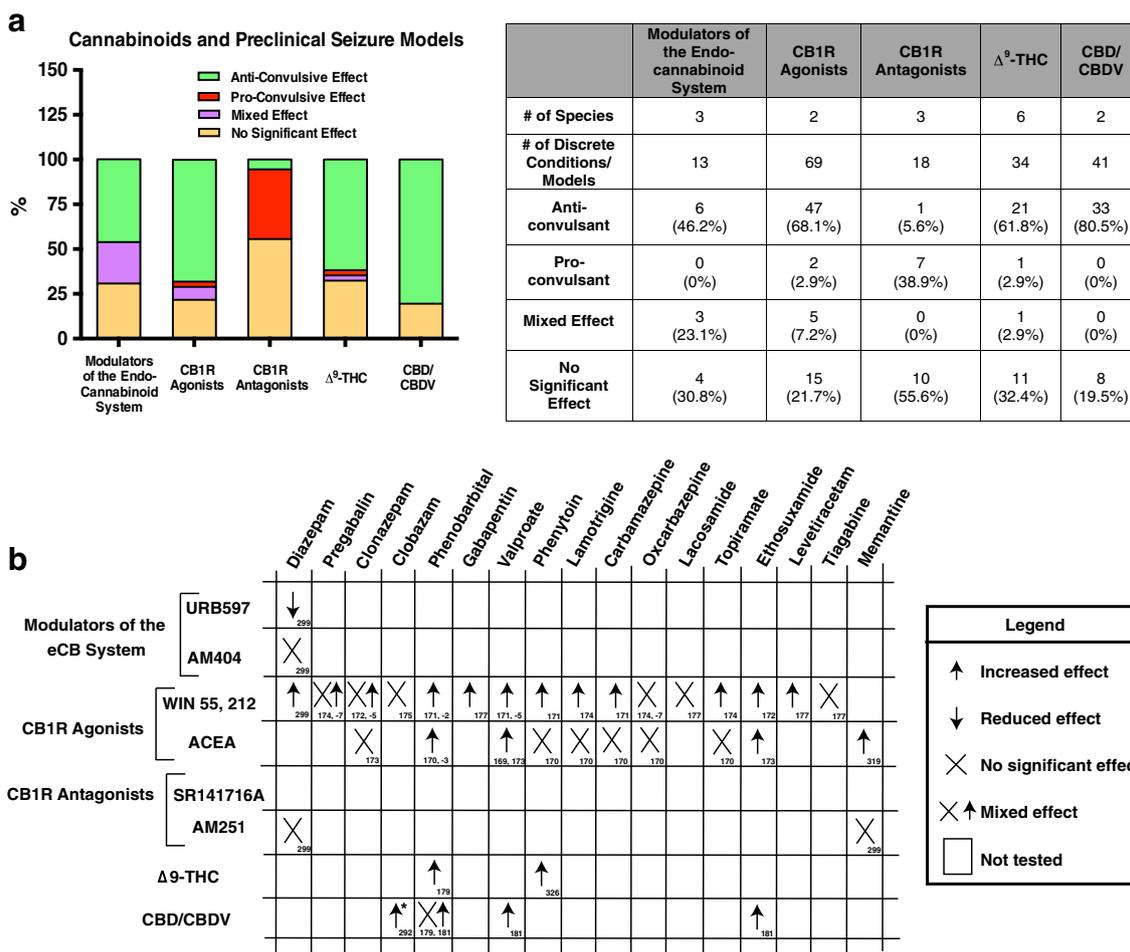

Fig. 4 Summary of cannabinoids and preclinical seizure models. (A) Composite data from 175 preclinical seizure models (e.g., maximal electroshock, kainic acid) or discrete experimental designs (e.g., with combined antiseizure medications). Pro-/antiseizure effects are subclassified by given intervention: 1) modulators of the endocannabinoid (eCB) system (e.g., fatty acid amide hydrolase inhibitor URB597); 2) cannabinoid type 1 receptor (CB₁R) agonists (e.g., WIN55212-2); 3) CB₁R antagonists (e.g., SR141716A); 4) Δ⁹-

tetrahydrocannabinol (Δ⁹-THC); and 5) cannabidiol (CBD)/cannabidivarin (CBDV). (See [Supplementary Material](#) for complete description of preclinical studies.) (B) Summary of preclinical data on cannabinoid interactions with antiseizure medications. Sources indicated in boxes. *Recent evidence from a phase I clinical trial suggests that CBD/CBDV elevates serum concentrations of clobazam and N-desmethyloclobazam in human pediatric patients with treatment-resistant epilepsy [292]. ACEA = arachidonyl-2'-chloroethylamide

epilepsy clinic in Germany) [252, 253]. One percent of the medical marijuana users in California (~2500=total patient population) use cannabis to control seizures [254]. In a telephone survey of 136 patients with epilepsy, 21.0 % were active users, 13.0 % were frequent users, 8.1 % were heavy users, and 3.0 % met Diagnostic and Statistical Manual of Mental Disorders-IV criteria for marijuana dependence.

The majority of patient and caregiver surveys found either beneficial effects or no significant effect of cannabis in patients with epilepsy. In a small, 1976 survey of 300 patients with epilepsy, cannabis usage had no effect on seizure frequency in 30 % of patients, increased seizures in 1 patient, and decreased seizures in another [255]. A 1989 12-year retrospective study reported 10 % of 47 patients with “recreational drug-induced [tonic-clonic] seizures” had consumed cannabis prior to seizures, although this was confounded by recent cocaine, amphetamine, or LSD

(lysergic acid diethylamide) usage. No seizures were reported following cannabis use alone [256]. A single epidemiological study provided limited evidence that cannabis may possess anti-seizure properties in humans. In a study of illicit drug use and new-onset seizures in Harlem utilizing a case-control methodology, cannabis used within 90 days before hospitalization was associated with a 2.8-fold decreased risk of first seizures among men but not women [257]. In a telephone survey of adult patients from a tertiary care epilepsy center, most active users reported beneficial effects on seizures (68 % reduced severity, 54 % reduced incidence), and 24 % of all subjects believed marijuana was an effective therapy for epilepsy. No patient reported a worsening of seizures with cannabis use [258]. The majority (84 %) of patients in a German tertiary care center reported that cannabis had no effect on their seizure control [253].

A 2013 survey of 19 parents of children with treatment-resistant epilepsy investigated the use of high CBD:Δ9-THC ratio artisanal marijuana products. These parents were primarily identified from social media and included 12 children with Dravet syndrome (DS). Of the 12 children with DS, parents reported that 5 (42 %) experienced a >80 % reduction in seizure frequency and 2 (11 %) reported complete seizure freedom. The single child with Lennox–Gastaut syndrome (LGS) was reported to have a >80 % reduction in seizure frequency. In addition to seizure control, parents reported positive effects of increased alertness (74 %), better mood (79 %), improved sleep (68 %), and decreased self-stimulation (32 %), and rare AEs of drowsiness (37 %) and fatigue (16 %) [259]. A more recent retrospective case study described 75 patients from Colorado with treatment-resistant epilepsy who moved to Colorado for oral cannabis extract treatment. Oral cannabis extract treatment controlled seizures in 57 % of patients, reduced seizures by >50 % in 33 % of patients, and showed greater effectiveness in patients with LGS (88.9 %) than in patients with DS (23.0 %). Reported additional benefits included improved behavior/alertness (33 %), language (10 %), and motor skills (10 %), as well as rare AEs of increased seizures (13 %) and somnolence/fatigue (12 %). Interestingly, the study also reported a significant, independent “placebo effect” of families moving to Colorado for treatment (see “Placebo Effect”) [260]. Collectively, these surveys suggest a predominantly antiseizure (or no significant) effect of cannabis usage. However, it is essential to consider the limitations of subjective self-reporting, potentially biased sampling of patient advocacy groups (over-reporting positive effects), and uncontrolled differences in CBD:Δ9-THC content in various strains of cannabis in these studies.

Clinical Trials

A recent Cochrane review assessed 4 primary clinical trials to examine the efficacy of medical marijuana in seizure control (summarized in Table 2, adapted from [11], [13]). Two of these studies demonstrated a partial antiseizure effect of CBD [261, 262], while 2 showed no significant effect [263, 264]. However, all 4 studies included significant limitations, including low study sizes, insufficient blinding or randomization, or incomplete data sets. The authors of the Cochrane review and a recent meta-analysis from the American Academy of Neurology both emphasized the need for follow-up placebo-controlled, blinded, randomized clinical trials examining the role of CBD in seizure control [12, 13].

Phase I Clinical Trial for CBD in Treatment-resistant Epilepsy

Preliminary preclinical and clinical evidence reveal the therapeutic potential of CBD to reduce seizures with high

tolerability and low toxicity. Accordingly, CBD represents a highly desirable treatment alternative for patients with early-onset, severe epilepsy such as DS and LGS. In addition to pharmacoresistant seizures, these patients suffer from severe neurodevelopmental delay, intellectual disability, autism, motor impairments, and significant morbidity and mortality [265, 266]. As patients with DS and LGS require effective and better-tolerated therapies and represent relatively homogeneous populations, they stand out as candidates for an initial trial of CBD safety and efficacy.

Study Design and Results

Investigator-initiated open-label studies at 10 epilepsy centers using Epidiolex (GWPharma, Salisbury, UK; 99 % CBD) collected data on 213 patients with treatment-resistant epilepsies. This predominantly pediatric population had a mean age of 10.8 years (range 2.0–26.0 years). CBD was added to existing AEDs; there was an average of 3 concomitant AEDs. The average baseline was 60 per month for total seizures and 30 per month for convulsive seizures.

The primary goal of the study was to assess safety but seizure diaries were obtained for convulsive, drop, and total seizures to provide a potential signal regarding efficacy. Twelve-week or longer continuous exposure data were obtained for 137 patients and were used in efficacy measures. The most common epilepsy etiologies were DS and LGS syndromes; others included Aicardi syndrome, Doose syndrome, tuberous sclerosis complex, CDKL5, Dup15q syndrome, and many others. At week 12, total convulsive and nonconvulsive seizures showed a median percent reduction from baseline of 54 %, and total convulsive seizures showed a median percent reduction from baseline of 51 %. In patients with DS ($n=23$), CBD reduced convulsive seizure frequency by 53 %, and 16 % of DS reached complete convulsive seizure freedom by week 12. Atonic seizure frequency among patients with LGS ($n=10$) was reduced by a median of 52 % at week 12. AEs >10 % included somnolence (21 %), diarrhea (17 %), fatigue (17 %), and decreased appetite (16 %). Nine patients (4 %) were discontinued for AEs. The investigators concluded that CBD reduced seizure frequency across multiple drug-resistant epilepsy syndromes and seizure types and was generally well-tolerated in the open-label study. Randomized controlled trials (RCTs) are now ongoing for DS and LGS.

Safety Issues

There is a strong tendency to equate “cannabis as a natural therapy” with “cannabis as a safe therapy”. This a priori assumption—the naturalistic fallacy—is countered by many instances of toxic or deadly plants (e.g., amatoxins in mushrooms) and animals (e.g., tetrodotoxin in puffer fish). A more muted naturalistic view is that if side effects occur with

cannabis, they would be less severe than those from drugs produced by the pharmaceutical industry. A recent *Epilepsia* survey of 776 individuals found that 98 % of the general public supported the use of medical marijuana for severe cases of epilepsy, compared with only 48 % of epileptologists. Similarly, the majority of the public and a minority of epileptologists thought that there was sufficient safety (96 % vs 34 %) and efficacy (95 % vs 28 %) data for medical marijuana use in severe epilepsy. This significant disparity in opinion between professionals and the lay public, possibly swayed by the appeal of natural remedies, emphasizes an increased need for further research and public education regarding medicinal cannabis and epilepsy [267].

As with efficacy, the most valid assessment of side effects is with RCTs. RCT data on the safety of Δ 9-THC and CBD in adults comes from trials of cannabinoid-containing medications, including nabixomols [Sativex (GWPharma) 1:1 Δ 9-THC:CBD], purified cannabis extracts [Cannador, Institute for Clinical Research, IKF, Berlin, Germany, (2:1 Δ 9-THC:CBD)], synthetic Δ 9-THC analogues Dronabinol and Nabilone. These drugs have been approved by many international regulatory agencies. In a meta-analysis of 1619 patients treated with nabiximols for neurological indications (mainly pain, spasticity, spasm, or tremor) for 6 months or less, 6.9 % of those on cannabinoid therapies were discontinued because of adverse effects versus 2.25 % in the placebo groups [12]. Adverse effects occurring in at least 2 studies included nausea, dizziness, increased weakness, behavioral or mood changes, hallucinations, suicidal ideation, fatigue, and feeling of intoxication. No deaths from overdose were reported [12]. However, our knowledge on the safety of these compounds in children is very limited.

The adverse health effects of recreational cannabis use were recently reviewed [268]. Δ 9-THC is presumed to be the major cannabinoid resulting in adverse acute and chronic health effects of cannabis. The 4-fold increase in Δ 9-THC content of confiscated cannabis in the last 20 years is associated with increased acute complications. In 2011, there were 129,000 emergency department visits for cannabis alone and 327,000 additional visits for cannabis in combination with other drugs. From 2004 to 2011, the rate of emergency department visits for cannabis toxicity doubled [268]. Short-term use can impair short-term memory, coordination, and judgment. In high doses, paranoia and psychosis can occur [137, 269]. Long-term use of recreational cannabis in adolescents is associated with addiction (9 % overall but 17 % among adolescents) and impaired cognitive and academic performance [270–274]. Additionally, cannabis treatment in animal and human studies altered brain development (especially with use in early childhood) and structure [272, 275–277], creating long-lasting functional and structural brain abnormalities [277–279]. Early and/or heavy cannabis use is associated with neurochemical abnormalities on magnetic resonance spectroscopy [272], impaired maintenance of neuronal cytoskeleton dynamics [277], decreased white matter development or integrity

[272, 275, 276], increased impulsivity [276], and abnormal activation patterns during cognitive tasks on functional magnetic resonance imaging [272, 280]. In patients with multiple sclerosis, use of cannabis is associated with impaired cognition and activation patterns on functional magnetic resonance imaging [281]. Further research is required to determine the short- and long-term effects of CBD alone, which may have lower toxicity than whole plant cannabis or Δ 9-THC.

Cannabidiol Formulations, Pharmacokinetics, Pharmacodynamics, and Drug–Drug Interactions

We are aware of 3 pharmaceutical products that are currently in trials or in development: 1) Epidiolex (99 % CBD derived from *C. sativa* plants, in a strawberry-flavored sesame oil), 2) synthetic CBD from Insys Therapeutics (Chandler, AZ, USA), and 3) Transdermal CBD gel from Zynerva Pharmaceuticals (Devon, PA, USA). Other CBD-containing products are available commercially and obtained online [e.g., Realm of Caring's Charlotte's Web (whole cannabis extract containing 50 mg/ml CBD)]. However, the quality control and consistency of these products may vary considerably. Indeed, a recent study by the US Food and Drug Administration tested 18 products, claimed to contain CBD, made by 6 companies. Of these, 8 contained no CBD, 9 contained <1 % CBD, and 1 contained 2.6 % CBD (<http://www.fda.gov/NewsEvents/PublicHealthFocus/ucm435591.htm>).

Because lipophilic cannabinoids (including CBD) have low water solubility, CBD is traditionally delivered orally in either an oil-based capsule or sublingual spray, permitting less variable pharmacokinetics in gastrointestinal absorption. A single 10-mg dose of nabiximols (equal parts CBD and Δ 9-THC) in humans produces a maximum serum concentration (C_{\max}) of $3.0 \pm 3.1 \mu\text{g/l}$ (buccal) [$2.5 \pm 1.8 \mu\text{g/l}$ (sublingual)] and maximum time (T_{\max}) of $2.8 \pm 1.3 \text{ h}$ (buccal) [$1.6 \pm 0.7 \text{ h}$ (sublingual)] [282]. CBD is primarily protein-bound in the blood, and preferentially deposits in brain and adipose tissue [283].

The cannabinoids are primarily metabolized by the liver cytochrome P-450 (CYP-450) enzymes. Both Δ 9-THC and CBD can inhibit CYP-450 metabolic activity, particularly the CYP2C isozymes at low concentrations and CYP3A4 isozymes at higher concentrations [284–289]. CYP2C and CYP3A4 are induced by carbamazepine, topiramate, and phenytoin, and inhibited valproate and other drugs [290]. The cannabinoids, particularly CBD, can inhibit other isozymes, including 2D6 and 1A1 [285, 291]. Therefore, use of Δ 9-THC or CBD could potentially contribute to bidirectional drug–drug interactions with antiepileptic and other drugs. In our open-label CBD study, patients treated with CBD had elevated levels of the nordesmethyl metabolite of clobazam [292], which may account for a portion of the apparent sedation, as well as efficacy, of CBD.

Table 2 Clinical trials of cannabidiol (CBD) and epilepsy (adapted from [11, 13])

Study	Seizure type	Population size	Treatment (subjects per group)	Continued AEDs?	Duration	Outcome	Toxicity	Limitations
Mechoulam and Carlini [261]	Treatment-resistant, temporal lobe epilepsy	9	CBD, 200 mg/day (4) Placebo (5)	NS	3 months	CBD: seizure free (2), partial improvement (1), no change (1); placebo: no change (4)	None	No baseline seizure frequency; no definition of improvement; unclear if AEDs were changed; not truly randomized or blinded; unknown if groups were matched
Cunha et al. [262]	Treatment-resistant, temporal lobe epilepsy	15*	CBD 200–300 mg/day (8*) Placebo (8*)	Yes	3–18 weeks	CBD: near seizure freedom (4), partial improvement (3), no change (1); placebo: no change (7), partial improvement (1)	Somnolence	Not clearly blinded (1 patient transferred groups); doses were adjusted in CBD group, not in placebo; CBD group received longer average treatment
Ames and Cridland [263]	Treatment-resistant epilepsy, intellectual/developmental disability	12	CBD 300 mg/day for 1 week; 200 mg/day for 3 weeks (6?) Placebo (6?)	NS	4 weeks	No difference between CBD and placebo	Somnolence	Brief letter to the editor, details lacking on specifics; discontinued owing to “technical difficulties in preparing the drug”
Tremblay and Sherman [264]	Treatment-resistant epilepsy	10–12†	CBD 100 mg once daily Placebo	Yes	3 months baseline, 6 months CBD or placebo, then 6 months crossover to alternative treatment	No difference between CBD and placebo (seizure frequency or cognitive/behavioral tests)	None	Differences in sample size reporting; data reported are incomplete (conference abstract)‡

AEDs = antiepileptic drugs; NS = not stated

*1 patient switched groups after 1 month

† Abstract and subsequent book chapters have different numbers

‡ Only truly double-blind study

Placebo Effect

The magnitude of the placebo response is related to the power of belief. Given the social and mainstream media attention selectively reporting dramatic benefits of artisanal cannabis preparations for children with epilepsy, there are high expectations on the part of many parents. The potent role of the placebo response was suggested by a recent survey of parents whose children with epilepsy who were cared for at Colorado Children's Hospital. A beneficial response (>50 % seizure reduction) was reported 3 times more often by parents who moved to the state compared with those who were long-time residents [260]. No differences in epilepsy syndrome, type of artisanal preparation, or other factor could account for this difference.

While studies have reported a significant placebo response in adult patients (such as those with Parkinson's Disease [293]), placebo response rates are particularly high among children and adolescents in a subset of disorders, including psychiatric (anxiety, major depression, and obsessive compulsive and attention deficit disorders), medical (asthma), and painful (migraine, gastrointestinal) conditions [294, 295]. As the current RCTs of CBD primarily target children with severe epilepsy, this may be an important issue. Among patients with treatment-resistant focal epilepsy, a meta-analysis found that the placebo response in children (19.9 %) was significantly higher than in adults (9.9 %), while the response to the AED was not statistically different in children (37.2 %) and adults (30.4 %) [296]. In one predominantly pediatric LGS trial, seizures were reduced in 63 % of placebo-treated patients and 75 % of drug-treated patients [297]. Paradoxically, the intense interest and strong beliefs in the efficacy of cannabis for epilepsy may elevate placebo responses and make it more difficult to demonstrate a true benefit in RCTs.

Legal/Ethical Concerns

The Drug Enforcement Agency (DEA) classifies cannabis and products derived from cannabis plants as Schedule I drugs. Schedule I drugs have a high potential for abuse and no currently accepted medical use; they are the most dangerous drugs of all the drug schedules with potentially severe psychological or physical dependence (DEA website; <http://www.dea.gov/druginfo/ds.shtml>). It is thus paradoxical that opiates and benzodiazepines, which have a much greater potential for psychological and physical dependence than cannabis, are classified as Schedule II drugs. With regard to the DEA's "claim" that cannabis-derived drugs have no currently accepted medical use, therapies such as nabiximols (CBD and Δ^9 -THC) and other products have been approved by regulatory agencies in >20 countries. These approvals are based on RCTs that establish efficacy and a favorable safety profile, including a low potential for abuse [228, 298].

The Schedule I categorization makes it challenging for investigators to study cannabis-derived cannabinoids in basic and clinical science. There is often a long and costly process to secure approvals and inspections to obtain cannabinoids, purchase a large safe, the weight of which may require clearance from engineers, and add security systems to the room and building in which they are stored. The Schedule I designation often prevents patients who live in developmental centers or residential homes from participating in clinical trials. The threshold of effort for basic and clinical investigators to study cannabinoids remains as high as ever, while the availability of these substances for parents to give is expanding rapidly. This has created a widening gap between knowledge and exposure, an especially relevant concern in children for whom safety data are largely lacking.

Conclusion

For over a millennium, pre-clinical and clinical evidence have shown that cannabinoids such as CBD can be used to reduce seizures effectively, particularly in patients with treatment-resistant epilepsy. However, many questions still remain (see Box 1) regarding the mechanism, safety, and efficacy of cannabinoids in short- and long-term use. Future basic science research and planned multicenter, placebo-controlled clinical trials will provide insight into cannabinoid function and the potential neuroprotective effects of the endocannabinoid system. These findings will increase our mechanistic understanding of seizures and may provide novel, targeted therapeutics for epilepsy.

Box 1 Unanswered questions and directions for future studies

1. How do the pro and anti-epileptic effects of cannabis change with development? Are there age-specific differences in responsiveness, side effects, and target receptor expression?
 2. What are the long-term effects of cannabis/cannabidiol use?
 3. Are certain types of seizures or genetic channelopathies more likely to respond to cannabidiol than others?
 4. What is the safety of cannabidiol in patients with special conditions (pregnancy, recent or planned surgery, vagus nerve stimulation, etc.)?
 5. How do synthetic cannabinoids ("spice" or "K2") dysregulate the central nervous system to induce seizures? What is their relative safety and toxicity relative to cannabis?
-

Acknowledgments Drs. Orrin Devinsky and Ben Whalley have received research support from GW Pharmaceuticals. We acknowledge FACES (Finding a Cure for Epilepsy and Seizures) for generous help in the preparation of this manuscript. R.W.T. is supported by grants from the National Institute of Mental Health (5R37MH071739) and the National Institute of Neurological Disorders and Stroke (5R01NS074785, 5R01NS024067).

Medical Cannabis in Arizona: Patient Characteristics, Perceptions, and Impressions of Medical Cannabis Legalization

William D. Troutt, N.M.D. & Matthew D. DiDonato, Ph.D.

Abstract—Many advances have been made toward understanding the benefits of medical cannabis. However, less is known about medical cannabis patients themselves. Prior research has uncovered many important patient characteristics, but most of that work has been conducted with participants in California, who may not represent medical cannabis patients throughout the United States. Furthermore, it is unknown if medical cannabis legalization, which typically imposes strict regulations on cannabis cultivation and sale, impacts patients' experiences acquiring and using cannabis. The goal of this study was to address these limitations by (1) examining the characteristics, perceptions, and behaviors of medical cannabis patients in Arizona; and (2) questioning participants with a history of cannabis use regarding their experiences with cannabis before and after legalization. Patients in Arizona share many characteristics with those in California, but also key differences, such as average age and degree of cannabis consumption. Participants also had positive perceptions of the effect of medical cannabis legalization, reporting that feelings of safety and awareness were higher after legalization compared to before. The results are discussed in relation to evidence from patients in other states and in terms of their potential policy implications.

Keywords—Arizona, medical cannabis, medical cannabis legalization, patient characteristics, perceptions

Support for the use of cannabis for medical purposes is growing throughout the United States. To date, 23 states and the District of Columbia have enacted laws legalizing medical cannabis, and 16 states have similar legislation under consideration. Recent polls also show that the majority of Americans believe that cannabis should be legalized for medical purposes (Anderson Robbins Research & Shaw & Company Research 2013; Associated Press-CNBC 2010), and the popularity of this sentiment has

increased over time (Anderson Robbins Research & Shaw & Company Research 2013).

Support may be on the rise, in part, due to research that shows the potential therapeutic effects of medical cannabis. Animal studies, for example, show that cannabis-derived extracts mitigate cancer cell proliferation and tumor growth (Aviello et al. 2012) and have antidepressant-like effects (Jiang et al. 2005). Studies also show that cannabis may be beneficial for humans. Bar-Sela and colleagues (2013) found that nausea, vomiting, weight loss, sleep disorders, and pain were reduced in cancer patients after 6–8 weeks of cannabis use. Studies also show that cannabis significantly reduces chronic pain (see Lynch and Campbell 2011),

inflammatory bowel disease (Allegretti et al. 2013), post-traumatic stress disorder (Greer, Grob, and Halberstadt 2014), and seizure disorders (Lorenz 2004).

Although many advances have been made in understanding the benefits of medical cannabis, less is known about US medical cannabis patients themselves. Demographically, most patients are White, male, and approximately 35 to 45 years of age (Bonn-Miller et al. 2014; Grella, Rodriguez, and Kim 2014; Ryan-Ibarra, Induni, and Ewing 2015; Aggarwal et al. 2013; Ilgen et al. 2013; Nunberg et al. 2011; Reinerman et al. 2011; Aggarwal et al. 2009; Reiman 2009; O'Connell and Bou-Matar 2007; Harris et al. 2000). Most patients report medicating with cannabis daily (Bonn-Miller et al. 2014; Ilgen et al. 2013; Reinerman et al. 2011; O'Connell and Bou-Matar 2007), consuming six to nine grams of cannabis per week (Bonn-Miller et al. 2014; Reinerman et al. 2011; O'Connell and Bou-Matar 2007), and prefer inhalation as the method of consumption (O'Connell and Bou-Matar 2007).

Studies also show that the majority of patients use medical cannabis to relieve pain. However, patients also report using cannabis to treat a variety of other conditions, including anxiety, sleep apnea, hypertension, incontinence, and depression (Aggarwal et al. 2013; Nunberg et al. 2011; Reinerman et al. 2011). Generally, patients report that medical cannabis is effective for helping them manage their condition(s) (Bonn-Miller et al. 2014; Ryan-Ibarra, Induni, and Ewing 2015; Aggarwal et al. 2013; Harris et al. 2000). For example, Aggarwal and colleagues (2013) found that, on a scale from 1 to 10, where 10 indicated absolute symptom control, patients reported that cannabis provided symptom control in the range of 7 to 10 across a variety of conditions. Patients also often reduce their use of other medications (i.e., prescription and over-the-counter drugs) when using medical cannabis (Nunberg et al. 2011; Aggarwal et al. 2009; Reiman 2009, 2007).

Though these studies are informative, one limitation is that most were conducted with samples of patients living in California. California patients may not represent those living in other areas of the country because the regulations that govern patients in California are different from those in other states. For example, residents of California may legally obtain medical cannabis to treat a number of ailments, including any chronic or persistent condition that considerably limits major life activities or that, if not alleviated, may compromise the patient's safety or health (California Senate Bill 420 2003). Because the list of conditions for which the legal medical use of cannabis is granted in other states is often less inclusive, patients from these states may differ from those in California.

Considering that medical cannabis has been legalized in many states, there is an opportunity to paint a more comprehensive picture of American medical cannabis patients by conducting similar studies in other geographic locations.

Scientists have begun to conduct such research through the examination of patients living in Washington State (Aggarwal et al. 2013, 2009) and Michigan (Ilgen et al. 2013). Our first goal was to continue this line of research by studying medical cannabis patients in Arizona. To aid comparisons with previous research, we assessed patient characteristics, behaviors, and perceptions that have been examined in prior studies. These included patterns of use (e.g., frequency of consumption, amount of consumption, preferred method of consumption), degree of relief experienced when using medical cannabis, and use of other medications.

In addition to the limited research on medical cannabis patients outside of California, to our knowledge there has been no systematic examination of patients' perceptions of the outcomes of medical cannabis legalization. One objective of legalizing cannabis for medical use is to safeguard its acquisition and production, which often involves strict regulation of its cultivation and sale. For instance, the rules and regulations of the Arizona Medical Marijuana Program require that those authorized to operate medical cannabis dispensaries and cultivation facilities enact strict security policies and procedures (Arizona Department of Health Services Medical Marijuana Rules 2012). In addition, many dispensaries and facilities employ third-party laboratories to test cannabis products for possible contaminants. However, it is unknown if such regulations translate to changes in patient safety or product quality.

Because individuals who use cannabis medicinally are those most affected by these regulations, surveying patients regarding their experiences purchasing and using medical cannabis may uncover the changes legalization has had on patient safety and product quality. In particular, patients with a history of using cannabis medicinally prior to legalization can provide their perspective on the changes that legalization has generated. The second goal of the present study was to determine the effectiveness of measures invoked to regulate and secure the cultivation and sale of medical cannabis by examining the perceptions of patients that used cannabis medicinally prior to legalization. Patients were asked to compare their perceptions of safety, product knowledge, and the effectiveness of cannabis for treating their condition(s) before and after legalization. Because of the regulations imposed with the legalization of medical cannabis, we hypothesized that patients would feel greater safety, have better knowledge, and that cannabis effectiveness would be greater after legalization.

METHOD

Participants and Procedures

Participants were 367 patients recruited from four medical cannabis dispensaries located throughout Arizona. The majority of the patients were male (63.8%), and

ranged from 18 to 83 years of age ($M = 45.78$ years; $SD = 13.76$ years). Most of the patients were White (86.4%), whereas the rest were Hispanic (6.3%), Black (2.5%), Native American (1.9%), Asian (0.8%), or Other (2.1%). These figures are similar to those reported by the Arizona Department of Health Services (2014) for this patient population.

To protect patient confidentiality, the authors did not directly contact patients, but approached dispensary owners to request assistance in recruiting participants. Dispensary owners informed their patients of the study, and interested patients were directed to a website that provided information about the research, including a description of the study, an explanation of patients' rights as participants, and information regarding the collection and storage of participant responses (i.e., responses were anonymous and would be stored on a password-protected server and/or computer only accessible to the researchers). If the patient agreed to participate, he or she checked a box indicating his or her agreement and the survey questions appeared.

Measures

Patient conditions. Participants were asked to select from an extensive list of conditions for which they use medical cannabis to control or treat. For each condition selected, participants completed subsequent questions and rated them on five-point Likert-type scales regarding the degree of relief experienced overall (1 = No relief at all; 5 = Almost complete relief), the degree of relief compared to other medications (1 = Much less relief; 5 = Much more relief), and the use of other medications since using medical cannabis (1 = I use other medications much less frequently; 5 = I use other medications much more frequently). Higher scores indicated greater relief or more frequent use of other medications.

Patterns and methods of cannabis use. Patients reported on the frequency ("On average, how frequently do you medicate with medical cannabis?": "Less than once per month" to "Several times per day") and amount ("On average, how much medical cannabis do you consume in a month?": "Less than one gram" to "More than one ounce") of consumption. Patients also completed a single-item measure regarding their preferred method of consumption (smoking, edibles, tinctures, vaporizing, raw consumption, or oils).

Perceptions of prior medical cannabis users. Participants were asked if they had used cannabis to treat their condition(s) before its legalization in Arizona. Those who replied "yes" were asked to complete four additional items. These items included the perceived safety of acquiring cannabis ("Compared to when you did not have a medical marijuana card, acquiring cannabis as a medical marijuana card holder feels": 1 = Much more dangerous; 5 = Much safer), knowledge of strain

characteristics ("Compared to when you did not have a medical marijuana card, your knowledge of what strain you are acquiring and its characteristics is": 1 = Much worse; 5 = Much better), confidence in a safe product ("Compared to when you did not have a medical marijuana card, your confidence that you are receiving a safe, uncontaminated product is": 1 = Much lower; 5 = Much higher), and product effectiveness for treating their condition(s) ("Compared to when you did not have a medical marijuana card, the effectiveness of the cannabis you receive to treat your condition is": 1 = Much worse; 5 = Much better).

RESULTS

The conditions for which patients reported using medical cannabis are displayed in Table 1. Consistent with previous research, the majority of patients reported suffering from chronic pain. Other commonly reported conditions included anxiety, depression, headaches, insomnia, muscle spasms, nausea, and stress.

Figure 1 shows the distributions of patients for frequency of cannabis use (Figure 1A), amount of cannabis consumed per month (Figure 1B), and preferred method of cannabis consumption (Figure 1C). The large majority of patients (83.7%) reported using medical cannabis several times per week or more, with most using medical cannabis daily (61%). Most patients consumed one-half of an ounce of cannabis or less per month (78.1%), and the most popular method of consumption was inhalation (i.e., smoking or vaporizing; 67.2%).

Perceived Effectiveness of Medical Cannabis

Patients' perceptions of the effectiveness of medical cannabis for treating their condition(s) are presented in Table 1. The values reflect the percent of patients who reported experiencing, overall, *a lot of relief* or *almost complete relief* from their symptoms and conditions when using medical cannabis (second column), *a little more relief* or *much more relief* from medical cannabis compared to other medications (third column), and using other medications *a little less frequently* or *much less frequently* when medicating with cannabis (fourth column).

For many of the conditions, patients reported that cannabis was effective for helping them manage their ailments. For example, at least 70% of patients reported experiencing *a lot of relief* or *almost complete relief* for 24 of the 42 conditions. Similarly, for 27 of the 42 conditions, at least 70% of patients reported experiencing *a little more relief* or *much more relief* from medical cannabis compared to other medications. Finally, at least 70% of patients reported using other medications *a little less frequently* or *much less frequently* for 24 of the 42 conditions.

TABLE 1
Percent of Patients Who Experience Relief and Less Frequently Use other Medications Due to Medical Cannabis Use, by Condition

Condition	Number of patients (%)	General relief ^a	Relief compared to other medications ^b	Less frequent use of other medications ^c
Alcohol Dependency	23 (6.3%)	91.30%	100%	100%
Anxiety	181 (49.3%)	82.90%	79.30%	85.90%

Sleep Apnea	31 (8.5%)	58.10%	85.00%	66.60%
Stress	164 (44.7%)	87.20%	91.60%	79.10%
Tourette's Syndrome	4 (1.1%)	100%	100%	—
Tremors	6 (1.6%)	50.00%	100%	100%
Vomiting	31 (8.4%)	71.00%	87.50%	82.40%
Wasting	6 (1.6%)	50.00%	66.70%	100%
Weight Loss	24 (6.5%)	62.50%	80.00%	70.00%

^aThe percent of patients with this condition who reported that they experienced a lot or almost complete overall relief.
^bThe percent of patients with this condition who reported that they experienced a lot or almost complete overall relief.
^cThe percent of patients with this condition who reported that they use other medications a little or much less frequently.

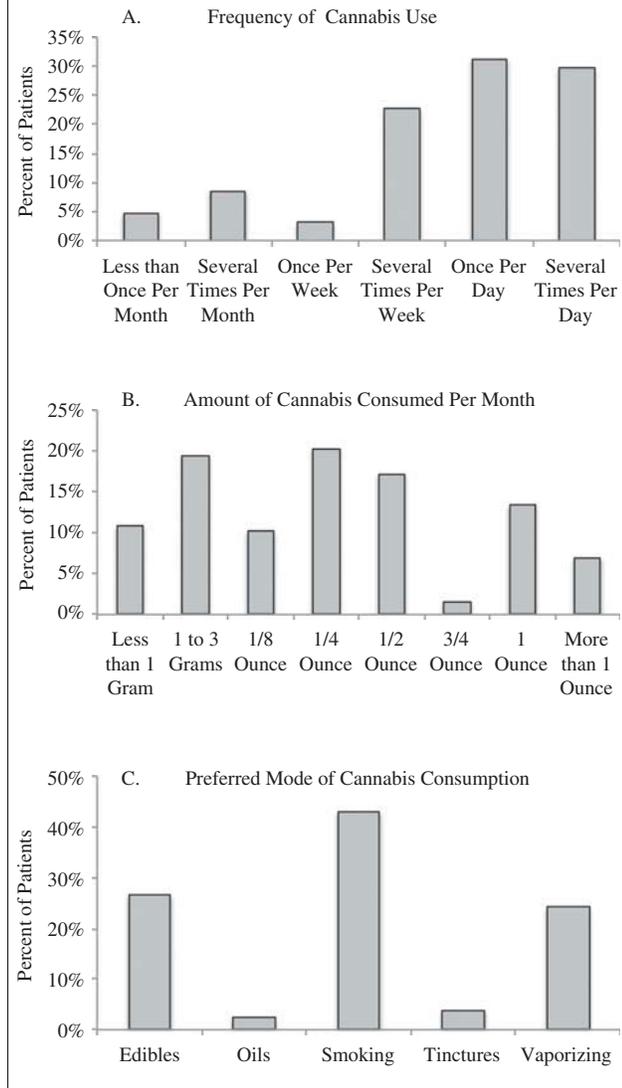

Perceived Effects of Medical Cannabis Legalization

Nearly two-thirds of participants (*n* = 239) reported using cannabis medicinally prior to legalization. These patients were asked to compare their current experiences

acquiring, their knowledge of, and their experiences using medical cannabis to their experiences and knowledge before legalization. Distributions of the patient's responses are shown in [Figure 2](#). Compared to their experiences

FIGURE 1

Distributions of patient responses, by percentage, for cannabis-related behaviors and perceptions: (A) the frequency of patient’s cannabis use; (B) the amount of cannabis consumed by patients per month; (C) patient’s preferred mode of cannabis consumption.

before legalization, 89.1% of patients reported that acquiring cannabis after legalization felt *somewhat safer* or *much safer*, 80.3% reported that their knowledge of the cannabis strains they acquired was *somewhat better* or *much better*, 85.4% reported that they had *somewhat more confidence* or *much more confidence* that they were purchasing a safe and uncontaminated product, and 79.5% reported that the medical cannabis was *somewhat more effective* or *much more effective* for treating their condition(s).

DISCUSSION

The goals of this study were to (1) examine the characteristics, perceptions, and behaviors of medical cannabis patients in Arizona; and (2) question participants with a history of cannabis use regarding their perceptions of safety acquiring cannabis, the quality of the cannabis they have obtained, their knowledge of the cannabis, and its perceived effectiveness, before and after legalization.

Patient Characteristics, Perceptions, and Behaviors

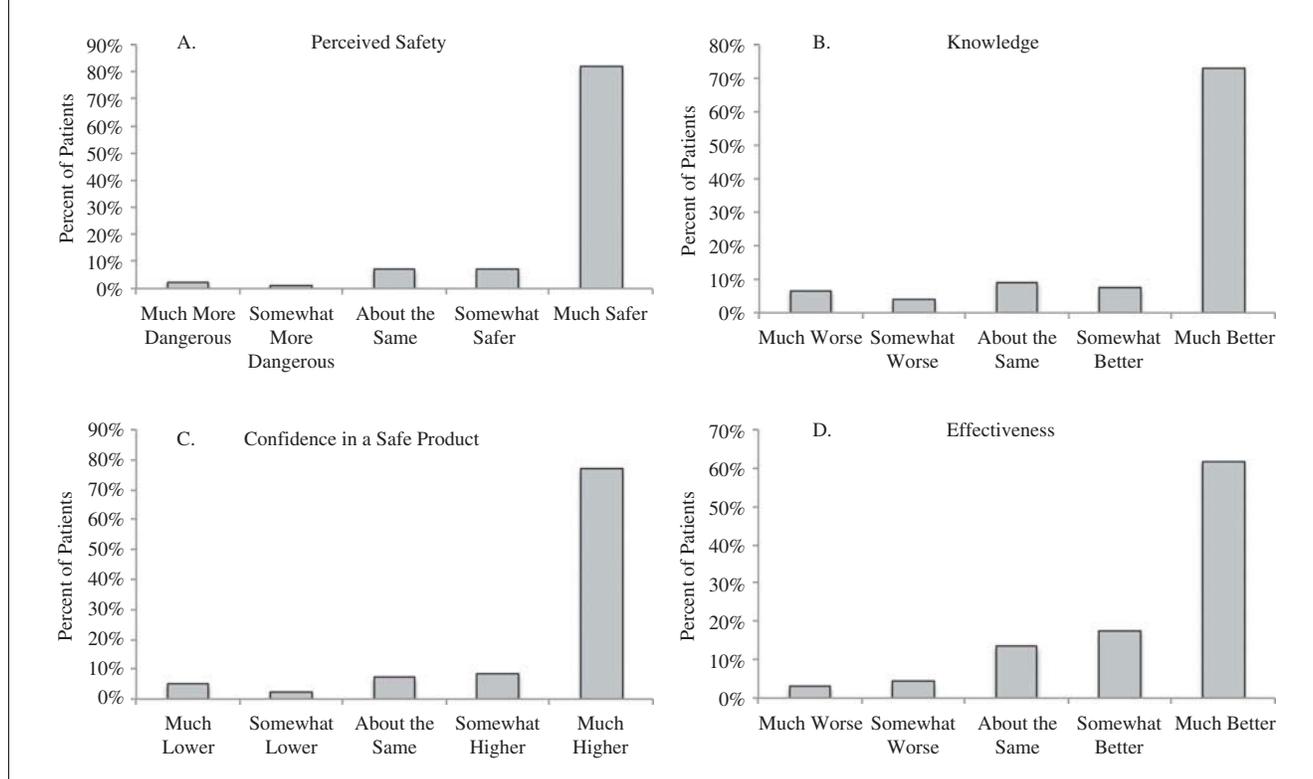

Consistent with research in other states (Bonn-Miller et al. 2014; Aggarwal et al. 2013; Ilgen et al. 2013; Nunberg et al. 2011; Reinerman et al. 2011; Aggarwal et al. 2009; Reiman 2009; O’Connell and Bou-Matar 2007; Harris et al. 2000), participants in the present study were mostly White men. Average patient age, approximately 46 years, differed from that in other states. For example, average ages reported in studies of patients from California range from 28 to 41 years (Bonn-Miller et al. 2014; Grella, Rodriguez, and Kim 2014; Reiman 2009, 2007; Harris et al. 2000). Average patient age is somewhat higher in Colorado (42 years of age; Colorado Department of Public Health and Environment 2014) and Washington State (41 to 47 years of age; Aggarwal et al. 2013, 2009). In Michigan (46 years of age; Murphy 2013) and Montana (47 years of age; Montana Department of Public Health and Human Services 2014), average patient age more closely approximates that of Arizona.

State-level variation in the average age of medical cannabis patients may in part be explained by the conditions that qualify a person to use medical cannabis in each state. For example, the qualifying conditions in Arizona, Colorado, Montana, Michigan, and Washington State are less inclusive than those in California, and are generally limited to more debilitating diseases. Individuals who suffer from more serious conditions may also be older, which may account for higher average patient ages in states other than California. The variability in these statistics underscores the risk of generalizing findings from patients living in California to those residing in other states and highlights the importance of studying patients throughout the United States. State-level differences in regulations also present an opportunity to explore how such regulations shape patient characteristics. A potential avenue for future work may be to study and compare patients in all states that have legalized the medical use of cannabis, ideally using a national sample to aid state-level comparisons.

Participants in the present study reported that, on average, they consumed cannabis on a daily basis and that inhalation was the preferred method of consumption, patterns of use that reflect those found in prior work (Bonn-Miller et al. 2014; Ilgen et al. 2013; Reinerman et al. 2011; O’Connell and Bou-Matar 2007). However, previous research shows that patients consume between

Downloaded by [Ecole Hautes Etudes Commer-Montreal] at 15:35 01 September 2015

FIGURE 2
Distributions of patient responses, by percentage, of their current experiences acquiring and knowledge of medical cannabis compared to their experiences before legalization: (A) the perceived safety of acquiring cannabis; (B) knowledge of medical cannabis characteristics; (C) perceived confidence in a safe product; and (D) perceived effectiveness of cannabis for treating their condition(s).

six and nine grams of cannabis per week or, equivalently, 0.85 to 1.25 ounces per month (Bonn-Miller et al. 2014; Reinerman et al. 2011; O’Connell and Bou-Matar 2007). This is in contrast to the findings of the present study, which show that 78% of patients consumed 0.5 ounces of cannabis per month or less.

State-level differences in average patient age, in particular, may affect variation in consumption. Patients in Arizona are, on average, older than those in California, and older patients may consume less cannabis than younger patients. Evidence from the present study supports this hypothesis, as there is a small, but significant, negative correlation between age and the amount of cannabis consumed per month ($r = -.11, p < .05$). Relatedly, Grella and colleagues (2014) found that younger patients visited dispensaries more frequently than older patients. Although there are likely other factors that contribute to consumption disparities, these findings also highlight the importance of studying medical cannabis patients across the US.

Patients reported using medical cannabis to treat a variety of conditions. The most commonly reported conditions included chronic pain, muscle spasms, nausea, anxiety, arthritis, depression, headaches, insomnia, and stress. Patients also reported that cannabis was effective for treating the symptoms of many of these conditions, findings that are consistent with previous research (Bonn-Miller et al. 2014; Ryan-Ibarra, Induni, and Ewing 2015; Aggarwal et al. 2013; Harris et al. 2000). This effectiveness included feelings of general relief and relief compared to other medications. The conditions for which the highest proportions of patients reported relief included alcohol dependency, anxiety, bowel distress, depression, insomnia, muscle spasms, and stress. Furthermore, patients reported using other medications less frequently when using cannabis. This is consistent with findings from other studies of patient perceptions (Reiman 2007, 2009; Nunberg et al. 2011; Reinerman et al. 2011), as well as a study of opiate overdose mortality, which showed that states with legalized medical cannabis had significantly lower opiate overdose mortality compared

Downloaded by [Ecole Hautes Etudes Commer-Montreal] at 15:35 01 September 2015

to those without legalized medical cannabis (Bachhuber et al. 2014).

Medical cannabis may benefit Arizona patients suffering from a variety of conditions. This conclusion has potential policy implications, as patients report deriving benefit not only for conditions that fall under the list of conditions that qualify a person to use medical cannabis (e.g., cancer, chronic pain, muscle spasms), but also for conditions that are not listed (e.g., anxiety, depression, insomnia). Officials in Arizona previously considered research on post-traumatic stress disorder (PTSD; Greer, Grob, and Halberstadt 2014) in their decision to include PTSD among Arizona's qualifying conditions. Thus, officials may consider the findings from the present study, in conjunction with other research, to determine the suitability of expanding the list of qualifying conditions in Arizona.

Legalization and Patient Experiences

The present study was, to our knowledge, the first to examine the effect of legalization on patient's experiences with medical cannabis. Regarding safety, the majority of patients reported feeling safer acquiring medical cannabis after legalization, and their confidence that they were acquiring a safe, uncontaminated product was higher. Patients also reported that their knowledge of the strains they acquired was better and that the cannabis they acquired after legalization was more effective for treating their condition(s) than the cannabis they acquired before legalization.

These findings show that the Arizona medical cannabis program has had some success, as regulations have provided a safe environment for patients to acquire a safe and high-quality product. However, the potential negative effects of medical cannabis legalization were not assessed in the present study. For example, participants in other studies have reported difficulties affording legal medical cannabis (Aggarwal et al. 2009), a factor which may preclude some individuals from taking advantage of the program, leaving them seeking other, potentially illegal means of cannabis acquisition. Other factors, such as limits on the amount of cannabis that can be purchased or legal

issues related to medical cannabis use, may also have negative consequences for some segments of the patient population.

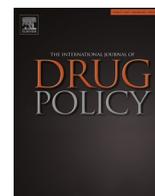

The results of this study should be considered in light of some limitations. First, participant recruitment was conducted through medical cannabis dispensaries. Although this is a common method of recruitment (e.g., Bonn-Miller et al. 2014; Grella, Rodriguez, and Kim 2014; Aggarwal et al. 2013; Reiman 2009, 2007; Harris et al. 2000), such samples may have a positive bias for medical cannabis, as individuals who medicate with cannabis but for whom it was not effective are unlikely to be available to participate. However, at least one study using a large, representative sample of current and former medical cannabis users reported similar findings (Ryan-Ibarra, Induni, and Ewing 2015), lending validity to the results of the present study and those of previous research. Second, relatively few patients reported using medical cannabis for some of the conditions. Although this is not surprising, given the low incidence of some conditions, conclusions should be tempered for these conditions with respect to the effectiveness of medical cannabis for providing relief and/or for use as a substitute for other medications. Finally, patients' experiences acquiring and their knowledge of medical cannabis before and after legalization were assessed retrospectively, using a single measurement time-point.

Despite these limitations, this study has significance for understanding the characteristics, behaviors, and perceptions of Arizona medical cannabis patients. Additionally, it highlights the importance of studying patients throughout the US and understanding the potential effects of state-level regulatory differences on patient populations. The findings regarding the effectiveness of cannabis for treating various conditions have potential policy implications for the state of Arizona, as patients reported that cannabis was effective for treating conditions that currently do not qualify individuals for medical cannabis use. Furthermore, the results showed that the majority of patients report positive experiences as a result of legalization, although more work is needed to fully understand the consequences of Arizona's medical cannabis program.

ABSTRACT

Background: In 2014 Health Canada replaced the Marihuana for Medical Access Regulations (MMAR) with the Marihuana for Medical Purposes Regulations (MMPR). One of the primary changes in the new program has been to move from a single Licensed Producer (LP) of cannabis to multiple Licensed Producers. This is the first comprehensive survey of patients enrolled in the MMPR.

Methods: Patients registered to purchase cannabis from Tilray, a federally authorized Licenced Producer (LP) within the MMPR, were invited to complete an online survey consisting of 107 questions on demographics, patterns of use, and cannabis substitution effect. The survey was completed by 271 respondents.

Results: Cannabis is perceived to be an effective treatment for diverse conditions, with pain and mental health the most prominent. Findings include high self-reported use of cannabis as a substitute for prescription drugs (63%), particularly pharmaceutical opioids (30%), benzodiazepines (16%), and antidepressants (12%). Patients also reported substituting cannabis for alcohol (25%), cigarettes/tobacco (12%), and illicit drugs (3%). A significant percentage of patients (42%) reported accessing cannabis from illegal/unregulated sources in addition to access via LPs, and over half (55%) were charged to receive a medical recommendation to use cannabis, with nearly 25% paying \$300 or more.

Conclusion: The finding that patients report its use as a substitute for prescription drugs supports prior research on medical cannabis users; however, this study is the first to specify the classes of prescription drugs for which cannabis it is used as a substitute, and to match this substitution to specific diagnostic categories. The findings that some authorized patients purchase cannabis from unregulated sources and that a significant percentage of patients were charged for medical cannabis recommendations highlight ongoing policy challenges for this federal program.

Background

The past two decades have witnessed a resurgence of interest in the therapeutic potential of cannabis, with several nations and jurisdictions developing regulations to allow for access to cannabis for medical purposes (Fischer, Murphy, Kurdyak, Goldner, & Rehm, 2015). One potential salutary consequence of these developments

is the substitution of cannabis for other substances (Allsop et al., 2014; Lucas et al., 2013, 2016). Indeed, examinations of jurisdictions with legal access to medical cannabis have reported reductions in negative health outcomes associated with the use of other substances, such as opioid overdose (Bachhuber, Saloner, Cunningham, & Barry, 2014), and cannabis substitution has been forwarded as a mechanism to help explain these public health benefits. Consistent with this proposal, several large surveys confirm that medical cannabis users report substituting cannabis for other medications (Lucas, 2012a; Lucas et al., 2013, 2016; Reiman, 2009). Although extant surveys have provided broad evidence of cannabis substitution, the extent to which cannabis is

used to substitute for distinct classes of substances by distinct patient groups has not been systematically examined from a patient-centred perspective. The present study addresses this knowledge gap by examining the extent to which physician-authorized medical cannabis users report using cannabis as a substitute for specific classes of substances, and by disaggregating this examination according to condition-based patient group. We also add to the nascent literature on medical cannabis use by describing patient characteristics, patterns of use and barriers to access.

In 2001 Canada became one of the first nations to develop a program to allow access to cannabis for medical purposes. The program has undergone numerous convolutions, culminating in the 2014 establishment by Health Canada of the Marihuana for Medical Purposes Regulations (MMPR) (Walsh et al., 2013), and ultimately in the Access to Cannabis for Medical Purposes Regulations in August 2016. One of the primary changes of the MMAR was the authorization of multiple Licensed Producers of cannabis: as of August 2016 >30 federally authorized Licensed Producers provide hundreds of strains of cannabis, as well as cannabis extracts to approximately 67,075 patients (Office of Medical Cannabis, 2016). The ACMPR adds regulations by which patients can produce their own cannabis, an option that was removed in the transition from MMAR and MMPR, and subsequently re-established through a court decision (Allard et al. v. Canada).

In contravention of the MMPR/ACMPR, a large number of patients access cannabis through community-based outlets known as dispensaries or compassion clubs, as well as from friends and other sources. In addition, although many Provincial medical colleges expressly forbid physicians from charging patients for providing patients with medical cannabis prescriptions, 3rd party patient aggregator services have emerged that provide cannabis prescriptions, occasionally in exchange for a substantial fee. To date, the prevalence of this practice among clients of LPs has not been explicitly examined. In addition to providing a more granular examination of cannabis substitution, this study also adds to the growing literature chronicling patterns of medical cannabis use and user characteristics using a novel sampling methodology: whereas prior studies generally queried self-identified medical cannabis users who may not have obtained physician authorization (Lucas, 2012b; Lucas et al., 2013; Walsh et al., 2013), to our knowledge this is the first study since the establishment of the MMPR to include only those medical cannabis users with confirmed physician authorization to access cannabis for therapeutic purposes.

Design and methods

A password protected 107 question online cross-sectional survey was made available in French and English for a 2 week period in July 2015 to patients of Tilray—a licensed producer of cannabis. 1310 participants were notified of the opportunity to participate in this study via direct email to patients that had opted in to receive online communication from Tilray upon registration. Participants were compensated \$10 credit for Tilray cannabis. The study was approved by Institutional Review Board Services, and gathered data on demographics, patient experiences, patterns of use, and cannabis substitution effect. Respondents were not forced to answer a given question in order to proceed to the next and as such the number of recorded responses varies across items. All reported percentages are based on number of responses rather than on the entire sample; we accompany all reported percentages with number of responses.

Findings

The survey was started by 301 participants, and completed by over 90% of respondents ($n=271$). The 30 non-completers only filled out the demographic section of the study, and based on this information did not differ on age, gender, education, income or work status compared to those that completed the survey. The primary demographics of respondents corresponds with the greater Tilray patient population but was more male and Caucasian, single, disabled and of lower income than the general Canadian population, with over-representation in Western Canada and Ontario, and under-representation in Quebec (see Table 1 for demographic characteristics).

While an increasingly common medical treatment, cannabis is often used for symptom relief rather than as a curative agent, therefore it's important to distinguish between the primary conditions for which cannabis is officially prescribed by a physician, and the specific symptoms for which patients report relief. For example, while a patient might report having a prescription for MS, the list of symptoms impacted might include chronic pain, spasticity, and insomnia. In this survey, respondents could select a single primary condition from a drop-down list, but could then select multiple symptoms affected by the medical use of cannabis. In regards to conditions, pain-related conditions were the most common, reported by 53% of participants ($n=144$; chronic pain 36%; ($n=98$), arthritis 12% ($n=32$), headache 5% ($n=14$)). The second most prominent class was mental health (eating disorder, PTSD & psychiatric disorder), reported by 15% ($n=41$). Other prominent conditions included gastrointestinal I disorders (11%, $n=29$), insomnia (7%, $n=18$) and multiple sclerosis (4%, $n=11$).

In regards to symptoms; the most highly endorsed were chronic pain (73%, $n=197$), stress (60%, $n=162$), insomnia (57%, $n=155$), depression (46%, $n=126$) and headache (32%, $n=87$). Gastrointestinal (GI) issues also featured prominently, with 29% ($n=79$) citing appetite loss and another 29% ($n=79$) nausea. Cannabis was perceived to be very effective at symptom relief, with 95% ($n=257$) reporting that it “often” or “always” helped alleviate their symptoms.

Patterns of use

The mean age of initiation was 18.50 (SD = 7.42) for recreational use and 34.13 (SD = 13.74) for medical use, as determined by responses to the question “How old were you when you first used cannabis” followed by “How old were you when you first used cannabis for medical purposes?”. It is notable that participants readily distinguished between their recreational and medical use of cannabis, with recreational cannabis use preceding medical use for 81% ($n=220$) of respondents, with 16% ($n=44$) reporting no history of recreational cannabis use, and 3% ($n=7$) reporting precedence of medical use prior to recreational use.

In regard to frequency, 88% ($n=238$) reported using cannabis at least daily, and the modal amount used per day was 1–2 g, with 29% ($n=79$) using a larger amount.

In regard to methods of use, 90% ($n=243$) had tried joints, 86% ($n=234$) vaporizers, 76% ($n=207$) oral/edibles (such as baked goods, butter, tincture, etc.) and 16% ($n=44$) had used cannabis-infused topical ointments. Regarding primary methods of use, vaporizers proved most popular (38%, $n=102$), followed by joints (25%, $n=67$), oral/edibles (14%, $n=37$), waterpipe/bongs (12%, $n=33$), pipes (11%, $n=30$), and topicals (1%, $n=2$). Regarding preferred method, vaporization was rated most highly by a plurality (44%, $n=119$), with oral/edibles second (23%, $n=63$). Respondents overwhelmingly reported that not all strains/types of cannabis were “equally effective” at relieving symptoms (77%, $n=210$): 82%

^a As of July 31, 2015.^b Statistics Canada. Canadian census, 2011. <https://www12.statcan.gc.ca/census-recensement/2011/dp-pd/prof/index.cfm?Lang=E>.

(n = 222) reported a preferred cannabis type; 25% (n = 68) indicas, 21% hybrids (n = 56), 18% favoring strains high in cannabidiol (CBD) (n = 50), and 18% sativas (n = 48). While many Licensed Producers continue to identify cannabis by these phenotypes (*Cannabis sativa* and *Cannabis indica*) in keeping with classifications found in the black market, there is a growing academic debate about whether these classifications represent real and distinct genetic classifications, with evidence suggesting that the label of indica or sativa is not consistent with the actual genetics of many of these strains (Sawler et al., 2015). However, evidence that cannabinoids and terpenes are found at different ratios within each distinct cannabis phenotype supports the subjective differences between strains commonly reported by patients.

Cannabis substitution effect

Overall, 71% (n = 186) of participants report substituting cannabis for either prescription drugs, alcohol, tobacco/nicotine or illicit substances, with 63% reporting substitution for

prescription medication (n = 166), 25% for alcohol (n = 66), 12% for tobacco/nicotine (n = 31), and 3% for illicit substances (n = 9). To facilitate interpretation of substitution for prescription medications, pharmaceuticals were classed into the following 4 categories: *opioids*, *benzodiazepines*, *antidepressants* and a category of *other medication* that included diverse substances that were less frequently endorsed (e.g., NSAIDs, Methylphenidate). Respondents were allowed to report up to three medications for which they substituted cannabis; of those who explicitly listed prescription substitution 59% (n = 92) reported substituting for a single class of medications, 33% (n = 52) reported substituting for two classes, and 8% (n = 13) reported substituting cannabis for three classes. The most common form of substitution was for opioids (32%, n = 80), followed by benzodiazepines (16%, n = 40), and antidepressants (12%, n = 31) (Table 2). The reasons most frequently ranked as being most important for substituting cannabis for prescribed medications were “less adverse side effect” (39%, n = 68); “cannabis is safer” (27% n = 48), and “better symptom management” (16%, n = 28).

Table 2
Substitution for prescription medications.

Class	n	%
Opioids (Oxy/Oxyneo/Percocet/hydromorphone/morphine/codeine derivatives, etc.)	80	32
Benzodiazepines	40	16
Antidepressants	31	12
Other medication	100	40

Supplementary analyses examined variation across diagnostic groups, and indicated that respondents who used cannabis for pain-related conditions were more likely to substitute cannabis for opioids (42% (n = 57) vs. 20% (n = 23), $\chi^2 = 13.78(1)$, $p < 0.01$), whereas respondents who used cannabis to address mental health were more likely to substitute cannabis for benzodiazepines (31% (n = 12) vs. 13% (n = 28), $\chi^2 = 7.75(1)$, $p < 0.01$) and for antidepressants (26% (n = 10) vs. 10% (n = 21), $\chi^2 = 7.69(1)$, $p = 0.01$) (Fig. 1). Our data suggested no relationship between age, amount of cannabis used, mode of administration, access or affordability on substitution effect.

Access

Although all respondents accessed cannabis from Tilray, 21% (n = 56) also reported purchasing cannabis from another Licensed Producer, 25% (n = 67) purchased from dispensaries, 18% (n = 47) from a friend, and 8% (n = 20) buy from an illicit dealer. In total, 42% (n = 111) of respondents reported accessing from one or more unregulated sources. Regarding cost, 44% (n = 118) spend less than \$250 monthly and 78% (n = 212) spend less than \$500 per month on cannabis, whereas 4% spend \$1000 or more (n = 11). Capacity to “often” or “always” afford to buy enough cannabis to relieve symptoms was reported by 40% (n = 109), leaving 60% (n = 162) who report “sometimes” or “never” affording sufficient cannabis. Similarly, 53% (n = 146) reported choosing between medical cannabis and other necessities (food, rent, other medicines . . .) in the past year due to finances. Only 3% (n = 7) cited having 3rd party insurance coverage, and another 3% (n = 8) reported getting the cost of cannabis covered through Veterans Affairs Canada.

Finding a supportive physician was a reported challenge, with 31% (n = 78) having changed doctors in relation to medical cannabis use, and 55% reporting feeling discriminated against by their doctor because of medical cannabis use (n = 139). Paying a physician or clinic a fee for recommendations to use medical cannabis was reported by 55% (n = 140), with a modal price of between \$300–99 (n = 50) and

94% (n = 131) paying \$100 or more. It is therefore unsurprising that 29% (n = 75) reported that obtaining an authorization to use medical cannabis was “difficult” or “very difficult”.

Interpretation

The finding that patients using cannabis to treat pain-related conditions have a higher rate of substitution for opioids, and that patients self-reporting mental health issues have a higher rate of substitution for benzodiazepines and antidepressants has significant public health implications. In light of the growing rate of morbidity and mortality associated with these prescription medications (Bachhuber et al., 2014; Fischer, Rehm, Goldman, & Popova, 2008), cannabis could play a significant role in reducing the health burden of problematic prescription drug use. Indeed, a recent study of US states that have legalized medical cannabis, found that the number of prescriptions significantly dropped for drugs that treat pain, depression, anxiety, nausea, psychoses, seizures and sleep disorders, with the annual number of doses prescribed for chronic pain falling by more than 11% per physician (Bradford & Bradford, 2016). Additionally, according to Veterans Affairs Canada, a recent significant increase in the use of medical cannabis by patients is paralleled by a nearly 30% decrease in the use of benzodiazepines and a 16% decrease in the use of opioids (Hager, 2016). Moreover, the finding that cannabis might be used to substitute for multiple medications is particularly promising in light of concerns patients may have regarding adherence to complex pharmaceutical regimens, and attendant side effects (Brown & Bussell, 2011; Ingersoll & Cohen, 2008; Sylvestre, Clements, & Malibu, 2006). Indeed, tolerability of side effects was identified as a prominent reason for cannabis substitution.

The finding that medical cannabis is used primarily to treat chronic pain is consistent with past research (Ware et al., 2010; Ware, Wang, Shapiro, & Collet, 2015). However, the extensive self-

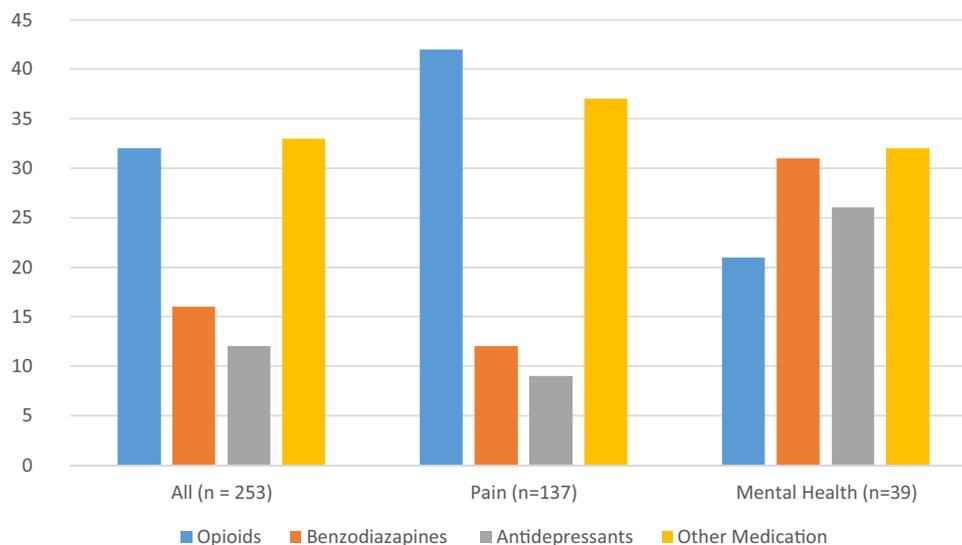

Fig. 1. Substitution by condition.

reported use to treat mental health conditions and associated symptoms represents a novel and interesting trend, and suggests that the conceptualization of cannabis as deleterious to mental health may not generalize across conditions or populations. Studies currently underway to investigate cannabis for the treatment of PTSD, anxiety, and other psychiatric conditions may soon provide more information on these potentially promising treatment options.

Our finding that most patients use 2 grams or less is consistent with past research (Carter, Weydt, Kyashna-Tocha, & Abrams, 2004; Clark, 2013; Hazekamp, Ware, Muller-Vahl, Abrams, & Grotenhermen, 2013). To our knowledge, this is the first patient survey to report vaporization as the primary method of ingestion, and non-smoked forms of ingestion as primary and preferred methods of ingestion. This marks a health conscious shift in medical cannabis use under the MMPR that may be attributed to a few factors: since patients in the MMPR require a physicians support to access medical cannabis, they may be more likely to be focused on safer methods of ingestion than non-MMPR patient populations; improvements in vaporizer technology and associated reductions in cost, patient outreach and education initiatives focused on safe and responsible use by cannabis vendors, and ongoing restrictions on smoking in the public realm.

Cannabis is rather unique as a therapeutic treatment in that many patients report some permeability between recreational and medical use (Walsh et al., 2013). However, unlike opioids where medical use via prescription often precedes recreational use and dependence (Fischer et al., 2008), the pathways between the medical and recreational use of cannabis are reversed, with previous recreational use often a precursor to prescription medical use, while the reverse is rarely the case. Although most respondents in this study had experience with recreational cannabis use prior to initiation of medical use (81%, $n=220$), transition from medical use to recreational use was only reported by 7 participants (<3%), which is suggestive of a low risk of abuse associated with medical cannabis. Additionally, with so many patients reporting use for the relief of mental health conditions like stress, insomnia and depression, much of this medical use is ultimately focused on improving psychological well being and quality of life. This perhaps blurs the lines between traditional biomedical approaches to disease and more holistic approaches (such as yoga or naturopathic medicine) used as adjunct treatments to address the symptoms, side-effects and psychological impacts of long-term illness/disability and/or the modern pressures of every day life. This is supported by previous research that has found that patients who use medical cannabis often cite depression and anxiety as a primary symptoms for which they seek relief, regardless of their actual medical condition (Bonn-Miller, Boden, Bucossi, & Babson, 2014; Ogborne, Smart, Weber, & Birchmore-Timney, 2000; Walsh et al., 2016), as well a growing amount of preclinical research supporting the use of CBD as a potential treatment for both anxiety (Blessing, Steenkamp, Manzanares, & Marmar, 2015) and depression (Linge et al., 2015).

Despite the legal protection and quality control offered through the MMPR, 42% of participants report accessing cannabis from unregulated sources which may be due to restrictions imposed on LPs by the MMPR during that period. At the time of this survey, LPs were only allowed to provide raw cannabis flowers, whereas other sources may have provided a diverse array of extracts and edibles. Since that time regulations have been altered to allow LPs to produce extracts, and to once again produce their own cannabis supply. Future research may determine whether this regulatory revision alters patient behaviour in regards to access through unregulated sources.

In light of consistent evidence that many lower income patients face affordability issues in regards to the cost of medical cannabis (Belle-Isle et al., 2014), the finding that so many patients had to pay high medical fees to gain access medical cannabis is concerning and suggests there may subsequently be an under-representation of low income patients in the MMPR/ACMPR.

Conclusions

The high rate of substitution for prescription drugs among patients with pain-related and mental health conditions suggests that medical cannabis may be an effective adjunct or substitute treatment to prescription drugs used to treat these conditions. Further research into the comparative efficacy of cannabis relative to front-line treatments for these conditions is warranted, and longitudinal research would help elucidate the context of cannabis substitution effect, and the potential impact of cannabis substitution on the quality of life of patients (in-progress, Lucas).

While the MMPR had only been in place for approximately 15 months when this survey took place, the findings that some authorized patients continue to purchase cannabis from unregulated sources and that a significant percentage of patients have had to pay high fees for medical cannabis recommendations highlight ongoing policy challenges for the federal medical cannabis program. As Canada's federal medical cannabis policy continues to evolve (both organically and in response to legal challenges) and as provinces and municipalities seek regulatory solutions to issues like dispensaries, personal production, and private medical cannabis clinics, it will be important to keep tracking the impact of these policy developments on patient access to and experiences with medical cannabis.

Limitations

The relatively low response rate to the survey (21%) leaves open the possibility this could potentially be an unrepresentative sample. It is not possible to confirm the impact of cannabis substitution on quantity of use of prescription drugs, alcohol or illicit drug use. Additionally, all data regarding the cannabis substitution effect in this study were self-reported by patients and did not benefit from biological drug detection to confirm use or non-use of a substance. In light of this potential bias, our characterisation of the therapeutic use of cannabis and/or cannabis substitution effect should be interpreted with caution pending replication by research that employs a more systematic recruitment approach, longitudinal monitoring, and biological drug testing.

However, these limitations are counterbalanced by several methodological strengths, including the large size of the sample, assurance that all participants were using medical cannabis with the support of a physician, and adherence to established standards for reporting Internet-based surveys (Eysenbach, 2004).

Declaration of interest

This study was funded by Tilray, a federally authorised medical cannabis production and research company. Philippe Lucas is currently employed as Vice-President, Patient Research and Advocacy for Tilray; however, his compensation is not tied in any way to the outcomes of this study.

Zach Walsh is currently the Primary Investigator in a Tilray-sponsored randomized clinical trial of medical cannabis and PTSD, but he receives no financial compensation for that study nor for assisting with the analysis and writing of this paper.

Acknowledgements

Funding for this study was provided by Tilray. We would like to thank all of the Tilray patients that have shared their thoughts and experiences with us, as well as Kim Crosby for assisting with some of the data analysis of this survey.

The medicinal use of cannabis in the UK: results of a nationwide survey

M. A. WARE,¹ H. ADAMS,² G. W. GUY²

Pain Centre,¹ McGill University Health Centre, Montreal, Canada; GW Pharmaceuticals plc,² Salisbury, UK

SUMMARY

The use of cannabis for medical purposes is a controversial but an important topic of public and scientific interest. We report on the results of a self-administered questionnaire study conducted in the United Kingdom between 1998 and 2002. The questionnaire consisted of 34 items and included demographic data, disease and medication use patterns and cannabis use profiles. Subjects were self-selected; 3663 questionnaires were distributed and 2969 were returned [1805 (60.9%) women, mean age 52.7 years (SD 12.7)]. Medicinal cannabis use was

reported by patients with chronic pain (25%), multiple sclerosis and depression (22% each), arthritis (21%) and neuropathy (19%). Medicinal cannabis use was associated with younger age, male gender and previous recreational use ($p < 0.001$). While caution must be exercised in interpreting these data, they point to the need for clinical studies of cannabis and cannabinoids with standardised and quality-controlled products.

Keywords: Cannabis; chronic diseases; epidemiology; pain; therapeutics

INTRODUCTION

The potential use of cannabis and related derivatives (cannabinoids) for medical purposes is currently under intense scientific investigation. Research efforts are predominantly focused on exploring the cellular and neurophysiological effects of agonists and antagonists on endogenous cannabinoid receptors in animal models, and a novel endogenous cannabinoid pathway is being described with roles in movement, pain, appetite and cardiovascular control. This scientific knowledge is emerging at the same time as increasing numbers of patients' reports of the effective use of herbal cannabis. It is therefore plausible that patients using cannabis as a medicine may be exploiting this novel neurophysiological signalling system. Further information on the alleged effects of cannabis may guide the development of cannabis-based medicines for symptoms of chronic diseases.

Few data are available on the patterns and prevalence of the medicinal use of cannabis. A large number of case reports of effective medicinal cannabis use have been published in peer-reviewed journals, including central thalamic pain and dys-

tonia (1), proximal myotonic myopathy (2), familial Mediterranean fever (3) and multiple sclerosis (MS) (4). In a telephone survey of adults in 2508 households in Ontario, Canada, 49 people (1.9%) reported using cannabis for a medical reason in the past year, mainly for pain or nausea (5). Wide-ranging effects of cannabis are noted in large case series: 50 self-selected medicinal cannabis users reported use for a variety of conditions including HIV/AIDS-related problems, chronic pain, depression, anxiety, menstrual cramps, migraine and narcotic addiction, as well as everyday aches, pains, stresses and sleeping difficulties (6). In a survey of 53 UK and 59 US patients with MS, cannabis was reported to affect spasticity, chronic pain of extremities, acute paroxysmal phenomena, tremor, emotional dysfunction, anorexia/weight loss, fatigue states, double vision, sexual dysfunction, bowel and bladder dysfunctions, vision dimness, dysfunctions of walking and balance and memory loss (7). In a survey of 15 chronic pain patients who admitted to using cannabis medicinally, pain, sleep and mood were most frequently improved, while doses used were modest (8).

Several prospective studies among specific patient populations have now been published. In a survey of ambulatory patients with HIV/AIDS in three HIV clinics in eastern Canada, 35% reported current use of cannabis (9). This is higher than an estimated prevalence of 30% in British Columbia (10) and 15–23% in California (11,12). In a survey of 220 patients with chronic non-cancer pain, 10% reported continuing medicinal use (13). The prevalence of medical cannabis use among patients with MS has been estimated at 14% (14). Large population-based surveys are needed to further describe the characteristics of medicinal cannabis users and their reasons for use.

METHODS

A cross-sectional survey was conducted to collect data from self-selected medicinal cannabis users in the UK. Patients were identified by word of mouth and through patients' support groups. A questionnaire instrument was developed for postal distribution and self-administration. A stamped addressed envelope was provided to improve response rates. The questionnaire consisted of 34 items including binary (yes/no) responses, Likert scales and open-ended questions. Information collected included demographics (age and gender), disease and symptom status and patterns of cannabis use both medicinally and non-medicinally. Patients were asked to select their diseases and/or symptoms from a list, and space was provided for additional information. Disease and symptom information was accepted as reported by the patient in the questionnaire responses, and no attempt to validate these diagnoses was made.

Data were single-entered into a relational database (MICROSOFT ACCESS 2000). Missing data and outliers were excluded from the analysis; these accounted for less than 5% of the total responses for the variables of interest. Data were imported and analysed using a standard statistical package (STATA version 8, Houston, TX, USA). Categorical data were compared using Pearson's χ^2 -tests. Ordered categorical data were analysed using Mantel-Haenzel tests. Significance was set at the 95% level, and all tests were two sided. The database was registered with the Data Protection Act 1998.

RESULTS

Over the period 1998–2002, 3663 questionnaires were distributed, and 2969 were returned (81% response rate).

Demographic Information

The mean age of the 2969 subjects was 52.7 years (SD 12.7), of whom 1805 (60.7%) were female. MS was the most common disease, reported by 1753 subjects (59%), while 1280 reported neuropathy (43%), 1125 reported chronic pain (33%) and 777 reported arthritis (26%). There was considerable overlap among these conditions.

Cannabis Use Patterns

Ever Use of Cannabis for Medicinal Purposes. A total of 947 (31.9%) subjects reported ever having used cannabis for medical purposes. The remainder were assumed to be never users. The median duration of medicinal use among 616 subjects for whom the duration of use data were available was 4 years [interquartile range: (2–7)]. The demographic profile of medicinal cannabis users is summarised in Table 1, compared to the never users. Medical cannabis use was associated with male

Table 1 Characteristics of ever-medicinal cannabis users

Variable	Medicinal cannabis use				Total	p-Value
	Ever	%	Never	%		
Age (years)						<0.001
<45	395	55	325	45	720	
45–50	171	39	265	61	436	
50–59	274	30	643	70	917	
>60	104	14	620	86	724	
Gender						<0.001
Male	439	40	649	60	1088	
Female	508	30	1209	70	1717	
Non-medical cannabis use						<0.001
Yes	357	66	182	34	539	
No	575	28	1454	72	2029	

gender, younger age and non-medical use ($p < 0.001$ for all tests).

Continuing Use of Cannabis for Medicinal Purposes. Of those who had ever used cannabis medicinally, 543 (18.3% of total sample) persons reported continuing to use cannabis for medical purposes, while 403 (13.6%) said they no longer used it. The 30 diseases or symptoms for which continuing medical cannabis use was most common are summarised in Table 2, along with the median duration of use for each condition. As noted above, some subjects reported cannabis use for more than one purpose. Reasons given for no longer using cannabis for medical purposes are also summarised in Table 3.

Patterns of Cannabis Use

Frequency of Use. Patients were asked how many days per week they usually used cannabis for medicinal purposes. Of 946 responses, 333 (35%) used 6–7 days per week, 219 (23%) used 3–5 days per week, 139 (15%) used 1–2 days per week, 73 (8%) used less than 1 day per week and 182 (19%) reported 'other'.

Reasons for Trying Cannabis. When asked why they decided to try cannabis for medical purposes, 585 said it was because a friend, family member or acquaintance had suggested it, 519 said they read a book or article about cannabis, 177 said they had been prior users and found out 'by accident', 152 said their doctor had suggested it and 128 gave other reasons.

Modes of Administration. Smoking was the most common means of administration, reported by 777 (82%) of medical cannabis users. The modes of administration were: eating was reported by 406 (43%) subjects, tea by 267 (28%), sublingual spray by 20 (2%) and 118 (12%) used other means.

Amount of Cannabis Used. Nine hundred and sixteen subjects reported amounts of cannabis used for medical purposes. Of these, 18 used 10 or more grams per day, 60 used 5–9 g

Table 2 Thirty diseases and symptoms for which continuing cannabis use is most commonly reported

<i>Disease/symptom</i>	<i>Number</i>	<i>%</i>	<i>Median years of use (interquartile range)</i>
Multiple sclerosis	249	11.61	3 (2–6)

per day, 107 used 3–4 g per day, 249 used 1–2 g per day, 153 used several grams per week, 107 used several grams per month and 222 used only occasionally when needed.

Change in Amount Used. Seven hundred and seventy-seven subjects reported on whether the amounts of cannabis needed to control symptoms had changed over time since they had started; 54 said they needed much more, 171 needed a little more, 514 said it was about the same, 31 said they needed less and seven said they needed much less.

Table 3 Reasons for stopping medicinal cannabis

<i>Reason</i>	<i>Number of responses</i>	<i>% of number stopping</i>
Unable to find supply	207	7
Could not afford	169	5.7
Did not like side effects	40	1.3
Did not work	25	1
Did not like 'high'	20	0.7
Other	173	5.8

Perceived Effects of Cannabis

Overall Effectiveness. Of 948 reported users, 648 (68%) reported that cannabis made their symptoms overall much better, 256 (27%) said a little better, 36 (4%) said no difference and eight subjects said a little worse (four subjects) or much worse (four subjects).

Effectiveness Compared to Other Medications. When asked how cannabis compared to other medications overall, 412 of 916 subjects (45%) said it worked much better than prescribed medications, 261 (28%) said it was somewhat better and 45 (5%) said it was about the same; only 27 subjects said that prescription medicines worked better than cannabis (18 somewhat better and nine much better). One hundred and seventy-one (19%) subjects said it was impossible to tell.

Side Effects Compared to other Medications. When asked to compare the undesirable effects of cannabis to those of prescribed medicines, 872 subjects responded, of whom six found that cannabis produced much worse side effects, 23 found somewhat worse side effects and 54 said the side effects were about the same. Two hundred and sixty-four (30%) subjects stated that side effects of prescribed medicines were somewhat worse and 294 (34%) said they were much worse. Two hundred and thirty-one (26%) stated that it was impossible to tell.

Effects on Other Medication Use. Of the 909 subjects responding to this question, 374 stated that their use of cannabis had changed their use of other medications, while 521 said it had not. Fourteen were not coded.

Return of Symptoms on Stopping. Of the 876 subjects responding, 673 said their symptoms returned or got worse when they stopped using cannabis, and 203 denied any worsening on stopping cannabis.

Non-medicinal Cannabis Use. Five hundred and thirty-nine (18%) subjects reported ever having used cannabis for reasons not related to disease (assumed to mean non-medical use), while 2029 subjects stated that they had never used cannabis for non-medical purposes. Medicinal cannabis use was significantly associated with recreational use ($p < 0.001$) (Table 1).

DISCUSSION

To our knowledge, this is the most extensive survey of medical cannabis use among chronically ill patients conducted to date. Before any conclusions may be drawn, however, the potential limitations of the study must be addressed.

The sample of patients recruited for this study was not selected through any systematic procedure or by random recruitment. The questionnaire was distributed primarily by word of mouth to patients and patients' support groups, and

the high rate of response (81%) suggests that this was a highly motivated population. Therefore, there is potential for a strong selection bias to inflate the estimated of reported effectiveness of cannabis (assuming the responses reflect mainly 'successful' cannabis users) and to minimise the adverse effects. The subjects were chronically ill patients with a range of comorbid conditions, and the need for additional symptom relief may explain the self-reported on-going medical cannabis use prevalence of 18%. However, this is not out of the range of other prevalence surveys in MS (14%) (14) and chronic pain (10%) (13). However, because of the potential for bias, we caution against drawing any conclusions with respect to the efficacy of cannabis from this study. It is important, however, to recognise these results as contributing to our understanding of what the perceived effects of cannabis are among these subjects.

Most of the awareness of this study was achieved by word of mouth between patients, spread by patients putting notes about the project into their various newsletters/magazines, etc. MS patients have a large active patient support network in the UK and may have raised the awareness of this questionnaire study. This would have the effect of weighting the sample towards this population. There is a noticeable paucity of data from subjects with HIV/AIDS and cancer, populations which are also associated with therapeutic cannabis use. We believe that at the time of analysis, awareness of this questionnaire was not very high among the HIV/AIDS and cancer 'network groups'.

The presence of a significant selection bias may also have the effect of excluding cannabis non-responders, persons who have tried cannabis and for whom it has not been of any use. This is a difficult group to target, and only randomly selected large-scale surveys would be able to identify the extent of this. Such studies usually rely on postal distribution and often have low response rates. Detailed estimates of response to any medication are best captured in formal clinical trials.

In spite of these limitations, we believe that this survey is the best available assessment of current medical cannabis use in the UK. Some key messages emerge from the findings. Our study found that 68% of users had found cannabis to make symptoms overall much better and 27% a little better, suggesting that over 95% of the patients using cannabis had obtained some benefit from cannabis. In spite of this, about half of these subjects had not continued to use cannabis. The reasons for this are illuminating: the lack of supply or cost were more commonly reported as reasons for stopping compared to ineffectiveness or intolerable side effects. This lends support to ongoing efforts to make cannabis-based medicines available for research purposes and lends credence to changes in public policy on compassionate grounds.

The study has found that ever use of medicinal cannabis is significantly associated with young age, male gender and non-medical use. This relationship has been found in other surveys

(13) and may represent a general bias towards medical cannabis use in this population. Alternatively, the association may be explained by factors which make clinical response to cannabis more favourable in this population. It is known that males and females respond differently to cannabis (15), and younger age groups may be better able to find and use cannabis as more socially 'acceptable'. This may particularly be true of the recreational users who would more likely have discovered medical use by 'accident' (19% of ever-medical users).

Finally, recent randomised controlled clinical trials have pointed to potential therapeutic benefits of cannabinoids for patients with MS (16) and chronic neuropathic pain (17). This suggests that patients' reports of the effectiveness of cannabis should not be discounted as purely anecdotal, but rather could serve as a valid indicator of target diseases and symptoms for cannabinoid drug development.

In conclusion, we believe that this survey presents a broad picture of the current state of cannabis use for medical purposes in the UK. The extent of use and the reported effects lend support to the further development of safe and effective medicines based on cannabis.

Conflict of Interest Statements

MAW is conducting research on the safety and efficacy of cannabis for pain management and supported by the fonds de recherche en sante du Quebec and the Canadian Institutes of Health Research. GWG is the Chairman and CEO of GW Pharmaceuticals, a pharmaceutical company which is developing cannabis-based medicinal extracts. HAA is an employee of GW Pharmaceuticals.

Role of the Funding Source. GW Pharmaceuticals was responsible for designing and administering the questionnaire, setting up the database and entering the data. The extraction and analysis of data and the preliminary report were performed by the principal author (MAW) under a service agreement with GW Pharmaceuticals. This paper represents a final report on these data with the collaboration of all the authors.

ACKNOWLEDGEMENTS

The authors acknowledge the contributions of the patients who responded to this questionnaire and of the software team who developed and administered the database.

Abstract

Introduction: Chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) is a chronic pelvic pain condition largely refractory to treatment. Cannabis (marijuana) use has been reported for a wide variety of chronic pain conditions, but no study has examined prevalence of cannabis use, symptom benefit or side effects, or frequency in CP/CPPS.

Methods: Participants were recruited from an outpatient CP/CPPS urology clinic (n = 98) and online through the Prostatitis Foundation website (n = 244). Participants completed questionnaires (demographics, CP/CPPS, depression, cannabis).

Results: The clinic sample included Canadian patients and the online sample included primarily American patients. Due to differences, groups were examined separately. Almost 50% of respondents reported using cannabis (clinic n = 49; online n = 89). Of the cannabis users, 36.8% of clinic and 75% of online respondents reported that it improved their symptoms. Most of the respondents (from the clinic and online groups) reported that cannabis improved their mood, pain, muscle spasms, and sleep. However, they did not note any improvements for weakness, fatigue, numbness, ambulation, and urination. Overall, the effectiveness of cannabis for CP/CPPS was "somewhat/very effective" (57% clinic; 63% online). There were no differences between side effects or choice of consumption and most reported using cannabis rarely.

Conclusions: These are the first estimates in men suffering from CP/CPPS and suggest that while cannabis use is prevalent, its medical use and benefit are unknown. This is an understudied area and the benefit or hazard for cannabis use awaits further study.

Introduction

Chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) is characterized by pain in the perineum, pelvic, and suprapubic areas or the external genitalia with variable degrees of voiding or ejaculatory disturbances.^{1,2} The prevalence is about

7.1% (range: 2.2%–16%), with a 6.7% median.³ CP/CPPS symptoms do not routinely remit, with 66% of community-based samples experiencing symptoms 1 year later,⁴ and patients showing no changes in pain, disability, or catastrophizing over 2 years later.⁵ CP/CPPS etiology is unclear and medical treatments are largely ineffective.⁶ Medications (antimicrobials, alpha-blockers, anti-inflammatories), as well as phytotherapy, biofeedback, thermal therapies, and pelvic floor training have been examined⁷ and may provide mild benefit,⁶ but most men continue to experience chronic pain.

Physicians may use opioids to manage CP/CPPS pain, but their efficacy is limited and physicians fear tolerance, misuse, and side effects, such as nausea/vomiting or sedation.⁸ Chronic pain patients are turning to alternate forms of symptom relief, yet no research on this is available for CP/CPPS. Cannabis sativa has been used for pain and symptom relief for thousands of years. In Canada and several American states, patients use medical cannabis for severe intractable illnesses. As an addition to opioid treatment for chronic pain, vaporized cannabis results in pain reduction without altering plasma opioid levels.⁹ Moreover, 71% of the available randomized controlled studies concluded that cannabinoids were associated with pain relief, with low adverse effects, and good tolerance.¹⁰ Cannabis may be used in conjunction with or substitute for prescription opiates resulting in reduced opiate use.¹¹ Wide ranging types, quantities, and frequency of cannabis use for pain relief have been reported, with chronic non-cancer pain patients reporting previous use (15%) or current use (10%).¹²

We examined cannabis prevalence among men experiencing CP/CPPS-like symptoms from a tertiary care urology department and from an online group. Although previous work has not examined cannabis use in CP/CPPS, it was expected that use would echo previous pain studies.¹² We also solicited patient self-reports on the side effects or potential benefits, frequency, and indication of future cannabis use.

Methods

Participants/procedure

Identical online and outpatient surveys were administered to an online community-based sample and a tertiary care outpatient CP/CPPS clinic sample. All participants remained anonymous and received no financial compensation. Clinic patients were approached after their appointments and briefed about this Research Ethics Board-approved study. Interested participants then provided written consent and received a package (letter of information, debriefing form, questionnaires, postage-paid return envelope) to complete and mail back. The online sample was recruited through the Prostatitis Foundation.¹³ Participants were a self-selected “availability” sample from site visitors. All participants were required to read and write in English. All questionnaires were in English.

Measures

Demographics

Participants completed questions on demographics (age, CP/CPPS diagnosis, health problems, tobacco use, medication use).

Medical symptoms

The National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI)¹⁴ assessed prostatitis-like symptoms and their impact on daily life (pain, urinary symptoms, quality of life) providing a score range from 0 to 43. The self-administered NIH-CPSI provides a valid, psychometrically robust outcome measure.¹⁴ Confirmation of CP/CPPS cases was based on NIH-CPSI pain/discomfort in perineum and/or with ejaculation and NIH-CPSI total pain score of ≥ 4 (0–21), used in the community^{15–17} and in the general population¹⁸ studies.

Depression

The Patient Health Questionnaire 9 (PHQ-9)¹⁹ is a reliable and valid self-report measure using 9 items to assess depressive symptoms. An item sum was used for the indexation of depression.

Experience with cannabis

We used a 21-question descriptive survey on experience with cannabis; questions were binary (yes/no), multiple choice,

and rating scales. Questions included whether participants had ever used cannabis, the purpose of use, relief of pain/effects with use, potential side effects, usage frequency, and usage method.¹² Participants rated personal experience with different modes of delivery using Likert scale-style responses.

Data analysis

Scores were excluded if $>15\%$ of the items were missing on measures. Participants who provided $\geq 85\%$ of items on a particular measure had the missing items imputed using means replacement procedures.²⁰ As a check on generalizability, primary comparisons between the online and clinic data were computed for age and domains of NIH-CPSI (quality of life pain, urinary), and the PHQ-9. If outcomes differed significantly, online and clinical samples would be examined separately. Due to the exploratory nature, unadjusted t-tests and descriptive analyses (chi-square) were used to evaluate differences between cannabis users and non-users.

Results

The total sample of participants was comprised of an online self-reported CP/CPPS sample ($n = 376$) and a tertiary care outpatient CP/CPPS clinic sample ($n = 100$). Two participants were excluded from the clinic sample and 35% ($n = 132$) of the online sample was excluded due to incomplete data. In the end, we had 244 online and 98 clinic participants. Missing data pattern for the online group was random.

The online group was on average 10 years younger than the clinic group ($p < 0.001$), with an average age of 44.57 (standard deviation 13.96) for the full sample (Table 1). The clinic sample was Canadian and the online sample was primarily American.

The online group reported more depressive symptoms, pain, poorer quality of life, and worse symptom scores (Table 2). For the remaining analyses, samples were examined across groups. Most of clinic (63.3%) and online (79.1%) participants reported a score of 4 or above on prostatitis cut scores ($\chi^2 = 9.24$, $p = 0.013$). While the clinic and online groups did not differ in terms tobacco use ($\chi^2 = 1.17$, $p = 0.340$), the online group (63.1%) consumed more medication for pain, mood, sleep, or spasms than the clinic group (47.4%) ($\chi^2 = 7.00$, $p = 0.01$). There were no group differences when asked if they had ever used cannabis ($\chi^2 = 0.87$, $p = 0.390$) (yes 50% clinic, 44.3% online). Examining only those previously using, 36.8% clinic and 75% of the online groups reported that cannabis improved their symptoms ($\chi^2 = 7.63$, $p = 0.006$).

Participants were questioned whether cannabis use made their symptoms “worse/no better” to “slightly/much better” (Table 3). The large majority of online and half of clinic participants reported that cannabis improved their mood by a

Table 1. Sample demographics

South America	6 (2%)	
Europe	54 (22%)	
Australia	4 (2%)	
Asia	15 (6%)	
Africa (Egypt)	3 (1%)	

SD: standard deviation.

“slightly/much better” degree (Fisher’s exact test $p = 0.026$). Across both groups, cannabis’ effects made pain “slightly/much better” ($\chi^2 = 2.48$, $p = 0.619$), as with muscle spasms ($\chi^2 = 0.51$, $p = 0.474$), sleep ($\chi^2 = 0.54$, $p = 0.461$), and a borderline majority for nausea ($\chi^2 = 0.51$, $p = 0.474$). Also a minority of participants reported “slightly/much better” improvement in weakness ($\chi^2 = 3.11$, $p = 0.078$), fatigue ($\chi^2 = 3.40$, $p = 0.065$), numbness ($\chi^2 = 1.16$, $p = 0.281$), ambulating ($\chi^2 = 0.64$, $p = 0.423$), and urination (Fisher’s exact test $p = 0.432$). When asked on overall effectiveness of cannabis for CP/CPPS, most participants (57% clinic, 63% online) reported cannabis as “somewhat/very effective” ($\chi^2 = 7.89$, $p = 0.051$).

There was an even distribution of side effects reported by the groups, with most suggesting “none” to “mild” side effects from cannabis use (70.3% clinic, 70.8% online) ($\chi^2 = 0.05$, $p = 0.972$) (Table 4). Also, if offered a choice, participants reported similar preferences for cannabis method across groups ($\chi^2 = 1.99$, $p = 0.370$), but smoking was a leading choice. There were no differences when asked about the preferred form of cannabis they had used ($\chi^2 = 2.59$, $p = 0.274$), although most participants listed herbal option (buds, sinsemilla, hydroponic). In current cannabis users, frequency did not differ between groups ($\chi^2 = 0.27$, $p = 0.88$), with most respondents using “rarely” (73.3% clinic, 77.3% online).

Discussion

This is the first study to document the initial prevalence and patterns of cannabis use in men suffering from CP/CPPS from an outpatient urology clinic and online. Almost 50% of participants used cannabis and almost 3/4 reported using it for symptom relief. These figures are bigger than those in other studies.¹² The samples were treated as separate during analyses because the online group was younger, reported greater depression, pain, and diminished quality of life. Interestingly, while examining only those having used cannabis, fewer clinic respondents reported benefit compared to the online group. This almost doubling of the reported

benefit by the online group may be related to symptom/disease severity differences in this study. The present data cannot describe factors underlying differences in benefit across groups, but this study is consistent with the suggestion that chronic pain is associated with lifetime marijuana use.²¹

Physicians should be aware and question patients on cannabis use. Despite a lack of information on the mechanisms of glycinergic cannabinoids for pain, cannabidiol, a major nonpsychoactive component of cannabis, suppressed chronic inflammatory pain in mice.²² Furthermore, the use of cannabis was not associated with analgesic tolerance in rats.²² It appears that cannabinoids’ anti-inflammatory action

stimulates cannabinoid receptors.²³ However, contrasting results about cannabis side effects discouraged the authors for suggesting its chronic use for pain relief due to associated cognitive deficits and gastrointestinal toxicity.²³

The online group reported greater distress and NIH-CPSI symptoms, but both groups showed trends where most reported improved symptoms like mood, pain, muscle spasms and sleep. However, no improvements were in weakness, fatigue, numbness, or ambulation. Improved symptoms for some patients might reflect the shared effects that pain/muscle spasm can have in regard to improving sleep and ultimately mood. Current research shows that unresolved chronic pain, continuing disease, obesity, and sleeping problems predict the persistence of pain, while issues like mood are weakly associated.²⁴ Of other note, cannabis use was not helpful for urinary symptoms, which can be very bothersome in patients with CP/CPPS.

This survey showed that the side effects of cannabis appear minimal, with most patients reporting “none” to “mild” side effects. More detailed information on the amount of cannabis use, the types used (medical vs. other) would be important to provide a more detailed pattern of examining benefits. If offered a choice on how to use cannabis, participants reported smoking as the preferred methods – this is similar with other studies.²⁵ There were no differences by groups – the herbal form was endorsed by most respondents. In regard to current frequency of use, most participants reported using cannabis “rarely;” further study into usage patterns may shed some light on whether participants use cannabis primarily to manage pain flares or muscle spasms, or to aid with sleep. If usage is associated with intermittent pains, as flares, then that may reflect the rarity of reported use.

Our study has its limitations. This initial survey cannot qualify the benefits/risks of cannabis use in CP/CPPS, and simply suggests rates for further comparison. Sample size was an issue in some analyses because finer detail in questions, such as symptom benefit, had to be collapsed into 2 categories (“worse/no change” and “slightly/much better”) from original categories (“much worse,” “slightly worse,” “no change,” “slightly better,” “much better”). Larger samples

are necessary to gather more accurate patterns of use and benefit.

Although our samples were not randomized or stratified, they represent tertiary care outpatient males diagnosed with CP/CPPS, as well as community-based men with CP/CPPS-like symptoms. More online participants reported a prostatitis cut score. Perhaps the clinic men experienced reduced symptoms under the care of a specialist, but there was no opportunity to verify this in our study. Future research should also collect healthcare utilization and previous treatments prior to the onset of cannabis use. This data would allow contrasts and provide insight into medical comorbidities prior to cannabis use. It would also be interesting to examine the associations between psychological pre-cannabis use pain-associated comorbidities, like catastrophizing, and patterns of use.

Conclusion

This is the first study to examine and report on cannabis usage and benefit in participants with CP/CPPS from a tertiary care and community “availability” sample. The current data suggest that almost 50% of men with CP/CPPS-like symptoms have used cannabis in their lifetimes and that a minority of clinic patients versus most online participants reported cannabis benefit. Future research should examine larger representative samples to further document usage patterns, fuller CP/CPPS symptom benefit, and associated factors with usage in predictive models. The ultimate study would be a randomized controlled trial prospectively evaluating the efficacy and safety of cannabis compared to either placebo or an active comparator.

Abstract

Background: There are indications that marijuana is increasingly used to alleviate symptoms and for the treatment of a variety of medical conditions both physical and psychological. The purpose of this study was to describe the health concerns and problems that prompt some adolescents to use marijuana for therapeutic reasons, and their beliefs about the risks and benefits of the therapeutic use of marijuana.

Methods: As part of a larger ethnographic study of 63 adolescents who were regular marijuana users, we analyzed interviews conducted with 20 youth who self-identified as using marijuana to relieve or manage health problems.

Results: Thematic analysis revealed that these teens differentiated themselves from recreational users and positioned their use of marijuana for relief by emphasizing their inability to find other ways to deal with their health problems, the sophisticated ways in which they titrated their intake, and the benefits that they experienced. These teens used marijuana to gain relief from difficult feelings (including depression, anxiety and stress), sleep difficulties, problems with concentration and physical pain. Most were not overly concerned about the risks associated with using marijuana, maintaining that their use of marijuana was not 'in excess' and that their use fit into the realm of 'normal.'

Conclusion: Marijuana is perceived by some teens to be the only available alternative for teens experiencing difficult health problems when medical treatments have failed or when they lack access to appropriate health care.

Background

There is lively public debate surrounding the use of medical marijuana. While some remain sceptical about the therapeutic value of marijuana, there is a growing body of research that emphasizes its salutary effects. The literature points to the use of marijuana among adults to alleviate a

variety of symptoms including pain, nausea, muscle spasm, insomnia, anorexia and anxiety as well as the treatment of a variety of medical conditions that are both physical and psychological [1-5]. However, less is known about adolescents' use of marijuana for therapeutic purposes.

Background Literature

For individuals who set out to "feel better" through the use of marijuana, use has also been referred to as "self-medication," a hypothesis which posits that people do not misuse substances solely for the experience of being "high;" rather, they do so as a means of gaining relief from psychological and emotional pain [6]. In contrast to the adult literature on marijuana use where therapeutic use is linked to treatment of specific symptoms and illnesses, in the adolescent literature there is less clarity about how to define non-recreational uses of marijuana.

A motivationally-driven approach is one way that researchers have attempted to understand marijuana use among adolescents [7]. It is proposed that different reasons for using marijuana may shape patterns and contexts of use, which in turn may be associated with different problems related to use. Social motives for marijuana use, for example, have been associated with patterns of recreational use (e.g., sensation seeking). Coping motives have been used to classify adolescents using marijuana for non-recreation purposes. Differences have been observed among youth using marijuana for social and coping reasons that support the motives framework. In contrast to youth aged 16–24 years using marijuana for social reasons, users of the same age reporting coping motives have been observed to have lower mental health, higher psychopathology, more psychosocial distress and more stressful life events than non-cannabis-using youth [8].

Although there is a large body of literature related to recreational use of marijuana among adolescents [9,10] less is known about other motivations for the use of marijuana in this population. Several hypotheses have emerged related to non-recreational uses of marijuana among adolescents. The "self-medication hypothesis" [11-14] is most closely associated with the therapeutic use of marijuana. Instrumental use is another term applied to taking drugs for specific pharmacological effects of the substance rather than for pleasure or recreational purposes. For example, Glassner [15] examined the notion of instrumental drug use in a qualitative study of young drug users, and found that marijuana was used for its calming effects, to relieve tension, and to gain self-confidence. Further, support for a typology of drug related beliefs that included relief-oriented beliefs [16] was demonstrated in a study of cannabis use in a sample of 285 French high school students [17]. In this study, four 'positive' relief-oriented beliefs were identified related to how the substance creates relaxation and calms anxiety, reduces suffering, relieves boredom, and makes one feel better. The presence of relief-oriented beliefs was the only predictor of cannabis dependence.

Associations between marijuana and psychological problems have also lead researchers to consider other possible

explanations, including whether marijuana use may reinforce psychiatric symptoms or increase the risk of developing a psychiatric illness later in life [18-21]. A full understanding of marijuana use and its potential adverse effects, however, will require further research.

The trend toward the use of marijuana for therapeutic purposes among adults raises questions regarding how this may influence young people's use of marijuana for similar reasons. Recent studies suggest that adolescents are aware that marijuana is sometimes used to gain relief from physical and psychological pain [22-24]. Furthermore, there is evidence suggesting that adolescents may be using marijuana for reasons that are analogous to adults who use marijuana for therapeutic reasons. For example, young marijuana users with coping motives report more stressful life events (e.g., death of a family member or friend), personal injury and illness than socially motivated marijuana users and non-users [8]. There is also indirect evidence that adolescents with mental health conditions might be seeking relief through marijuana use. In a sample of 992 adolescents in drug treatment programs in four U.S. cities, more than half had at least one comorbid mental disorder. In total, 72.5% of these youth were dependent on marijuana [25]. Among youth entering outpatient treatment programs for cannabis use disorders, 76% were reported to have concurrent mental health conditions [26]. Finally, in a sample of homeless young people in the UK who used a variety of drugs including marijuana, participants were found to be self-medicating to deal with the stress and problems they encountered including depression, loneliness, and physical problems such as aches and pains [13].

As part of a larger study to understand the culture of frequent marijuana use among young people, we were struck by the extent to which some participants spontaneously described using marijuana to gain relief from symptoms. In order to develop these emergent findings, we conducted a focused ethnography in which we examined the ways in which youth use marijuana to seek relief.

Methods

This study was designed to understand and describe adolescents' experiences in using marijuana for therapeutic reasons, and explore how their constructions of these experiences are influenced by social norms. Compared to other types of ethnographic studies, focused ethnographies occur on a smaller scale and seek to examine a specific problem or phenomenon [27]. Typically, focused ethnographies are time-limited, involve a limited number of participants drawn from a specific population who have experience and understanding directly related to the area of inquiry, and are conducted through selected episodes of participant observation and/or interview [28]. In this focused ethnography, both in-depth interviews and participant observation were employed.

We drew data from a larger ethnographic study of frequent marijuana use among adolescents conducted in two rural and one urban location in British Columbia (BC), Canada. In the study communities, as is the case in much of BC, marijuana is readily accessible to youth despite the fact that it is illegal to grow, sell or possess. The use of marijuana for medical reasons is legally supported in Canada in limited circumstances; individuals meeting the criteria are provided with cannabis or given a license to grow a limited quantity for personal use.

Ethical approval for this study was obtained from the University Behavioral Research Ethics Board. Given the sensitivity of the topic and because we successfully argued that teens were able to provide consent for research participation, we did not require parental consent. As a courtesy, we provided the youth with a parent/guardian information letter which outlined the study's focus as pertaining to attitudes about marijuana use in general. Participants were told that they could take the letter home if they so chose. Prior to the interviews, written consent was obtained from the participants. Confidentiality was ensured at the outset and participants were informed that all identifying information would be removed from the data.

Sample

In the larger study, participants were recruited by means of information fliers posted at high schools which invited youth to share their "views on marijuana use and teens." Youth who expressed interest in participating were screened for eligibility by the research team. Eligibility criteria included being 13–18 years of age and reporting having smoked marijuana at least once in the previous week. In total, 63 young people participated in the study. Although many youth described "feeling better" after they smoked marijuana, a subset [$n = 20$] explicitly described experiences of using marijuana on a regular basis specifically to manage, reduce or eliminate unpleasant and uncomfortable feelings or other health problems. They constructed marijuana as a treatment for health problems, often suggesting it had significantly greater benefit than other medical treatments they had been offered. None of these students were legally provided with cannabis for medical treatment or given a licence to grow marijuana for medicinal use. Characteristics of this sub-set of participants are presented in Table 1. The majority of youth using marijuana for relief were male, and the average age of initiation of marijuana was 13 years of age. Youth in this subset were of diverse ethnic backgrounds. Most [$n = 12$] indicated that they were "Canadian" or "Caucasian;" More specifically, 2 participants identified as First Nations, 6 individuals were part First Nations, 3 of UK descent and 3 were of European background including Italian, Croatian, and Ukrainian. Compared to those who

* some participants used marijuana for more than one reason

used marijuana for the purpose of relief, those recruited to this study who smoked marijuana for recreational purposes ($n = 43$) smoked marijuana less frequently (average of 11 days in the last 30 days) and used marijuana more often with others.

Data Collection

The primary source of data was in-depth, semi-structured interviews with youth to glean accounts of their experiences with marijuana. We used a short questionnaire prior to beginning the qualitative interview to collect demographic data and to assess history of marijuana use and current use. The questionnaire included items related to marijuana use including age of initiation, use in the last month, frequency and quit attempts. We also collected data on the time of day that individuals usually used marijuana.

The interviews were conducted using an interview guide. Broad discussion categories included: history and pattern of use, the reasons for their use, what they knew about marijuana, the sources of that information as well as contextual factors related to their use. Open-ended questions were posed in relation to each of these topics, as required during the interviews. Many of these youth were at ease when talking about their use of marijuana and needed little prompting. When youth described the use of marijuana to help them feel better, participants were asked to elaborate further on their experiences.

The tape-recorded interviews took place in privacy within the school setting and lasted from 1 to 2 hours. Participants were offered a \$20 honorarium. Field notes were used to record impressions of responses to the interview

and the interviewer's assessment of the quality of the interview. In addition, field notes were maintained to record pertinent observations within the school and in the larger community (e.g., noting school policies regarding marijuana use at school and the presence of graffiti related to marijuana in close proximity of the school; visiting favourite outdoor settings where some indicated that they preferred to smoke marijuana along with hemp shops where they purchased pipes and bongs and other paraphernalia).

Data Analysis

All data including transcribed interviews and field notes were reviewed several times by the research team paying close attention to young people's descriptions of experiences with the use of marijuana to address uncomfortable feelings or health problems, and the circumstances that surrounded this use. Close readings of the interviews by the investigative team involved highlighting potentially important comments, raising questions about the data, and identifying prominent dimensions of participants' experiences. During team meetings, interview data were discussed and emergent categories were identified to capture experiences related to marijuana use. These categories were organized into a coding framework and used to code the data. All coding was completed by one of the authors who completed a majority of the interviews (BMM). To code the data, we used [29] the NVivo software program designed for qualitative analysis of textual data. The program was also used to retrieve data coded under each category for a more nuanced analysis by the investigative team. Through reflective questioning of these data and detailed comparisons, themes were identified and discussed in team meetings.

Results

The Context of Using Marijuana for Relief

The teens situated their use of marijuana for relief of health problems in the context of difficult life events and illness experiences marked by a lack of supportive family networks, unexpected and sometimes traumatic losses of close friends or family members, and difficulties at school. Many indicated that they had few people to turn to help them; for some their parents were having difficulty coping with their own situations of unemployment, substance use, and marriage breakdowns and offered little support. Those living in households with a parent and step-parent had difficulty coping with unresolved feelings towards their estranged biological parent. Finally, several teens who made frequent moves with their families experienced social isolation at school and were subject to being bullied and teased.

Experiences with the medical system to address their health problems consistently fell short of the teens' expecta-

tations; their problems were either not taken seriously or the solutions offered were not helpful. For example, youth who reported they had been prescribed drugs such as Ritalin, Prozac or sleeping pills, stopped using them because they did not like how these drugs made them feel or found them ineffective. Despite visits to doctors, prescribed treatments and, for a few, hospitalizations, many of these teens perceived that they did not receive the help they needed from doctors.

A final contextual feature to these teens' lives were their observations of others' use of marijuana to deal with difficult circumstances or symptoms, including, in a few cases, parents and other significant adults in their life. For example, one young man reported that his mother was using marijuana while receiving cancer treatment. As he observed, "It helped her sleep and calmed her down." Others described how they were given advice from other teens about how marijuana could "help." Together these circumstances created a context where teens routinely turned to marijuana to manage physical and psychological problems in their lives. Marijuana was readily available, used by others in their network, and was perceived to provide an effective solution not offered to them from the medical system.

Regular Relief: Patterns of Using Marijuana for Persistent Problems

Most of the participants who consistently used marijuana for relief, smoked it when alone, often several times a day. For some, their day began and ended with using marijuana; they smoked before leaving home for school and prior to going to bed. Some indicated that they needed to smoke marijuana during the school day to manage symptoms, and when this occurred it was often in the company of friends. A few participants smoked marijuana for relief in adult company that included relatives and "older" friends who supported their need to use marijuana to manage symptoms.

There were two patterns of marijuana use for relief: intermittent and chronic. With intermittent use, youth routinely relied on marijuana to deal with short-term problems such as stressful situations or limited periods of physical pain. One 14 year old male described non-daily use occurring whenever he had a "really bad day." In the case of chronic use, daily marijuana was used for the relief of identified conditions such as depression, ADHD and to routinely settle at night or manage sleeplessness. Young people's descriptions of marijuana use for relief were imbued with language common to using pharmaceuticals. A number of these youth indicated how they carefully titrated their intake; others described their use as "moderate," involving a "few puffs," or just a "certain amount." Through experience, they had learned to hone

ways of using the right amount of marijuana to achieve a state of relief. As one male elaborated, he regulated his intake by mixing his marijuana with tobacco so as to get "just enough" marijuana to relieve regular states of agitation and high levels of stress. Along with skills at monitoring their intake of marijuana, these youth confidently shared in-depth knowledge of the strength and associated effects of different strains of marijuana.

Explaining the Need to Use Marijuana for Relief

The young people in the sub-sample were particularly articulate in describing their "need" to use marijuana. They were adamant and confident that marijuana provided relief from their health problems. The decision to smoke marijuana was stated in a straight forward fashion (e.g., "I started it to make myself feel better") and justified because they had a "reason for it." Participants also framed their marijuana use in a positive manner; in so doing, gave credence to the claim that this was the right course of action. As one girl elaborated on her daily use, "Pot helps me be me." Several described unpleasant physical sensations such as feeling "jittery" associated with the absence of marijuana. For these youth, regular marijuana use allowed them relief from these unpleasant symptoms so that they were able to feel "normal." One 18-year old male who used marijuana everyday indicated, "If anything, it makes you more normal." Of note, he had first started to use marijuana at the age of 13, and smoked it regularly for 5 years typically 4 times a day.

For these youth, the purpose of smoking marijuana was not specifically about getting high or stoned, nor was marijuana used for "pleasure." In fact, participants tended to differentiate their own use from peers who were recreational users who smoked marijuana when they were "partying" or "socializing." As one 16-year old male described his use, "I don't get a strong sense of euphoria, I just calm down a bit, that's just how it is for me." However, there were a few instances when female participants did smoke "to get high" for the purpose of "escaping reality," a strategy used to remove themselves temporarily from the challenging circumstances that accompanied their daily lives. The participants also distinguished themselves from the "stoner" stereotype, whose preferred activities were watching movies or listening to heavy metal music while smoking marijuana.

Some explanations of using of marijuana to feel better were further bolstered with a focus on use for described "health" reasons. As one 16-year old female indicated, her daily use of marijuana was "more of a health thing, than to get high." She reflected on her history of "mild depression" and her difficulties with antidepressants that had resulted in insomnia and a loss of appetite. She suggested that these health issues would re-surface in the absence of

marijuana, thereby providing solid rationale for her continued use of marijuana. One male situated his marijuana use within a perspective that medications are used to help deal with problems.

I bet you if I had never been put on Ritalin at a younger age, I might not have had the same opinion of drugs growing up, you know, because I was taught growing up that you take drugs to help you out with your problems, you know. [18 years, non-daily use]

Often, marijuana was compared to other substances in a way that suggested marijuana was the best option, further supporting ongoing use of marijuana for relief purposes. Some constructed marijuana as a "natural" substance that was preferable and considered "safer" than many pharmaceutical alternatives. One 14-year old female discovered that marijuana was a better option than dealing with the side effects of pharmaceuticals stating, "Well, my body, I have to be careful what pills I take. I have bad reactions to some medications. My body rejects it and I get really sick." Interestingly, one 18-year old who smoked twice a day on 21 days during the last month, went as far to describe himself as a "healthy marijuana user" adding, "It's not good for you, but then again, neither is MacDonald's and a lot of other things." The health claims in these descriptions served to explain the ongoing use of marijuana for relief.

Painful Lives: Types of Symptoms and Distress Requiring Relief

In the interviews the teens directly linked their use of marijuana with the management of difficult feelings (including depression, anxiety and stress), sleep problems, problems with concentration and physical pain. Each of these will be described in the following sections.

Difficult Feelings

Although some teens described using marijuana to deal with instances of being angry, experiencing a significant disappointment (e.g., with exam results), being afraid, or to forget the past, the most frequent uses were associated with dealing with depression, and managing stress and anxiety.

Depression

Six participants indicated they were using marijuana specifically to deal with depression and several others reported knowing teens that were doing the same. Dealing with difficult personal circumstances was a common theme for this group of teens and was linked to the loss of significant people in their lives, a family history of depression, financial worries at home, "fights" with parents, abuse, and too much "shit" in their lives. Several reported receiving treatment for depression in the form of antide-

pressants and counseling, sometimes over extended periods, yet with little relief. For others, these options were not available in part because "nobody wanted to listen" to them. As a last resort, these teens had opted to try smoking marijuana. In a relatively short time, marijuana helped them to feel better about themselves, happier and more like the person they "wanted to be" as well as alleviate other problems associated with depression (poor appetite, difficulty concentrating, poor sleep).

Not all participants agreed about the use of marijuana for depression. One 16-year old male used marijuana to deal with his unhappiness surrounding the conflict between his mother and father, and worried that he might be using pot too frequently. He reasoned that being happy all of the time was not natural, and that there was nothing wrong with being sad and confused sometimes. As a result, he tried to limit using marijuana to weekends with friends. Others believed that marijuana should only be used for certain types of depression because of the possibility of becoming more depressed by smoking pot:

I think it depends on the level of depression that you have. If it's like depressed because you are sick, then pot is helping you. It's making you happier. But if you're depressed about killing yourself, I don't think that it's a good idea to smoke pot just because it could bring you down more. It's hard to say, though, it's different for every person, right? That just how it makes me feel. [Female, 17 years, daily use]

Stress and anxiety

The use of marijuana to manage stress and anxiety was described by 12 teens in our sample. Dealing with bullying at school, heavy demands of school work, taxing shifts at work, and just "giving as much as you can" along side difficult relationships with parents or guardians, and receiving threats from neighbors all took its toll on these youth. For some, these experiences contributed to high levels of stress and anxiety, and for others uncomfortable levels of anger – both were difficult to manage. Although some had friends they could turn to, marijuana provided an additional source of stress relief that was ready at hand.

Lots of people know me, know I do pot and they think that I'm a pot head but really the thing they don't realize is that I have a reason for it. It's for my stress and an antidepressant. I get really upset. It [pot] helps me feel better about myself, because you know people don't do that [help me], like my friend [name] can, but nobody else can. [Female, 14 years, non-daily use]

There was general agreement among the teens that marijuana calmed them down, and helped them feel "not so nervous" and "not so uptight about everything." One teen

recognized, however, that despite the fact that marijuana could be a very effective stress reliever, it might not work for everyone:

Well as far as pot goes, the good thing is that it's definitely a stress reliever, hands down. I know lots of people who would be just a complete wreck if they weren't smoking pot but then there's also people who are a complete wreck because they do smoke pot, so it's kind of a hard thing. [Male, 16 years, non-daily use]

Sleep problems

Nine teens in our sample described using marijuana to help them sleep. The "trouble" they had with sleeping was a constant problem that many had experienced for years. One 16-year old, who also experienced mild depression, indicated that she "stopped sleeping for two years." Not only did the problem affect their school performance, but it was deeply disturbing to them. As another female described,

I have a really hard time sleeping. I can lay there for about four to five hours, just laying there. And I just finally had it, and I just feel like screaming I don't want to wake anyone up. So I go downstairs and ask my gran or my brother [for some marijuana] or I have a roach or two sitting around. [16 years, non-daily use]

Although one teen indicated that she had spoken to her mother about her problems sleeping, others indicated that the adults in their lives did not offer any support.

I have trouble going to sleep and waking up...My mum wanted to get the doctor to put me on sleeping pills but he said at such a young age it would cause like an addiction to them...I've had these problems since elementary school...I just, I can't go to sleep at night and then I like to sleep during the day. [Female, 14 years, non-daily use]

Many teens turned to pot and found almost immediate benefits in helping them sleep. Likened to a "magic sleeping pill" by one young male, the teens found it calmed their "busy minds," helped them relax and fall asleep quickly.

Focus/concentration

Three teens reported using marijuana to improve their concentration. They explained that they had difficulty focusing at school and that this affected their school performance. As one male explained:

Personally, I'm a very fast paced guy and my mind is always rushing, hard to gather my thoughts. I think a lot faster than I can speak. I get distracted very easily.

In social studies last year, I would talk and wouldn't do any work. But if I had just a little bit of pot, I could really focus my work. I could sit there and I'd work all day and finish everything and have no homework and be done by the end of class. [16 years, non-daily use]

These young people believed they could "think better" when they used marijuana because it allowed them to focus their thinking, and, slow it down in a way that was preferable. All suggested that these cognitive changes were linked to improved school performance. One teen, who self-identified as having "attention deficit, hyperactive disorder" shared the difficulties he experienced on Ritalin. He began smoking pot when he was 12 years of age and still on Ritalin.

Usually my mind is in over gear, right? I'm usually going about a mile a minute and my hands are moving way too fast, and I'm really fidgety. But if I have a puff of marijuana in a moderate use, by moderate I mean one to three to four puffs, depending on the quality....being toned down a bit I find really helps me....If I try to do homework at home without smoking pot, I just can't focus. I'll be looking at my schoolwork and for me with my ADHD this is how it's always been for me. Like school was just a constant story of this scenario before I smoked marijuana. [17 years, non-daily use]

Physical Pain

Five teens indicated they used marijuana to obtain pain relief, and several others shared similar stories about other youth. One male used marijuana to deal with pain associated with rehabilitation after a muscle injury, another used marijuana following an accident where he sustained 3rd degree burns and yet another because of plates in his back due to a car injury. Others suggested that marijuana reduced muscle pain after a hard day of skiing and helped with headaches, and that girls used marijuana for menstrual cramps. One 17-year old male used it daily and explained that marijuana "numbs your systems or senses [and] relaxes your muscles."

Considering the Risks of Using Marijuana for Relief

In spite of experiencing personal benefits from using marijuana for relief, some participants wrestled with their use of marijuana. One girl noted her own problematic use of marijuana that had quickly evolved into relying on it to deal with the regular stress in her life. As she pondered, she commented knowingly that it would be preferable to use it only when her stress level was "really" high.

I mean I started it, and I'm doing it for the wrong reasons...I think if I cut back and only did it when I was *really* stressed out or something, then, you know, really cut back, I think it would be okay. [14 years, non-daily use]

Although knowing that it was "harmful" to her body, she added that she found it difficult to quit using marijuana. Most youth were aware of the health consequences associated with marijuana use in general and their own use in particular. They noticed physical symptoms such as decreased stamina and shortness of breath with physical activities, while others worried about weakened immune systems and how it affected their energy level. Some recognized that they were addicted to marijuana. One male who had been using marijuana for six years framed it as something that he would address at a later date. "I'm trying to get through school and then worry about my dependency issue with marijuana."

Others noted that their marijuana use was linked to difficulties that they were having at school. One male concluded, "I think it brings marks down in one way and sometimes you don't understand things maybe as easily." Others recognized how their use had affected their memory. For a number of the participants, their knowledge of the risks of smoking marijuana was limited and, at times, incorrect. For example, as one 14-year old male who had started smoking marijuana in the past year to relieve muscle pain noted, "It's bad for your lungs, just it's 400 times lower than tobacco."

In what appeared to be an effort to minimize their use in the face of health risks, the teens emphasized that they were not using marijuana "in excess." One 18-year old summed up six years of using marijuana by saying, "I don't feel that I have a problem," adding that "it doesn't really have that many side effects." Some suggested that the benefits of smoking marijuana outweighed the risks. As noted, for those with difficulties sleeping at night, not being able to function the following day when sleep deprived was agonizing; marijuana use at night was preferable and provided a solution to that quandary. However, one male pondered both sides of his use of marijuana in dealing with his depression and was less optimistic:

Well, in some ways, it's helped me and some ways it hasn't. It's good when it's there, but when it's not, it kind of makes me sad. So it's hard like to try to keep up with staying happy all the time. [18 years, daily use]

Several participants made reference to the contradictions that they saw in their world regarding other licit substances and used that argument to make sense of and praise the benefits of marijuana over the risks.

And the thing is that if it's already used, they're already growing it for people that need it for medical help, then like why not.... Like no one has ever overdosed on marijuana, but people die everyday from alcohol, everyday from cigarettes and everyday from vast

amounts of things that the government has legalized, but they just won't legalize marijuana for some reason. It's never killed anyone, never really hurt anyone, it saves people's lives and they could make a good amount of money from it and drop crime rates, why don't they do it? [Male, 14 years, non-daily use]

Discussion

The findings of this study provide one of the first in-depth descriptions of youths' use of marijuana for non-recreational purposes, adding to the growing body of research on the use of drugs to self-medicate among young people. Teens involved in regular and long-term use of marijuana for relief constructed their use of marijuana as essential to feeling better or "normal" in situations where they perceived there were few other options available to them. Unlike the spontaneity typically involved in recreational use, these youth were thoughtful and prescriptive with their marijuana use – carefully monitoring and titrating their use to optimize its therapeutic effect. The findings also point to important contextual factors that further support youth's use of marijuana for relief that extend beyond the availability of marijuana and dominant discourses that construct marijuana as a natural product with medicinal properties.

Of key importance in the findings are the unmet health needs of these youth. Health issues such as depression, insomnia, and anxiety were significant problems that interfered with these youths' ability to function at school, maintain relationships with family and friends, and feel that they could live a normal life. The level of distress associated with these health concerns, along with the lack of effective interventions by health care providers and family members appeared to leave them with few alternatives. Researchers have reported that when adolescents in rural communities experience barriers to seeking health care, they think they can take care of the problems themselves [30]. Similarly, our study participants believed that their best option was to assume responsibility for treating their problems by using marijuana. Unpleasant side effects with prescribed medications and long, ineffective therapies resulted in little hope that the medical system could be counted on as beneficial. In contrast, marijuana provided these youth with immediate relief for a variety of health concerns. Nevertheless, the regular use of marijuana put youth at risk. Cannabis use has been identified as a risk factor for mental illness such as psychosis, schizophrenia [21,31,32] and psychiatric symptoms such as panic attacks [33]. Teens who smoked marijuana at least once per month in the past year were found to be three times more likely to have suicidal thoughts than non-users [34], and there is evidence that exposure to cannabis may worsen depression in youth [35]. Marijuana use among youth has also been associated with other sub-

stance use and school failure [36]. What is interesting is that the findings of this study suggest that youth have little awareness of some of these risks; rather, some are using marijuana to counteract these very problems (e.g., depression, school failure). Teens' perceptions that their health concerns were not addressed suggest that more attention is needed to assess these issues and ensure that other options are available to them. Parents and health care providers need to make a concerted effort to not only understand the pressures and influences on youth [37], but also gain a better understanding of the effect of youths' health problems on their ability to engage in healthy lifestyle choices.

Underlying problems related to youth health concerns also need to be addressed. In many situations, the participants' symptoms appeared to be directly related to their life circumstances. Along with the challenges inherent in being an adolescent in today's complex world, some teens were also trying to deal with significant losses (death of a close friend or family member), extremely difficult family relationships, disappointments with friends, school and sports, and a fragile family and peer support network. The risk of substance use increases substantially when youth are attempting to deal with these kinds of situations in isolation. Although marijuana provided the youth with temporary relief, the underlying situation often went unattended – leading the teens into a regular pattern of use. Appropriate guidance and targeted support from counselors and health care providers must be sensitive to meeting the needs of youth as they work through such situations and life altering events. In addition, adults working with youth must find better ways to talk with young people about how they are coping with their health issues, including their marijuana use. Based on the experiences of youth in this study, there is a wide range of support that may benefit youth including counseling, stress management, social skills training, anger management, study skills, pain management, and sleep hygiene. The youth in this study had minimal access to these types of resources.

The influence of the policy environment in Canada related to medical marijuana cannot be dismissed. The youth in this study were familiar with medical marijuana and its sanctioned use among those with serious illnesses; some knew individuals in their social network who were medical marijuana users. In addition, we acknowledge that the availability of marijuana in the study settings provided teens with opportunities to try marijuana to relieve symptoms. In locales where it is more difficult to access marijuana and penalties for possession of marijuana are harsh, teens with similar symptoms may use other approaches.

Despite presenting themselves as being sophisticated users of marijuana, with a rich knowledge of marijuana

acquired through direct experience, conversations and observations of others, the youth in our study did not appear to be well informed about the therapeutic use of marijuana. Targeted education for youth regarding the risks of marijuana and its appropriate use as a therapeutic agent is warranted, including the risks of legal sanctions. However, as Tupper [38] has suggested regarding drug education, fear-based approaches are unlikely to be effective when the reality of youths' observations and experiences suggest that few serious consequences stand in direct contrast to the "facts" teachers often provide. Alternative approaches are required that acknowledge the complexity of the issues that inform understandings of marijuana. Tupper suggests that drug education be framed using the metaphor of "drugs as tools" to allow "more nuanced understandings of the benefits and harms of drugs, depending on who is using them, in what circumstances, and for what purpose" (p. 235). This approach may be useful in education focused on marijuana.

This study was conducted in three locations in the province of British Columbia (BC) Canada and as such may not be generalized to other contexts. The province of BC is known for its illicit marijuana production [39]. And, in general the BC public is tolerant of marijuana use and support decriminalizing recreational use. In other contexts, teens might turn to other substances such as alcohol. The findings of this study provide a snapshot of these teens' use of marijuana. Further research is required to examine how this therapeutic use evolves over time.

Conclusion

In summary, this study highlights youths' efforts to address their health problems and their experiences in using marijuana for relief. Marijuana may be perceived by some teens to be the only available alternative for those experiencing difficult physical or emotional problems when medical treatments have failed or when they lack access to appropriate health care. As has been noted in other studies of substance use [40], understanding why adolescents use particular substances is key in developing appropriate educational and intervention programs.

Who is Using Cannabis as a Medicine and Why: An Exploratory Study[†]

Alan C. Ogborne, Ph.D.*; Reginald G. Smart, Ph.D.*;
Timothy Weber, B.A.** & Carol Birchmore-Timney, M.A.**

Abstract—This article reports on an exploratory study of medical cannabis users. Interviews were completed with 50 self-identified medical cannabis users recruited through notices in newspapers and on bulletin boards. They reported using cannabis for a variety of conditions including HIV-AIDS-related problems, chronic pain, depression, anxiety, menstrual cramps, migraine, narcotic addiction as well as everyday aches, pains, stresses and sleeping difficulties. A majority also used cannabis for recreational purposes, and many were longer-term cannabis users. However, there were some notable exceptions. Almost all smoked cannabis and many did so two to three times a day. Few admitted negative experiences with cannabis, although some problems evident to the researchers were not clearly admitted. Those who told their doctors about their medical cannabis use found doctors noncommittal or supportive. The results raise questions about the definition of medical cannabis use and about policies that might be developed to accommodate such use. Limitations of the study are noted and further research suggested. Research priorities include population surveys, studies involving larger, more representative samples of medical cannabis users and studies of medical cannabis use among people with HIV-AIDS.

Keywords—cannabis, HIV/AIDs, medical marijuana, self medication

Cannabis has a long history of use as a medicine, and during the 19th century extracts of cannabis were recommended by respected physicians for a wide range of medical conditions (Grinspoon & Bakalar 1997). Cannabis was considered to have analgesic, sedative, anti-inflammatory, antispasmodic, anti-asthmatic and anticonvulsant properties and promoted for the treatment of tetanus, cholera, pruritis, uterine dysfunction, labor and menstrual pains, gout, asthma, neuralgia, rheumatism, convulsions and

depression. Early in the 20th century the use of cannabis fell out of favor with the medical profession due to the discovery of newer, more stable and effective drugs. A synthetic form of THC (dronabinol or marinol) has since been developed for the treatment of nausea associated with chemotherapy and AIDS-related anorexia. However, until recently, cannabis has mainly been used illegally as a recreational drug with the intention of getting high rather than treating medical conditions.

Anecdotal and journalistic evidence indicating that cannabis is regaining popularity as a medicine has been accumulating since the 1970s. Personal testimonials from users and statements by lobbyists and some physicians have indicated that cannabis is used by people suffering from glaucoma, multiple sclerosis, epilepsy, mood disorders, and other disorders that cause pain, muscular tension or spasms (Campbell 1996). One study of people using a buyers' club

in California showed that many were using cannabis to treat AIDS-related symptoms or for a variety of chronic pain, neurological and psychiatric disorders (Harris, Mendelson & Jones 1998).

There are two published studies of medical cannabis use among people with HIV/AIDS. The first was a survey conducted during 1993/94 that involved patients of an AIDS clinic in Alabama (Dansak 1997). Of the 72 patients interviewed, 33 (46%) were currently using cannabis and almost all had used it before the onset of AIDS/HIV. Most current users had used cannabis for medical reasons as it had beneficial effects on gastrointestinal conditions such as nausea, vomiting, indigestion and appetite. A few also noted that cannabis helped alleviate depression and two noted that it reduced anxiety.

The second study of medical cannabis use by persons with HIV/AIDS was conducted in Hawaii (Wesner 1996) through an AIDS Newsletter. It reached 374 persons affected with AIDS or HIV but only 35% responded, and it is not clear whether respondents were more likely to have used cannabis than nonrespondents. Of those who did respond, 36.9% had used cannabis as a therapy for AIDS symptoms; of those who had also used prescription anti-emetics, 80% preferred cannabis. A third of those who had used cannabis medically had not discussed this with their doctors.

There are no published surveys of medical cannabis use among people suffering from chemotherapy-induced nausea, multiple sclerosis, epilepsy or other physical conditions for which cannabis is said to be helpful. However, several surveys have shown that cannabis use is common among psychiatric patients who often seem to use cannabis to medicate psychiatric symptoms (Beesley & Russell 1997; Rohnaar & Timmerman 1997; Mathers et al. 1991; Blackwell, Beresford & Lambert 1987).

The prevalence of medical cannabis use is not known except in Ontario, where the results from a province-wide survey of adults aged 18 and over indicate that about 2% had intentionally used cannabis for self-defined medical reasons at least once in the past year. This represents 7.6% of those who had ever used cannabis and 22% of those who had used cannabis in the last year. No comparable figures are available from other Canadian provinces or from other countries. The latest national drug survey in Canada was in 1994 and this showed that 7.6% of the adult population had used cannabis in the past year (Smart & Ogborne 2000). However, no questions about medical cannabis use were included.

The medical use of cannabis raises new and important medical, social policy and legal issues concerning the rights of people to use an illegal substance for medical reasons. In the United States and in Canada there is considerable public support for the medical use of cannabis and for the rights of physicians to recommend cannabis to people who might benefit from it (Lindesmith Centre 1998; Angus Reid Group

1997). Attempts have also been made to establish buyers' clubs to provide cannabis to those with legitimate medical needs, and several recent court rulings have been in favor of the rights of sick people to use cannabis for medical reasons. More information is therefore needed on the nature and extent of medical cannabis use and on motivations, characteristics and experiences of those involved. This is especially so because cannabis is used medically by some of the most vulnerable and sickest people. This article reports a study that explores why people use cannabis for medical reasons, the effects they get, their methods and patterns of use, their experiences with physicians and their encounters with the law. It provides an analysis of interviews with 50 cannabis users in Toronto.¹ These interviews were conducted to (1) assess the feasibility of a larger study involving medical cannabis users and (2) explore opinions and practices concerning the medical use of cannabis. Implications for further research and for social policy are considered in the discussion.

METHODS

Those interviewed were recruited mostly through notices placed in newspapers and on bulletin boards at the Addiction Research Foundation, downtown bookstores, grocery stores, restaurants, and laundromats, AIDS clinics and drop-in centres and an informal buyers' club. These notices invited those who had ever used cannabis for medical reasons to share their experiences in a confidential interview. A few respondents (less than five) were also recruited through contacts with professionals and through the use of snowball sampling. Those who called in response to information about the study and who said that they used cannabis for medical conditions were invited for an interview. Most interviews were conducted at the Addiction Research Foundation. Others were conducted in respondents' homes, at a drop-in centre, or a restaurant; two interviews were conducted by telephone. All those interviewed were paid \$10. All interview questions were open-ended and encompassed a range of topics. In this article, the focus will be on: (1) reasons for the medical use of cannabis; (2) other attempts to treat the conditions for which cannabis was used; (3) routes to cannabis use; (4) methods of use; (5) patterns and amounts of use; (6) sources of supply; (7) negative experiences with cannabis; and (8) experiences with physicians.

RESULTS

Fifty (50) individuals were interviewed over a six-month period. About 70 others inquired about the study but could not be contacted. Twenty others did not show up for interviews. Of the 50 people interviewed 33 (66%) were male. The average age was 38, with a range from 26 to 57.

TABLE 1
Main Medical Condition for which Cannabis Use was Reported: Number of Respondents

HIV/AIDS-related symptoms	11
Chronic or recurrent pain due to injury or of unknown origin	7
Clinical depression*	6
Chronic stress or anxiety**	3
Narcotic addiction	2
Menstrual cramps	2
Anorexia/bulimia	2
Asthma	2
Migraine	2
Multiple self-diagnosed minor ailments and everyday stress**	2
Epilepsy	2
Lupus	1
Graves disease	1
Vocal Tourette's Syndrome	1
Multiple sclerosis	1
Retinitis pigmentosa (night blindness)	1
Chemotherapy-induced loss of appetite	1
Unexplained nausea	1
Hepatitis	1
Crohn's Disease	1
Arthritis	1

*For which they had received medical or psychiatric treatment (not noted in text).

**Did not seek treatment.

Medical Reasons Reported for Cannabis Use

Table 1 shows the conditions for which respondents said they used cannabis. The majority (n=34) reported using cannabis to treat symptoms of organic illnesses or to treat pains due to accidents or unknown causes. The most common organic illness was HIV/AIDS (n=11). Others (n=9) said they used cannabis for serious psychological problems (clinical depression or chronic anxiety), anorexia (n=2) or symptoms related to narcotic addiction (craving and methadone-related nausea). One person claimed to use cannabis to treat chronic but unexplained nausea. Finally, two reported using cannabis to treat minor medical conditions and cope with everyday stresses.

A wide range of symptoms or conditions were reportedly relieved by cannabis including difficulty sleeping, physical pain, loss of appetite, nausea, seizures, tics and muscle spasms, craving for narcotics, loss of energy, depression and anxiety. Table 2 shows the frequency with which specific symptoms were mentioned. The total number of symptoms exceeds the number of respondents because many reported using cannabis for two or more symptoms or conditions. Typically nausea and loss of appetite were mentioned together as were depression and anxiety.

The reported reasons for taking cannabis varied greatly:

Its mostly for spasms. I use it for relaxing . . . I get a lot of pain running all down my neck. . . . I get a lot of spasms coz of the HIV . . . It [cannabis] helps because it relaxes me and gets rid of the muscle pains in my neck. (male with HIV).²

I can see clearer . . . a little sharper. . . . Sometimes my eyes start . . . pulsating . . . itchiness and stuff and after I do one of those [smoke a joint] . . . no problem. (male with retinitis).

If I have no marijuana I'm no good for nobody. . . . But the moment I smoke a joint I've got self-esteem, it makes me feel good. (male with HIV).

I could not control my focus . . . I have double vision . . . it [cannabis] helps me. . . . The condition of my eyes has improved and he [the doctor] could see this because he made me undergo tests. (male with eye problems related to Graves disease).

. . . to increase my appetite . . . my metabolism burns very fast. Can't gain an ounce . . . can't even maintain weight unless I eat five, six times a day. Can't bring myself to do that unless I smoke a couple of joints. (male with anorexia).

I have really excruciating pain and I find it [cannabis] helps. (female with chronic back pain).

He is currently using medical marijuana for pain relief for lupus and vascularities associated with lupus; capillaries break and it results in sores that are quite painful. A secondary use is to relieve nausea and pain associated with the drugs for lupus. (Interviewer notes on male with lupus).

If I'm seizing I will get someone . . . [and] they'll come by with a couple of joints and . . . take a puff . . . then in a few seconds or a few minutes I got no seizure problems whatever. It's amazing how it works. (male with epilepsy).

I take 30 pills a day . . . I feel nauseated most of the time . . . marijuana takes care of the nausea . . . prescriptions from the doctor . . . don't work as well. (male with HIV).

TABLE 2
Number of Respondents with Symptoms Reported to be Relieved with the Use of Cannabis*

Problems sleeping	28
Loss of appetite	21
Nausea or pain (including menstrual cramps and headaches)	14
Depression	12
Anxiety/tension	11
Ticks and muscular spasms	10
Seizures	4
Loss of energy	3**
Difficulty breathing (asthma related)	2
Craving for heroin	2
Anger	1
Eye irritation and double vision (in Graves Disease)	1

*Number of symptoms exceeds number of respondents because some respondents reported two or more symptoms that were relieved by cannabis.

**Includes one person who developed seizures following the onset of HIV infection.

... if you're feeling really, really bad some days ... eh maybe escape isn't the right word because it's a drug but it gives you some relief to make that go away for a while ... if I am really bad I don't take the Tylenol 3. I would rather take a few tokes. (female with multiple sclerosis).

It's an unexplained nausea ... to the point of vomiting ... I won't eat for three to four days and then I'll still be vomiting like dry heaves. I just like a little bit [of cannabis] ... it's just to make it go away ... (female with nausea).

To induce my appetite because I'm on methadone ... I lost about 25 pounds cause of it ... suppresses your appetite but it also make you nauseous ... I wasn't eating at all for three days at a time ... so I started smoking ... it worked for the nausea when I was pregnant ... and it helps me sleep. (female with nausea and narcotic addiction).

I find [prior to menstruation] my body goes through ... aches and pains and back pains ... and when I smoke marijuana it tends to relieve it ... I'm able to function ... as opposed to going and taking a Midol or going to my family physician ... for a synthetic prescription. (female with menstrual cramps).

I started smoking because that was the only way I could eat and function. Otherwise I had to stay in bed ... [I] was so sick. But when I smoked a joint I can clean the house ... eat ... but as soon as it passed I have to go back to bed. (female with HIV).

Bulimia, anxiety, depression ... what it does [cannabis] is it calms down my system so that I can eat and think rationally. I get all my stuff down and then it's time for bed. (female with anorexia).

[Cannabis] helps me with my nerves and sometimes with pain ... I don't know if I could ... live and be functional without it [cannabis] unless I got something under a doctor's care but because of my liver any pills are bad for me. (female with anxiety and hepatitis).

I use it [cannabis] to alleviate cravings for heroin. It helps me get through the day without using heroin. (male receiving methadone).

Nausea, which you suffer from a lot when you have Crohn's, [also] loss of appetite ... lot of pain it would help with that. Also ... with Crohn's you'd have a lot of like spasms of your stomach or your bowel inside and it would help with that. (male with Crohn's disease).

If I've got a boardroom meeting let's say at 3:00 today, at 1:00 I'll take a "butt" ... I'm very ... lucid. (male with Tourette's Syndrome).

Treatments Other than Cannabis Tried for Main Conditions and Symptoms

Other attempts to treat the symptoms and conditions that motivated self medication with cannabis were quite variable. In some cases it was not clear that alternatives to cannabis had been tried. However, in other cases cannabis was described as superior to other, more conventional, treatments:

[I've tried] Dilantin and phenobarbital but they were not controlling the seizures. ... I've not used any other medication (except cannabis) since 1971. (male with epilepsy).

Two specialists ... gave me pills ... but they didn't make a noticeable difference. ... I've tried health food stuff ... it just takes a little bit [of cannabis] ... to make it [nausea] go away. (female with chronic nausea).

So ... I tried ... Prozac. It did not help me ... it made me a different person ... very introverted ... withdrawn. (female with migraines and insomnia).

I was taking tons of medication ... a major dose of Anafranil [an antidepressant] and ... Rivatrol [an anticonvulsant] and ... they were getting me very lethargic and laid back ... what was happening was it was getting me so stoned and so happy ... my tics didn't go away ... [but] I couldn't give a hoot and hinny ... (male with Tourette's Syndrome)

They [doctors] gave me Tylenol 3s and they made me a bit groggy. ... I wanted to work ... I noticed that when I took a

bit of marijuana it alleviated the symptoms and allowed me to function normally. (male with repetitive strain injury).

I was on Serax [a sedative] once for almost a year but I found that taking Serax made me sick. It made my stomach feel real weird. So I discontinued it... marijuana makes you feel strange but it's a good kinda strange . . . it's not the kinda stone where you're walking around and your head feels like it's 15 miles high. (male with HIV).

I tried different pain killers and at first they seemed to be okay but . . . they stopped writing prescriptions for me. I found it [the marijuana] helped. It made me motivated and gave me energy and kept me active. (female with back pain).

I was taking Valium, diazepam . . . like I took it for like three years and then I started smoking marijuana . . . I didn't have the same feelings I had when I was taking the Valium. I felt more calm, more relaxed. . . . It was able to open my appetite to eat. (male suffering from depression).

Well, I suffer from depression and when you're really, really, really depressed a joint works a lot better. . . . I've tried all the antidepressants, like all of them and I've just given up on it. (male with depression).

Cannabis was, however, also sometimes used in combination with drug treatments that respondents found helpful.

I'm a chronic asthmatic, So . . . I'm using it [cannabis] in combination with . . . Beclavent which is a long-term steroid and occasional use of Ventolin, an immediate release asthmatic drug, just for when you're in a crisis situation . . . and I find a little marijuana on the side does help. (male with chronic asthma).

I fell down a flight of stairs . . . and found myself in a lot of pain . . . decided to stop taking the prescribed medication because I ballooned up to 235 pounds. . . . I'm back to taking Tylenol 3s but I've reduced my intake to more than half since I've started smoking [cannabis]. (Female with chronic pain).

Only one person with HIV/AIDS reported being prescribed Marinol[®] (synthetic THC) for HIV/AIDS-related anorexia and nausea. However, he claimed that this had no noticeable effects. Apart from the perceived medical advantages of cannabis, some respondents also valued cannabis because it was relatively inexpensive or "natural":

It [Marinol[®]] is like \$700 for a month's supply of 90 pills and that's the max you can get. . . . So that's why I'd rather buy cannabis on the street with the welfare cheque (male with HIV).

Because it's a natural, organic thing, instead of taking these chemical prescriptions which I don't like. I'm a naturalist and I'd rather do something that grows naturally. (female with anorexia, bulimia and depression).

I would much rather use something natural—a plant product . . . than a chemical or pharmaceutical drug coz I found that they have a lot of side effects. (male with Crohn's disease).

Routes to Cannabis Use

The majority (n=42) of interviewees had at least some experience with cannabis as a recreational drug, and some (n=30) described a long history of recreational use (seven to 35 years). In these cases self-defined, medical cannabis use typically started when recreational use was found to be helpful for medical or psychological problems:

I had lost a lot of weight . . . I was down to like 97 pounds. When I started smoking marijuana I started just smoking it casually . . . to be part of the crowd. But, I noticed the more that I smoked, the hungrier I got and the more that I eat, I found the better I sleep. (male with HIV).

I used to smoke when I was younger but that was when I guess when I started first smoking it was more recreational, with the guys sort of thing, then I stopped for quite a long period of time—I was a very hyper person. So . . . then I decided to smoke it again. (male with insomnia).

When I used to smoke it [cannabis] for recreation I was running a lot of track and field and that's . . . when I noticed when I . . . pulled muscles and so forth the pain wasn't there at all. (male with migraine).

I had tried it for recreational use back as a teenager . . . and I found that . . . there's times when I was feeling bad with my illness and I'd smoke some and I felt better. . . . So, um, I thought that it probably might work for me and . . . It worked better than most of the medicine I was taking. (male with Crohn's disease).

I've been smoking dope for 24 years. Originally, peer pressure, getting high, now I don't even get high, I smoke it to increase my appetite . . . Can't even maintain weight unless I eat five, six times a day. Can't do that unless I smoke a couple of joints. (male with anorexia).

Respondents with no, or very limited previous experiences with cannabis (n=9) started using it medically after reading about it or on the advice of others. Two reported that they first started using cannabis on the advice of a physician:

I was drinking beer at the time . . . a friend asked me if I wanted to try it and . . . was shocked to find out how it made me feel. It was just magic. (male with AIDS).

A friend made me some Sleepy Time tea with cannabis in it. (male with Tourette's Syndrome).

Dr. . . . was seeing me for epilepsy suggested that I smoke a joint before I came for the next visit . . . and I did. . . . he was having trouble controlling the epilepsy. (male with epilepsy).

Around four or five years ago I read and even my doctor had suggested that maybe that this was a good thing . . . because of my . . . problem with wasting. (male with HIV).

Methods of Cannabis Use

Smoking was the primary and the preferred method for using cannabis either because it was inherently enjoyable or

because of its advantages over other methods of use.

I just smoke it. . . . I have tried hash brownies and I've tried marijuana brownies . . . but to me the high is not the same . . . I smoke cigarettes constantly, right? . . . to smoke a joint is the same thing as smoking a cigarette except for you're getting a buzz off a joint (male with HIV).

I've eaten it in the past. . . . I've drunk it in tea. . . . put it in sauces and cooking . . . for me immediate effective relief is smoking . . . eating is too expensive . . . smoking you don't need as much to get the effect what-have-you and it's more immediate too. (male with epilepsy).

It's just easy to do [smoking] . . . you have to put it and just light it up . . . so it's a lot easier. (male on methadone).

Some advantages to eating or drinking cannabis were identified:

In tea form . . . it effects you faster, it's absorbed faster . . . but it is a totally different high. . . . It's more of a body type stone . . . relaxes your body whereas if you smoke it, it still has the same effect but it's more of a head stone as well. (male with Crohn's Disease).

I think it's longer lasting [eating or drinking marijuana] . . . don't have to worry so much about the smell of it. (female with pain from an accident)

I worry about the respiratory side effects and the social aspects—sometimes. . . . my partner doesn't like me to smoke in the house so I step outside and the neighbors can smell it and I'm not always comfortable with that. (male with multiple HIV-related problems).

It [cannabis] can make me lazy. . . . It makes me cough. (male with depression).

What about my lungs and throat and I don't want to be smoking at all. I'm a nonsmoker at heart. (female with chronic pain).

Only two respondents said that they never smoked cannabis. One was the person with Tourette's Syndrome who reported drinking cannabis in tea. The other was a woman who used cannabis in tea or banana bread for menstrual cramps. One respondent had a novel method of using cannabis:

I'm mixing it with alcohol. . . . crushed up as a paste and rub it on my chest as a plaster for like . . . lung infections or colds. (male with migraine).

Patterns and Amount of Cannabis Use

Thirty five (70%) of respondents typically smoked cannabis every day, and among these daily users, the majority smoked two to three times a day. Those using cannabis to stimulate their appetites used it at meal times, while those who ever used cannabis to help them sleep (n=28), used it later in the evenings.

Total daily consumption was, however, quite variable. One person reported smoking up to ten joints a day while another said that she made a joint last all day by only taking a few puffs before meals. Based on reports of the costs of cannabis and typical monthly expenditures the average monthly consumption was between one and two ounces, with a range from less than one quarter ounce to over three ounces. These estimates included daily users but excluded those who reported growing their own cannabis or getting it free.

Thirteen³ respondents reported that, in most cases their use of cannabis was closely associated with symptom relief or avoidance:

I start smoking about two weeks before my period begins. (female with menstrual cramps).

If I can do without it, I do without it. Even if I have my ties back I do without it. I like to keep it for that special moment . . . when I have to make a presentation . . . [at] a board meeting. (male with Tourette's Syndrome).

However, in the majority of cases (n=37) cannabis was also used recreationally and the distinction between medical and nonmedical use was blurred:

It's beautiful when you can sit down and smoke a little joint and just get wasted out of your face . . . yes we like the high. (male with HIV).

Sometimes a friend comes over in the morning of whatever and it's like a beer on a Sunday afternoon. . . . (female with nausea).

For those few (n=13)⁴ who said they did use cannabis recreationally, the cannabis high was either seen as a medical benefit or as a state to be avoided.

I just go with it . . . it makes me feel better you know, once I start feeling better then I know I'm there . . . I just look at it as a pleasant side effect . . . getting a bit high. (male with Crohn's Disease).

The high is the one that gives me the energy. (female with HIV).

Don't like getting high because the disorganization gets worse. (male with migraine headaches).

Sources and Methods of Supply

Almost all respondents obtained cannabis from regular dealers or friends. However, two reported that they grew their own and one reported going to a buyers' club.

It seems more legitimate (going to the buyers' club) than meeting someone on the street . . . and you don't know if you're gonna get ripped off or beaten up. (male with HIV).

Only two reported that they did not have established suppliers of cannabis and went in search of cannabis whenever

they needed it:

I have to go and wait for somebody to show up at these places where they sell . . . it's too far away and sometimes I go there and they're not there. (female with HIV).

I phone people who might know somebody coz nobody I know smokes. So I'm asking them to lean on their friends. (female with chronic pain).

Finally, one respondent said that he got cannabis from his doctor:

He just gets it for me and I have to come in to get it . . . so I never get accosted by anybody. (male with HIV).

Negative Experiences Associated with Cannabis Use

About a third of those interviewed reported being stopped and searched for cannabis or other drugs and drug paraphernalia at some time. These were typically long-term recreational users, but two who saw their use of cannabis use as strictly medical had also been arrested and charged. One won a court case by convincing the judge that the cannabis was used for medical reasons, while the second was preparing to challenge a conviction for possession on the same grounds. A third, strict medical user with AIDS had been contacted by the police following a complaint from a neighbor. However, no arrest was made and the respondent felt that the police were "very humane" when they suggested that he could avoid upsetting the neighbor by smoking on a private balcony.

That cannabis is an illegal drug weighed on the minds of most respondents and they were careful to avoid being arrested. However, medical use was also seen as potentially giving immunity to serious legal consequences:

I'm HIV positive. . . . What are you going to do? Gonna send me to jail? (male with HIV).

Some respondents had been harmed by their use of cannabis, but this was not always acknowledged. One, who saw cannabis and drug use generally in a very positive light, had been severely hurt while riding a bicycle under the influence of cannabis and had since continued a dysfunctional lifestyle involving the heavy use of cannabis and other drugs. Another gave an incoherent account of how cannabis had helped him psychologically, but it appeared that some of his problems (anxiety and depression) were drug-induced. One other respondent, who suffered from depression, also speculated that this may have been made worse by cannabis use.

Having to buy on the street resulted in a financial burden for most interviewees. The appetite stimulant effects of cannabis were negative consequences for two respondents who were not using it for that reason. Most did not see cannabis as having any negative effects. However, the following negative effects were each mentioned by at least

one respondent: rejection by family members, lethargy, apathy, cough or throat irritation from smoking, thirst, loss of concentration, short-term memory loss, paranoia, severe intoxication and depression.

Many interviewees were using cannabis two or more times a day for a long time and they could be expected to experience withdrawal symptoms if they ever stopped using. However, none expressed significant concerns about cannabis dependence:

I am dependent already, it doesn't bother me. cuz I'm still ok and it helps me lead a healthy life. (female with HIV-related anorexia).

No, I'm not concerned about becoming dependent. . . . I know it's slightly habit forming but it's not a chemical addiction like cigarettes. (male with Crohn's Disease).

I do get some withdrawal effect . . . here is a little bit of concern mostly because it's illegal. . . . if I could just get it at the drugstore I wouldn't have much concern. (male with chronic pain).

I think it's more of a psychological addiction than a physical one for me because I've gone days without it. If I became dependent it would be more emotionally than physically. (male with HIV).

Experiences with Physicians

Only twelve respondents said that they had not told their physicians that they were using cannabis for medical or other reasons. Others had told their physicians and found their reactions mostly noncommittal but sometimes clearly positive. Only three said their doctors discouraged them from using cannabis:

Well he [the doctor] doesn't approve of it but in a stupid little way he does approve of it because he knows that from my . . . personal experience telling him of just how much good it's done for me. (male with HIV).

My psychiatrist is very old school. He's telling me that I can become addicted. . . . He would rather see me go through surgery and nerve blocks. (male with chronic pain).

Almost all of those with HIV/AIDS had told their physicians about their use of cannabis and had found physicians to be very understanding and supportive. Physicians were also reported as being sympathetic or supportive of cannabis use by at least one respondent suffering from nausea and weight loss associated with methadone treatment, chronic pain, epilepsy, menstrual cramps, Crohn's Disease, repetitive strain injury, and depression.

SUMMARY AND DISCUSSION

This exploratory study shows that cannabis was being used for a range of medical reasons. Among those interviewed

the most common conditions associated with cannabis use were HIV/AIDS-related problems, chronic pain, depression and anxiety. However, cannabis was also used to treat menstrual cramps, anorexia, narcotic addiction, migraine, Tourette's Syndrome, lupus, Grave's Disease, epilepsy, retinitis, chemotherapy-induced loss of appetite, Crohn's Disease, arthritis and everyday aches, pains, stresses and sleeping difficulties. Specific symptoms that were reportedly relieved by cannabis included sleeping difficulties, nausea, loss of appetite, pain, depression and anxiety, tics and seizures, loss of energy, breathing difficulties, craving for heroin, anger and vision problems. Typically, medical cannabis use followed recreational use and the majority of those interviewed were long-term, and sometimes heavy, recreational users. Most continued to use cannabis recreationally as well as medically. However, the sample also included some people whose use of cannabis was primarily initiated by the desire to treat medical conditions for which other treatments were unsatisfactory.

Almost all interviewees smoked cannabis and only two regularly used it in other forms (in tea or baked in a muffin). The majority used cannabis two to three times every day. Cannabis was usually obtained from friends or regular dealers but one person obtained it from his doctor. Respondents were acutely aware that possession of cannabis was illegal and they took precautions to avoid arrest. About a third, mostly those who used cannabis recreationally, had been stopped by police and searched for drugs. Three of those who had only used cannabis for medical reasons had been involved with the police but only two had been charged and one had won a court case. Few admitted negative experiences associated with cannabis use or expressed concerns about being dependent on it. However, some problems that seemed evident to the researchers were not always clearly acknowledged as related to cannabis (accidents, dysfunctional lifestyle, psychological problems). Most respondents had told their doctors about using cannabis for medical reasons and their doctors were supportive or noncommittal. Doctors were seen as supportive of cannabis use by most respondents with HIV/AIDS.

The present study did not, of course, seek to determine if the reported medical benefits of cannabis were real or imagined or if they should be attributed to placebo effects, other treatments or natural recovery. It is likely that the medical benefits of cannabis were sometimes overstated, especially by long-term recreational users with positive views of cannabis. Although respondents thought that their physicians supported their use of cannabis, it is not known if this was really the case. Some respondents also seemed to ignore negative consequences of cannabis use such as dependence and withdrawal.

Many reported benefits of cannabis were consistent with those reported elsewhere. Cannabis was typically used for its sedative, analgesic, antispasmodic, appetite stimulating, anticonvulsant and euphoric properties. These

properties were well known in the past century when cannabis was used to treat conditions that required medications with these properties. Although scientific evidence in favor of medical cannabis is limited (Gurley, Aranow & Katz 1998), self-treatment with cannabis could become popular as more users publicize their own experiences. This is especially so if the everyday aches and pains and psychological problems are promoted as medical reasons for using cannabis.

The boundaries of medical cannabis use will be of concern if more medical cannabis cases come to court. In the Canadian cases where medical necessity was successfully used as a defense against a charge for the possession of cannabis, the defendants had chronic and serious medical conditions (epilepsy and AIDS) and were strongly supported by their physicians. Others who are able to convince the courts that their use of cannabis brings relief to otherwise untreatable conditions may also do well in court. However, those who use cannabis for less serious conditions that can be successfully treated by other means may not fare so well, especially without a supportive physician.

The boundaries of medical use are also of concern if new policies on medical cannabis use are developed. If such use encompasses use for self-diagnosed conditions then policies might be needed to ensure that all those who want to use cannabis for these conditions have access to quality-controlled cannabis products. If on the other hand, medical use is to be defined as use with the approval of a physician, more restrictive access will be needed.

At present there are no completely satisfactory ways to deal with the issues of medical cannabis use. Apart from the difficulty of defining "medical," there are presently many uncertainties about the objective benefits of cannabis as a medicine as well as legitimate concerns about side effects and the risks associated with cannabis smoking. Many issues could eventually be resolved through scientific research, including research on alternative methods of delivery such as nasal sprays. In the meantime, there are humanitarian reasons for devising ways to ensure that the seriously ill who find cannabis helpful can have access to a quality-controlled product.

Studies of this sort always have limitations. The sample was small and drawn from one area of one city. Respondents were self-selected. The sampling strategy may have excluded those who were very sick and those who feared being identified as cannabis users. It may also have been biased towards HIV/AIDS cases as notices were put in AIDS clinics. A wider distribution of notices to psychiatric, neurological, pain and cancer treatment centres, clinics, or self-help groups may have attracted a wider range of users or a greater representation of some types. However, the study had limited resources and initially there was a concern that large numbers would come forward for interviews, but this was not the case. It took four months before

50 interviews were completed and only about 120 calls about the study were received.

It is clearly important to learn more about the extent of medical cannabis use in the general population and in populations at high risk. The present study suggests that priority should be given to studies of cannabis use among people with HIV/AIDS. Issues of concern should be the nature and extent of cannabis use as well as biomedical studies that assess the effects of cannabis on biological systems. Studies of interactions between cannabis and the drugs used in HIV/AIDS treatment should also be given priority.

NOTES

1. The notice soliciting the interview referred to marijuana and not cannabis on the assumption that most medical

users would refer to cannabis this way. The name cannabis will be used throughout this paper except when quoting respondents who referred to cannabis as marijuana.

2. All quotes use respondents own words. However, redundant words and phrases and those not directly relevant to a particular topic have been omitted. Words in brackets were added by the authors to clarify respondents statements.

3. Approximate number. Some accounts of use patterns were difficult to interpret.

4. See previous footnote.

Around-the-Clock Oral THC Effects on Sleep in Male Chronic Daily Cannabis Smokers

David A. Gorelick, MD, PhD¹, Robert S. Goodwin, DO, PhD¹, Eugene Schwilke, PhD¹, Jennifer R. Schroeder, PhD², David M. Schwobe, PhD¹, Deanna L. Kelly, PharmD³, Catherine Ortemann-Renon, PharmD, PhD⁴, Denis Bonnet, MD⁴, and Marilyn A. Huestis, PhD¹

Abstract

Background and Objectives— 9-tetrahydrocannabinol (THC) promotes sleep in animals; clinical use of THC is associated with somnolence. Human laboratory studies of oral THC have not shown consistent effects on sleep. We prospectively evaluated self-reported sleep parameters during controlled oral THC administration to research volunteers.

Methods—Thirteen male chronic daily cannabis smokers (mean \pm SD age 24.6 \pm 3.7 years, self-reported smoking frequency of 5.5 \pm 5.9 (range 1–24) joint-equivalents daily at study entry) were administered oral THC doses (20 mg) around-the-clock for 7 days (40–120 mg daily) starting the afternoon after admission. The St. Mary's Hospital Sleep Questionnaire was completed every morning. Plasma THC and 11-OH-THC (active metabolite) concentrations were measured in venous blood samples collected every evening. Changes in sleep characteristics over time and associations between sleep characteristics and plasma cannabinoid concentrations were evaluated with repeated measures mixed linear regression.

Results—Higher evening THC and 11-OH-THC concentrations were significantly associated with shorter sleep latency, less difficulty falling asleep, and more daytime sleep the following day. In contrast, the duration of calculated and self-reported nighttime sleep decreased slightly (3.54 and 5.34 minutes per night, respectively) but significantly during the study.

Conclusions—These findings suggest that tolerance to the somnolent effects of THC may have occurred, but results should be considered preliminary due to design limitations.

Declaration of Interest

Authors Bonnet and Ortemann-Renon are employees of Sanofi-Aventis. The other authors report no conflicts of interest. The authors alone are responsible for the content and writing of this paper.

Scientific Significance—Somnolence from oral THC may dissipate with chronic, high-dose use. This has implications for patients who may take chronic oral THC for medicinal purposes, including cannabis dependence treatment.

INTRODUCTION

Cannabis, the most widely used illegal drug,¹ generally promotes sleep by activating cannabinoid CB1 receptors.^{2,3} This also is true of its primary psychoactive constituent, 9-tetrahydrocannabinol (THC), whose oral formulation is approved for medical use in many countries. The approved product labeling for synthetic THC (dronabinol, Marinol® Untimed Pharmaceuticals, Marietta, GA) includes somnolence as a common side effect, reported in up to 10% of patients in clinical trials. However, human laboratory studies involving controlled administration of oral THC have not shown consistent effects on nighttime sleep latency or duration with single 1.5–30 mg doses,^{4,5} 20–40 mg daily for up to 14 days,^{4,6,7} or 210 mg daily for 16 days.⁸ Interpretation is limited by small sample sizes (2–10 subjects per study) and heterogeneity in degree of cannabis use at the time of study.³ We are not aware of any prior study that evaluated the relationship between sleep characteristics and plasma cannabinoid concentrations.

As part of a larger study on human cannabis withdrawal⁹ (registered as NCT01041170 at www.clinicaltrials.gov), we had the opportunity to evaluate effects on nighttime sleep of around-the-clock oral THC (increasing from 40 to 120 mg daily) for 7 days in 13 male chronic daily cannabis smokers. Furthermore, we examined the correlation of sleep effects with evening plasma cannabinoid concentrations.

METHODS

Participants

The study was approved by the institutional review boards of the National Institute on Drug Abuse (NIDA) Intramural Research Program, the University of Maryland School of Medicine, and the Maryland Department of Health and Mental Hygiene. All participants provided written informed consent when not acutely intoxicated or in withdrawal. Inclusion criteria were 18–45 years old, smoked cannabis for the prior 1 year and averaging daily use for at least 3 months prior to admission, cannabis use within 24 hours of admission, urine specimen positive for cannabinoids in the 30 days prior to study entry, normal cardiac function, and IQ ≥ 85 (based on the Wechsler Abbreviated Scale of Intelligence). Exclusion criteria consisted of past or present clinically significant medical disease that might interfere with safe study participation; history of psychosis or any current DSM-IV axis I disorder (other than cannabis, caffeine, or nicotine dependence, or simple phobia); current physical dependence on substances other than cannabis, nicotine, or caffeine; history of clinically significant adverse events associated with cannabis intoxication or withdrawal, for example, psychosis; ≥ 6 alcohol drinks/day ≥ 4 times/week in the month prior to study entry; sesame oil allergy; or current interest or participation in drug abuse treatment.

Participants were admitted to a secure research unit the evening before Day 1, 17.5–21 hours before their first oral THC dose. The unit had 24-hour staffing, ensuring that subjects had no

access to drugs except those provided in the study. Fourteen participants enrolled in the study; 13 completed.

Oral THC Administration

An escalating dose design was utilized. Oral synthetic THC (dronabinol, Marinol®) was administered in 20 mg capsules with increasing frequency (every 4–8 hours) for total daily doses as follows: 40 mg on Day 1; 100 mg on Days 2–4; and 120 mg on Days 5 and 6. All dosing occurred between 06:00 and 24:00, except for a 02:00 dose on Day 3. The first dose was administered on Day 1 at 15:00, 17.5–21 hours after admission to the research unit. This regimen standardized cannabis tolerance across participants while minimizing adverse events previously reported with 30 mg THC doses.¹⁰

Assessments

Sleep—Participants' sleep characteristics prior to admission to the research unit were assessed with the Johns Hopkins Sleep Center Sleep History Questionnaire (SHQ) (92 six- or seven-point Likert scale items)¹¹ and the Boredom–Eveningness Questionnaire (MEQ) (6 clock time items and 13 four-point Likert scale items)¹² completed within one week of admission. This data provided baseline sleep characteristics prior to THC dosing.

After admission, subjects completed every morning (08:00–10:15) the St. Mary's Hospital Sleep Questionnaire,¹³ a 14-item instrument assessing duration and quality of the previous night's sleep. This questionnaire has previously been employed in outpatient¹⁴ studies of cannabis smokers.

In addition, the subjective feeling of “sedated” was assessed with a 100 mm Visual Analogue Scale (VAS) every night at 20:00 (as part of a larger battery of 11 VAS evaluating symptoms of cannabis intoxication and withdrawal).⁹ The VAS was anchored at the left with “not at all” and at the right with “most ever.” The VAS score was the number of mm the participant marked to the right of the left anchor point.

Pharmacokinetics—Peripheral blood was collected periodically through an indwelling venous catheter for quantification of THC and its pharmacologically active metabolite 11-hydroxy-THC (11-OH-THC). Specimens were collected in heparinized tubes, stored on ice no more than 2 hours prior to centrifugation, and separated plasma stored refrigerated at 4°C until analysis by two-dimensional gas chromatography mass spectrometry with cryofocusing (2D-GCMS),¹⁵ with a limit of quantification of 0.25 ng/ml for THC and 0.5 ng/ml for 11-OH-THC. Specimens were collected the evening of admission and thrice daily (08:00 or 10:00, 20:00 or 20:30, and 22:00 or 22:30) on Days 1–8. Plasma cannabinoid concentrations in six of these participants were previously reported.¹⁶

Statistical Methods

Comparisons between variables employed *t* tests. Associations between pairs of variables were evaluated with Pearson correlation coefficients. Changes in sleep characteristics over time and the associations between sleep and participant characteristics were evaluated with repeated measures mixed linear regression, which allowed inclusion of data from the three

non-completers. Participant baseline characteristics of age, years of regular cannabis use, and joints smoked per day were used as static covariates; study day, feeling sedated the night before, and plasma cannabinoid concentrations as time-varying covariates. Separate regression models were fit for each sleep variable, using an unstructured covariance structure and random intercept. Regression coefficients are reported as mean \pm SE. A p -value <0.05 was considered statistically significant. All analyses were conducted with SAS version 9.2 (SAS Institute, Cary, NC).

RESULTS

Participants

Fourteen participants enrolled in the larger study⁹: one was discharged prior to receiving any medication because the study was terminated, one withdrew after 1 day of oral THC dosing for personal reasons, two were discharged on the fourth day of dosing (one due to premature ventricular contractions and one due to psychological reactions to THC), and 10 completed 8 days of dosing. All 13 participants (13 male, 10 African American, 2 Caucasian, 1 mixed race, mean \pm SD age 24.6 ± 3.7 years) who received THC are included in this analysis. These participants first smoked cannabis at 14.0 ± 2.4 years of age and began regular (at least weekly) smoking at age 15.6 ± 3.7 years. All but one participant reported at least 1,000 lifetime cannabis uses; eight reported at least 5,000 uses. All participants smoked cannabis joints and/or blunts (cannabis wrapped in tobacco leaves); five also had smoked hashish in the past. Seven participants reported lifetime experience with cannabis tolerance (needing to smoke more to get the same effect); five of these seven also reported experiencing cannabis withdrawal. At the time of study entry, participants averaged 5.5 ± 5.9 (median = 3, range 1–24) joints daily. All participants self-reported cannabis smoking in the 24 hours prior to admission; all had a positive cannabinoid urine test upon admission.

All 13 participants were lifetime cigarette smokers; 9 were daily smokers at the time of study entry, averaging 17.9 ± 18.8 (median = 10, range 2–50) cigarettes daily. The remaining 4 participants abstained from tobacco smoking for 4 and 6 months, and 8 and 10 years prior to admission. All participants were lifetime alcohol drinkers, although two abstained for 1 month prior to study entry. The 11 current drinkers averaged 12.1 ± 10.9 (median = 12, range 0.25–32) standard drinks per week over the 3 months prior to study screening. Two participants reported current oral amphetamines intake, averaging two pills each week. There was no other current illicit drug use.

Pre-admission Sleep Characteristics

Ten participants reported no sleep problems prior to admission. Three reported one sleep problem each: one prolonged sleep latency (1 hour), one disturbed sleep (“tossing and turning”), and one early morning awakening. The majority of participants (10 of 13) reported good to very good sleep quality on the SQI. Four participants reported “almost always” smoking cannabis to help sleep; eight others reported “sometimes” smoking cannabis for this purpose. In contrast, only four participants “rarely” ingested alcohol to help sleep and two “rarely” took sleeping pills. No participant reported ever taking other

medication to help sleep. Quantitative pre-admission sleep characteristics are listed in Table 1.

Internal Validity of St. Mary's Hospital Sleep Questionnaire Data

In-bed time was earlier than fall-asleep time for all participants on all days. Get-out-of-bed time was later than wake-up time on all except two questionnaires. Calculated hours of nighttime sleep (time woke up \pm time fell asleep) did not differ significantly from self-reported duration of sleep: mean difference $.03 \pm .6$ hours ($t = .5$, $p = .61$), median and modal values both zero. Similarly, calculated sleep latency (time fell asleep – time got into bed) did not differ significantly from self-reported how long to fall asleep: mean difference $.063 \pm .33$ hours ($t = 1.9$, $p = .06$), median and modal values both zero.

Conceptually related sleep variables were significantly associated in the expected directions. Difficulty falling asleep was positively associated with sleep latency, that is, participants reporting greater difficulty falling asleep also reported longer duration of time to fall asleep ($.52 \pm .13$, $p = .0002$). Duration of nighttime sleep was positively associated with both depth of sleep ($.22 \pm .085$, $p = .012$) and quality of sleep ($.39 \pm .090$, $p < .0001$). Number of nighttime awakenings was negatively associated with both depth of sleep ($-.49 \pm .12$, $p < .0001$) and quality of sleep ($-.71 \pm .12$, $p < .0001$).

First Night Sleep Characteristics

Participants spent a mean (\pm SD) of 7.1 ± 1.3 hours in bed and 5.9 ± 1.3 hours asleep their first night on the research unit, prior to receiving any oral THC. Their sleep latency was 1.0 ± 0.7 hours and they reported 1.6 ± 1.9 nighttime awakenings. Almost one-third (30.8%) reported little or no difficulty falling asleep (23.1% reported a lot or extreme difficulty), less than one-quarter (23.1%) reported less than average depth of sleep, 84.6% reported good sleep quality, and a majority (61.6%) reported being completely alert (less than a third [30.8%] reported any drowsiness) the next morning (ie, morning of Day 1).

First night sleep characteristics (assessed by the St. Mary's Hospital Sleep Questionnaire) were not generally similar to participant's self-reported typical pre-admission sleep characteristics (assessed by the SQI). Correlations between first night and typical pre-admission hours in bed, sleep duration, sleep quality, and next morning alertness were generally low and not significant ($-.17$, $p = .57$; $.27$, $p = .37$; $-.17$, $p = .59$; and $-.52$, $p = .07$, respectively). In particular, hours in bed and sleep duration were shorter on Day 1 than pre-admission, while ratings of sleep quality were higher (Table 1).

Changes in Sleep Characteristics with Oral THC Dosing

The first THC doses, administered the afternoon of Day 1 (20 mg each at 15:00 and 20:00), after at least 17.5 hours of abstinence, had no acute effect on sleep parameters compared to the first night on the research unit, before THC administration (ie, comparing Day 2 vs. Day 1 values, Table 1). There were small but statistically significant decreases in both calculated hours asleep (mean 3.54 fewer minutes per night; $-.059 \pm .026$, $p = .025$) and self-reported hours of nighttime sleep (mean 5.34 fewer minutes per night; $-.089 \pm .031$, $p = .005$) over

the 7 nights of the study. None of the other eight sleep variables showed any significant change over the 7 days of oral THC dosing (Table 1).

Association of Sleep Characteristics with Plasma Cannabinoid Concentrations and Subject Baseline Characteristics

Higher evening plasma concentrations of THC, its active metabolite 11-OH-THC, and THC + 11-OH-THC, were significantly associated with shorter sleep latency ($-.0091 \pm .0045$, $p = .046$; $-.022 \pm .0091$, $p = .015$; and $-.0069 \pm .0031$, $p = .028$, respectively) and lower self-rated difficulty falling asleep ($-.015 \pm .0064$, $p = .023$; $-.028 \pm .013$, $p = .035$; and $-.010 \pm .0044$, $p = .023$, respectively). Evening plasma concentrations of THC and THC + 11-OH-THC also predicted more hours of daytime sleep the following day ($.019 \pm .0075$, $p = .011$; and $.013 \pm .0052$, $p = .017$, respectively). There were no other significant bivariate associations.

Duration of regular cannabis smoking was positively associated with hours spent in bed and morning alertness upon waking. For every additional year that a participant had used cannabis regularly, they spent .08 hours longer in bed ($.081 \pm .040$, $p = .046$) and reported .35 units greater morning alertness ($.35 \pm .17$, $p = .043$). African American participants were associated with fewer hours of daytime sleep ($-1.55 \pm .24$, $p < .0001$). Intensity of self-reported sedation in the evening was positively associated with number of awakenings that night ($.029 \pm .012$, $p = .014$).

DISCUSSION

This study showed the feasibility of assessing sleep characteristics in adult chronic daily cannabis smokers exposed to around-the-clock dosing with oral THC for 7 days on a secure residential research unit. The study found no acute effect of THC on sleep characteristics the second night on the research unit (after at least 17.5 hours of abstinence). This finding is consistent with previous single-dose human laboratory studies with 1.5–30 mg THC,^{4,5,17} but not with animal studies² or clinical reports of somnolence associated with oral THC (dronabinol) use. It is possible that any sleep-promoting effect of the initial oral THC doses (40 mg) was counteracted, and thereby masked, in our study (and in prior human laboratory studies) by the sleep disturbance engendered by admission to an unfamiliar environment (the research unit).¹⁸ Such a novelty-induced transient insomnia would also explain the dissimilarity between participants' self-reported typical pre-admission sleep characteristics and their sleep characteristics on the first night on the research unit. This issue could be addressed in future studies by administering THC only after subjects had spent sufficient time in the research environment to ensure complete adaptation.

Around-the-clock THC dosing was associated with a small (about 5 minutes per night) but statistically significant decrease in overall hours of nighttime sleep during the 7 dosing days. This suggests the possible development of tolerance to any somnolent effect of THC. However, higher evening plasma concentrations of both THC and its active metabolite 11-OH-THC were associated with shorter sleep latency and less self-rated difficulty falling asleep that night, and THC alone and in combination with 11-OH-THC was associated with more hours of daytime sleep the following day, suggesting that cannabinoids maintained

some of their sleep-promoting properties throughout the study. This is consistent with participants' reported pre-admission intake of cannabis as a sleep aid. The mechanisms contributing to the balance between the acute somnolent effect of cannabinoids and development of tolerance to this effect with around-the-clock dosing for 7 days remain unclear. A modest worsening of sleep characteristics with chronic oral THC dosing may not have been detected in prior human laboratory studies because of small sample sizes. We are aware of three such studies administering oral THC for at least 6 days: one had two subjects,⁶ one three,⁴ and one seven subjects.⁸

The findings of this study should be considered preliminary because of design limitations. First, all data was collected by participant self-report, rather than staff observation or polysomnography. However, the major data collection instrument employed, the St. Mary's Hospital Sleep Questionnaire, is widely utilized in clinical research,¹⁹ and has been used in studies of cannabis smokers.¹⁴ Furthermore, the high degree of consistency on several internal validity checks suggests that participants were providing valid data. Even if there were some inaccuracies in the sleep data, one would have to assume a varying bias over time to completely invalidate the within-subject findings of this study. Second, there was no THC placebo group. Thus, it remains possible that stronger than observed somnolent effects of higher evening plasma cannabinoid concentrations were masked by other non-pharmacological factors in the research setting. Third, THC dosing began while participants were likely in early acute cannabis withdrawal and data collection began the first night on the research unit. Thus, the observed findings could have been influenced by both cannabis withdrawal and acclimation to sleeping in a new environment.

CONCLUSIONS

This study, with a sample size almost double that of previously published human laboratory studies, observed only modest sleep-enhancing effects of around-the-clock dosing with oral THC (40–120 mg daily) for 7 days in 13 male daily cannabis smokers. The effects of such THC dosing on sleep were limited to shorter sleep latency and less difficulty falling asleep associated with higher evening plasma cannabinoid concentrations. The overall amount of nighttime sleep decreased slightly during the study, suggesting that tolerance to the somnolent effects of THC may have occurred. These findings are largely inconsistent with reports of somnolent side-effects with clinical oral THC therapy, but should be considered preliminary because of design limitations. Larger studies with objective sleep measures (eg, polysomnography) in subjects acclimated to the research environment before exposure to THC are warranted.

Abstract: Cannabis has been widely used as a medicinal agent in Eastern medicine with earliest evidence in ancient Chinese practice dating back to 2700 BC. Over time, the use of medical cannabis has been increasingly adopted by Western medicine and is thus a rapidly emerging field that all pain physicians need to be aware of. Several randomized controlled trials have shown a significant and dose-dependent relationship between neuropathic pain relief and tetrahydrocannabinol – the principal psychoactive component of cannabis. Despite this, barriers exist to use from both the patient perspective (cost, addiction, social stigma, lack of understanding regarding safe administration) and the physician perspective (credibility, criminality, clinical evidence, patient addiction, and policy from the governing medical colleges). This review addresses these barriers and draws attention to key concerns in the Canadian medical system, providing updated treatment approaches to help clinicians work with their patients in achieving adequate pain control, reduced narcotic medication use, and enhanced quality of life. This review also includes case studies demonstrating the use of medical marijuana by patients with neuropathic low-back pain, neuropathic pain in fibromyalgia, and neuropathic pain in multiple sclerosis. While significant preclinical data have demonstrated the potential therapeutic benefits of cannabis for treating pain in osteoarthritis, rheumatoid arthritis, fibromyalgia, and cancer, further studies are needed with randomized controlled trials and larger study populations to identify the specific strains and concentrations that will work best with selected cohorts.

Keywords: randomized controlled trials, tetrahydrocannabinol, addiction, social stigma, fibromyalgia, neuropathic pain

Medical cannabis in history and society

Cannabis sativa (cannabis) has been used therapeutically for almost 5,000 years, beginning in traditional Eastern medicine.¹ Some of the earliest evidence for this is found in the *pen-ts'ao ching*, the world's first pharmacopeia, compiled based on ancient Chinese practices from as early as 2700 BC.¹ It was not until 1841 that medical cannabis was introduced into Western medicine through the work of William O'Shaughnessy, an Irish physician, who encountered “Indian hemp” in Calcutta. By the late 19th century, medical cannabis became widely disseminated in the Americas; cannabis-based extracts, tinctures, cigarettes, and plasters produced by early prominent drug companies^{2,3} were indicated for a wide range of conditions, many of which were related to pain.^{1,4} Even Sir William Osler, the preeminent Canadian internist, wrote in *The Principles and Practice of Medicine* (1892) that “Cannabis Indica is probably the most satisfactory remedy for migraines”. However, the medical use of

cannabis fell from favor in the 1930s and 1940s when fear escalated that recreational use of cannabis may be related to violence, crime, and other socially deviant behaviors. At that time, widespread prohibitive legislation banning the use of cannabis-based medicines occurred across the world.² More recently, the medical use of cannabis has been reintroduced in a number of countries for the treatment of a variety of conditions, including pain.^{5,6}

Indeed, support for medical cannabis appears to be on the rise. Overwhelmingly, patients prescribed medical cannabis for pain-related illnesses report being highly successful with pain reduction as well as with reducing their use of other medications. In a recent large survey of medical cannabis users in Arizona, 77% of fibromyalgia patients, 63% of patients with arthritis, and 51% of patients suffering from neuropathic pain reported experiencing “a lot or almost complete overall pain relief”.⁷ Most patients with these conditions (94% of patients with fibromyalgia, 81% of arthritic patients, and 61% of patients with neuropathy) also found that they were able to lower their use of their other medications such as narcotic opioids.⁷ In fact, 75% of opioid-dependent medical cannabis users reported experiencing “a lot or almost complete overall relief” from opioid dependency.⁷ Studies such as this shed light onto the wide range of clinical uses of medical cannabis, making it highly useful, since evidence from controlled clinical trials is still emerging.

Studies examining the characteristics of medical cannabis patients in the US have revealed that the majority medicate daily⁷⁻⁹ and consume 6–9 g of cannabis per week.⁸ In Canada, 42% of medical cannabis patients reported medicating two to three times per day, and 40% consume >14 g per week.¹⁰ In both Canada and the US, most patients choose inhalation as their preferred method of consumption.^{7,10}

In addition to patients with access to prescribed medical cannabis, there is also a huge population of users who consume cannabis recreationally or for self-defined medical reasons. Cannabis is the most commonly used illicit drug in the world,¹¹ with 7% of adults in the US reporting use within the last 30 days and 34% reporting having used in 2015.¹² Interestingly, only 53% of adult cannabis users in the US consume cannabis exclusively for recreational purposes, while the other 47% of users consume cannabis “in part or entirely for medicinal purposes”, with 10% using solely for medicinal purposes.¹² In Canada, ~4% of residents over the age of 14 reported at least one instance of past-year cannabis use to treat self-defined medical conditions in 2004.^{13,14}

Cannabis and pain: mechanistic considerations

The cannabis plant contains many biologically active chemicals, including ~60 cannabinoids.¹⁵ The cannabinoids are a group of molecules that bind to cannabinoid receptors and include three varieties: phytocannabinoids, which are derived from cannabis plants; synthetic cannabinoids (such as nabilone [Cesamet] – a synthetic analog of Δ^9 -tetrahydrocannabinol [THC] with a high bioavailability [$\geq 60\%$]¹⁶⁻¹⁹); and endogenous cannabinoid receptor ligands or endocannabinoids. THC is the primary psychoactive component found within cannabis, and has been shown to have analgesic effects.²⁰ However, increasing evidence has highlighted numerous roles for other phytocannabinoids, particularly cannabidiol (CBD), a non-psychoactive component with anti-inflammatory,²¹ analgesic,^{22,23} and antipsychotic^{24,25} properties. THC and CBD (Figure 1) are biosynthesized as delta-9-tetrahydrocannabinolic acid and cannabidiolic acid, respectively, from a common precursor,²⁶ and require decarboxylation by heat or extraction to produce THC and CBD properties.²⁷ Other phytocannabinoids with potential therapeutic applications include cannabigerol, cannabichromene, cannabinol, cannabidivarin, and tetrahydrocannabivarin.²⁸

THC mimics the action of the endogenous cannabinoid receptor ligands anandamide and 2-arachidonylglycerol.²⁹ Both THC and anandamide are partial agonists of CB1 receptors,^{27,29} which are primarily expressed in the central nervous system, especially in areas associated with pain, including the spinal trigeminal nucleus, amygdala, basal ganglia,³⁰ and the periaqueductal gray.^{31,32} At the cellular level, centrally expressed CB1 receptors are localized on the terminals of presynaptic neurons.³³ The endocannabinoids that bind these receptors act as retrograde signaling molecules; that is, they are synthesized postsynaptically and travel backward across the synapse to inhibit presynaptic neurotransmission.³⁴ It is believed that, within regions associated with nociception, THC induces analgesia by binding presynaptic CB1 receptors, inhibiting neurons activated by pain in these areas.

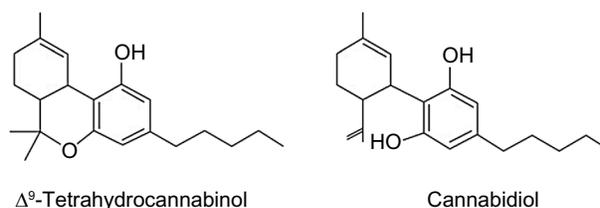

Figure 1 Diagram showing the chemical structure of Δ^9 -tetrahydrocannabinol and cannabidiol.

CBD has intrinsic analgesic and anti-inflammatory properties of its own^{22,23,35} and antagonizes several adverse effects of THC, including sedation,^{27,36} tachycardia,^{27,37} and anxiety.³⁸ CBD also ameliorates the psychoactive effects of THC,³⁸ a concern for many medical cannabis patients. Unlike THC, CBD has low affinity for CB1 receptors³⁹ and exerts analgesic actions by binding multiple proteins related to pain. For example, CBD has been shown to bind TRPV1 and mediate its desensitization³⁹ and to inhibit inactivation of anandamide,³⁹ both of which contribute to its analgesic actions. CBD also has potent anti-inflammatory properties,²¹ and may reduce pain by indirectly limiting inflammation at the site of injury.

Cannabis and pain: clinical evidence

Although significant preclinical data have highlighted the potential therapeutic benefits of smoked cannabis for pain relief in patients suffering from osteoarthritis, rheumatoid arthritis, fibromyalgia, and cancer, no randomized controlled trials (RCTs) have been carried out for these conditions.⁴⁰ However, several RCTs have evaluated the analgesic efficacy of cannabis for patients with neuropathic pain.^{41–46} In a recent meta-analysis, the individual participant data from five of these studies were synthesized to determine the overall effect of inhaled cannabis on chronic neuropathic pain.⁴⁷ All studies included in the meta-analysis compared the analgesic efficacy of cannabis with THC content ranging from 3.5% to 9.4% against that of placebo, and had periods of follow-up ranging from days to weeks.

The proportion of patients who participated in the five RCTs with a >30% improvement in chronic pain score following cannabis therapy was determined, and these patients were classified as “responders”, effectively creating a useful dichotomy for comparing response data between interventions. The meta-analysis concluded that inhaled cannabis results in a number needed to treat value to reduce chronic pain by >30% of 5.6. This needed to treat value rivals that of currently available therapeutics for chronic neuropathic pain,⁴⁸ which is typically well above 8.^{47,49–51} The authors also found that the analgesia provided by cannabis was dose-dependent, with higher THC content producing more pronounced pain relief. This finding provides additional support for the notion that cannabis is an effective analgesic for chronic neuropathic pain.

Cannabis and cancer

Medical cannabis is also used for some cancer patients to relieve symptoms including nausea and vomiting (often caused by some cancer treatments such as chemotherapy

and radiation therapy), loss of appetite, and pain. However, more research is required to identify strains and dose of medical cannabis that provide the optimal symptom relief with minimal side effects for this population.⁵²

Pharmacokinetics

To date, most pharmacokinetic studies of cannabinoids have focused on the bioavailability of inhaled THC, which varies substantially in the literature, likely due to differences in factors such as breath-hold length, source of cannabis material, and method of inhalation.^{53,54} In general, 25%–27% of the available THC becomes available for the systemic circulation after smoking.^{55,56}

The latency of effect onset for inhaled cannabis is shorter than that for cannabis consumed orally, requiring only minutes from the time of consumption to see observable changes, compared to hours when taken by the oral route.^{57–59} Furthermore, cannabis taken orally results in lower peak THC levels in the blood, but effects are observed for a longer period of time.⁵³

Hepatic cytochrome p450 enzymes govern cannabinoid bioavailability. THC is metabolized primarily by CYP 2C9, 2C19, and 3A4,⁵³ and drugs that inhibit these enzymes, including proton pump inhibitors, HIV protease inhibitors, macrolides, anti-mycotics, calcium antagonists, and some antidepressants, can increase the bioavailability of THC.^{60–62} Conversely, drugs that potentiate hepatic enzymes responsible for metabolism of THC will lower its bioavailability. Examples include phenobarbital, phenytoin, troglitazone, and St John’s wort.^{60,62}

Common concerns regarding cannabis

Patients

When it comes to patient concerns, an acronym to remember is HASH.

“High” feeling

Contrary to common misconceptions about patients seeking access to medical cannabis, many patients prefer to avoid “feeling high”. This can be mitigated fairly easily through prescribing practice, since the psychoactive effects of cannabis are primarily associated with high-THC strains. Strains of cannabis containing high levels of CBD generally make patients feel less high, since CBD acts as an antagonist to the psychoactive effect of THC.³⁸ A number of high-CBD, low-THC strains are available for patients concerned about feelings of highness and euphoria.

Acquisition cost

Medical cannabis is not typically covered by insurance plans in Canada. This can cause a significant concern for chronic pain patients who are often disabled, retired, or unable to work.⁶³ Fortunately, special pricing is available through some licensed producers for individuals receiving federal and provincial financial assistance. Examples of financial assistance for medical cannabis pricing include the Canadian Pension Plan-Disability, the War Veterans allowance, and the Ontario Disability Support Program. The price of medical cannabis is not currently regulated in Canada. The price is set by the Health Canada-authorized licensed producers and generally ranges from \$5 to \$15 per gram.⁶⁴ Generally, higher THC content is associated with a higher price per gram.

Social stigma

Many chronic pain patients considering medical cannabis anticipate disapproval from their friends and family. It is not uncommon for patients to avoid disclosing their medical cannabis use to their loved ones altogether, despite experiencing significant improvements in their pain management and quality of life. These concerns are rooted in societal stigmatization of cannabis and can often be mitigated by enabling patients to medicalize their approach to disclosure. By explaining to friends and family that cannabis has been prescribed to them as a medicine which is used to treat a variety of conditions, patients may avoid some of the stigmatization associated with use of medical cannabis. Empowering patients with evidence-based knowledge will significantly facilitate this process.

How to? Lack of understanding of route of administration

Many chronic pain patients have limited or no experience using cannabis. Certainly, some degree of education is required for inexperienced patients to become aware of their options for routes of administration and to understand how to exercise each method. This includes instructions for purchasing, grinding/milling, weighing, vaporization, joint rolling, and derivative making. Clinicians are not commonly familiar with these processes as it is not included in the current medical curriculums. However, it would be valuable for clinicians to gain knowledge in these matters to help answer patient questions and inform their prescribing practices. This education can be provided to clinicians in the future through Continuing Medical Education hours. Currently, this education is offered to patients by some licensed producers. Furthermore, clinics may have educators (ie, nurse educators and other scientifically trained staff) to educate patients on

these matters. Newly prescribed patients should also be made aware of practical and legal limitations, including barriers to traveling with the medication.

Physicians

Credibility–criminality–clinical evidence

In 2014, upward of 1,500 studies were published on cannabinoids. Knowledge is rapidly expanding and has led to a change in attitudes toward medical cannabis. A popular example of this change was the apology by Dr Sanjay Gupta in 2009 for not better appreciating cannabis as a potential therapeutic drug.⁶⁵ As we move toward greater acceptance of the medicinal benefits of cannabis, increasingly, there is a need for the establishment of evidence-based guidelines to assist clinicians in their prescribing practices in order to optimize patient care and quality of life.

Relatedly, some regional differences in the accessibility of medical cannabis have been reported.⁶⁶ Accessing medical cannabis from a friend or acquaintance was more common in the Prairies and Maritimes compared to British Columbia and Ontario,⁶⁶ suggesting reduced accessibility to authorized sources of medical cannabis in the Prairies and Maritimes. Examination of patient forums suggests that one reason for these regional differences may be a lack of physicians willing to prescribe medical cannabis in these regions. Providing physicians with evidence-based guidelines and training in prescribing practices will likely decrease such barriers to accessibility of medical cannabis.

Patient addiction

It has been shown that one in every eleven individuals (9% of individuals) consuming cannabis will become dependent on the drug.⁶⁷ Unfortunately, this statistic is based on individuals consuming all types of cannabis, irrespective of purpose for consumption (ie, medical or nonmedical) and strain. Regardless, an incidence of dependency of one per eleven is still significantly lower than those of approved pharmaceuticals commonly used for chronic pain management.⁶⁸ Monitoring for cannabis dependency is recommended for all patients.

Canadian medical cannabis regulations

In July 2001, Health Canada granted access to cannabis for medical purposes to Canadians with the support of their physicians under the Marihuana Medical Access Regulations (MMAR).⁶⁹ Under this regulation, patients were given the following options: 1) applying to access Health Canada's supply of dried marihuana under the MMAR, 2) applying for a personal-use production license, and 3) designating someone

to cultivate on their behalf with a designated-person production license. The Medical Marijuana Access program was replaced by the Marijuana for Medical Purposes Regulations (MMPR) in April 2014.⁷⁰ Following this change, production of legal medical marijuana is authorized to licensed producers. A list of the Health Canada-authorized licensed producers can be found on Health Canada's website.⁷¹ A foreign corporation could operate as a licensed producer in Canada if the "corporation that has its head office in Canada or operates a branch office in Canada and whose officers and directors are all adults".⁷²

With the introduction of the MMPR in Canada, physicians are advised to follow the guidance set forth by their provincial college. The aim of the MMPR is to treat medical cannabis like other narcotics used for medicinal purposes whenever possible. Under the MMPR, the patient must consult with a medical doctor or a qualified nurse practitioner. A signed "medical document" is submitted to a Health Canada-approved licensed commercial producer of marijuana, granting the patient access to the program. These medical documents are treated similarly to prescriptions. They must meet specific requirements, including patient name, date of birth, physician information, including license number and signature, a daily allotment in grams, and a length of time for the access not exceeding 1 year. A physician may also indicate specific strains and/or an amount of THC allowed to the patient. While there is no legal requirement for licensed producers to follow strain and THC recommendations, many will abide by the request of the physician. Dispensaries and compassion clubs are not permitted under MMPR, so appropriate steps should be taken to ensure a patient is only being referred to Health Canada-approved organizations. Once the patients purchase the medication from the company, it is shipped to their home, or that of their caretaker. Alternatively, arrangements may be made for the licensed producer to transfer the drug to the health care prescriber, from which it can then be obtained by the patients. It should be noted that Health Canada neither approves nor regulates medical cannabis like it does pharmaceutical drugs. Thus, the medical document issued by physicians for medical cannabis is distinct from, and only partially analogous to, a prescription. Instead, the medical document can be viewed as a recommendation to the medical cannabis program. In Quebec, a distinction is made that physicians should not provide such a document unless it is part of a recognized research project and only for specified conditions. Other provincial colleges will have their own requirements. A recent decision by the Supreme Court of Canada has overturned the original requirements

for licensed producers and patients to only sell and consume dried cannabis. This decision allows the sale of fresh, dried, and oil forms of cannabis to patients. Though, as of writing, no licensed producer has yet to be granted permission to sell fresh and oil alternative forms to patients.

Prescribing considerations

As mentioned, prescription and recommendation of medical cannabis at this point is largely nonspecific. Patients are recommended to the medical cannabis program but not necessarily a specific strain. Increasingly, an understanding of how specific strains of medical cannabis can offer benefit for specific ailments is appreciated by those recommending the use of medical cannabis. Unfortunately, the body of evidence supporting these practices is limited, due to an overall lack of investigation, which prevents physicians from making informed decisions to best improve the risk–benefit relationship of medical cannabis in their patients.

Many colleges recommend that Canadian physicians treat medical cannabis as they would any other prescribed narcotic drug. This often includes the use of patient–physician agreements on appropriate use and informed consent of the new medication. Physicians should also consider other following factors when recommending medical cannabis to their patients.

Amount

MMPR requires the recommending physician allot a set amount of cannabis to which a patient will have access on a daily basis. Medical cannabis programs report average patient use of between 0.68 and 1.5 g per day.^{40,73} As a physician increases the amount of medical cannabis a patient is allowed access to, so too does the risk for diversion. However, patients report using up to 10 g of cannabis per day for self-medication purposes. Both the amount the patients currently use for self-identified medical reasons and their preferred route of administration should be taken into consideration when recommending an amount of medical cannabis.

Strain selection and recommendation

Given that evidence supporting the use of specific medical cannabis strains for various pain ailments is lacking, recommending a strain type to a patient can be difficult. The decision is often determined by a number of factors, including financial concerns, potential risk to the patient, and specific goals of the patient (such as to improve sleep or to avoid feeling high). Typically, recommendations are made based on medical history, cannabis use history, and

financial barriers. Once all of these factors have been considered, a strain is selected by the clinician from a range of varieties recommended for medical use by Health Canada from authorized licensed producers. Each licensed producer produces different strains suitable for various medical purposes. Using the principles of “start low, go slow” titration, individuals with little or no experience, histories of bipolar disorder, strong familial schizophrenia, and/or a history of substance abuse begin their process with medical cannabis on a CBD-dominant strain. Patients with a history of cannabis use and no significant risk factors are initially prescribed a strain with higher THC content and maximal CBD content. If patients fail to get relief from their initial strains, an increase in the THC content is recommended in a stepwise fashion, as long as serious risk factors are not present. If risk factors are present, the risk–benefit analysis for this patient must be readdressed. Many colleges recommend indicating an amount of THC a patient would be permitted to access with a licensed producer. Unfortunately, the current regulatory environment in Canada does not require a licensed producer adhere to the recommendation. Likewise, there is rarely any guidance on prescribing strains with CBD content.

Route of administration

Many patients have concerns about medical cannabis smoke, which contains many of the same carcinogenic chemicals as tobacco smoke.⁷⁴ Ultimately, the optimal route of administration to be recommended will depend largely on the desires and capabilities of the patient.

Inhalation by vaporization is the most effective route at delivering the medicinal cannabinoid content of medical cannabis,⁷⁵ and both dried and extracted medical cannabis can be used in a vaporizer. Sometimes, vaporization can be burdensome for patients. Indeed, loading a vaporizer requires some degree of dexterity, which may be limited in certain populations of pain patients, such as those with rheumatoid arthritis and osteoarthritis. Patients may also complain of the temperature of vapor created by vaporization. Many patients require fairly extensive education regarding the use of a vaporizer.

Oral ingestion of medical cannabis typically refers to consumption of cannabis oils or edibles. These are generally produced by infusing a lipophilic substance, like an oil or butter, with cannabis, which is then used in drops or in food. Indeed, a number of recipes have become available online for the use of cannabis oil and butter in food, though some patients dislike the strong flavor. For patients with respira-

tory illnesses, the oral route is preferable. This method is limited, however, by lower absorption and bioavailability than for inhaled cannabis. Another potential concern is a lack of research on the effectiveness and safety of orally consumed cannabis for pain conditions. Given the increased latency of effect onset from orally consumed medical cannabis, patients should be cautioned to wait an adequate amount of time to feel the effects of the cannabis before readministering. While issues of dosing and effectiveness exist for orally administered cannabis, it is typically well tolerated by patients.

Sublingual tinctures are another, less common, route of administration for medical cannabis. Typically, these tinctures are extracted with ethanol, but vinegars and glycerine may also be used. The extracts are dropped under the tongue and held for a period of time sufficient to permit absorption by the branches of the lingual artery, including the sublingual and deep lingual arteries. If used properly, onset of action and bioavailability may be faster and higher for this route compared with oral administration, as is often observed with other drugs.⁷⁶ Tinctures may be a favorable option in the future, as they mitigate the dosing and bioavailability issues associated with orally ingested cannabis and eliminate issues of tolerability with inhaled cannabis. However, the use of tinctures is not widespread today, and evidence supporting the therapeutic use of tinctures is limited. Moreover, patients often complain of the taste. In Canada, there is currently a sublingual cannabinoid pharmaceutical known as Sativex. This is approved for multiple sclerosis (MS)-related neuropathic pain or spasticity and for cancer-related pain. A case series has also been published on its effectiveness for fibromyalgia.⁷⁷

Alternative routes of administration include transdermal ointments and balms, ophthalmic drops, and rectal suppositories. While rarely used, all of these routes may have therapeutic potential for patients, though little research has been done to assess this likelihood.

Follow-up frequency

When introducing a patient to medical cannabis for the first time, it is important to schedule frequent follow-ups until a strain has been selected that meets the treatment goals of both patient and physician. Since this process may require changes such as route of administration, an active follow-up schedule may be required to provide the patient with adequate knowledge to continue safely and confidently. Once a patient has been stabilized, follow-up visits should focus on monitoring for adverse reactions, including dependence.

In Canada, the medical document that is produced to allow a patient access to cannabis acts as a license. Thus, if the patients' medical document expires while they are in possession of medical cannabis, they may be open to criminal charges. The timing of a patient's follow-ups is an important nonmedical issue as well.

Contraindications

Several contraindications have been identified for medical cannabis recommendations. Due in part to the illicit nature of cannabis, research is lacking and there is a significant knowledge gap in this area, and medical cannabis recommendations should always be made with careful consideration of the current health status of the patient.

Psychosis

As previously mentioned, individuals suffering from, or at a high risk of developing, schizophrenia or other psychotic illnesses should only be recommended the use of cannabis under well-monitored conditions. The use of strains with minimal or no THC content is recommended.

Bipolar disorder

Recently, Kim et al found that cannabis use was significantly associated with lower rates of remission of bipolar spectrum patients over a 2-year follow-up period.⁷⁸ Studies have also found an association between cannabis misuse and earlier onset of bipolar disorder.⁷⁹ Thus, the use of low-THC content strains is recommended for these patients.

Cannabis allergies

It is estimated that *C. sativa* allergies are found in 8% of the general population, although the incidence may be higher among individuals who identify as users of cannabis.⁸⁰ Avoidance is recommended for patients with cannabis allergies to avoid potentially lethal anaphylaxis. However, mild rhinoconjunctivitis symptoms can be treated with antihistamines, intranasal steroids, and nasal decongestants.⁸¹ Immunotherapy has been used to treat cannabis allergies,^{82,83} but this is not common practice.

Adverse effects

Findings from the currently available research suggest that the safety profile of the short-term use of medical cannabis is acceptable.⁸⁴ A systematic review of 23 RCTs and eight observational studies of medical cannabis found that 96.6% of the adverse effects reported in the trials were not serious. The most commonly reported adverse effect was dizziness

(15.5%). Rates of serious adverse effects did not vary between the group of participants assigned to medical cannabis and controls.⁸⁴ Other commonly reported adverse effects are drowsiness, feeling faint or light headed, fatigue, headache, impaired memory, and disturbances in attention, concentration, and ability to think and make decisions.⁸⁵ However, further research on the long-term safety profile of medical cannabis use is required.^{86,87}

Case studies

Neuropathic low-back pain

A 49-year-old, single male patient reporting chronic lower back pain due to diagnoses of spinal stenosis, degenerative disc disease, and neuropathic pain including sciatica for over 20 years presented at our clinic. In-clinic recorded pain score for the patient was 9/10 on a numerical rating scale. Positive DN4 (>4/10) and Freynhagen Pain Detect Questionnaire (>19/35) scores were recorded. The patient also had diagnoses of gastroesophageal reflux disease, irritable bowel syndrome, and anxiety. At the time of meeting, the patient was using nabilone 0.25 mg daily, pregabalin 300 mg daily, ibuprofen 400–600 mg daily, omeprazole 40 mg daily, baclofen 20 mg daily, and clonazepam 0.5 mg daily. After several unsuccessful attempts at pain control using physiotherapy, chiropractic, osteopathy, acupuncture, corticosteroid injections, oxycodone, and Percocet, the patient confided he turned to illicit cannabis for pain relief on a daily basis, primarily in the evening after work.

The patient was prescribed 1 g per day of a cannabis strain containing 9% THC and 13% CBD to be administered by a vaporizer. At 60 days of follow-up, the patient's pain was lowered to a weekly average of 3/10 on a numerical rating scale. The patient also indicated he did not see a need for pregabalin, and had begun the process of lowering his daily dose. Surprisingly, the patient also reported far fewer symptoms of his irritable bowel syndrome, claiming near-remission.

Fibromyalgia – widespread neuropathic pain

A 57-year-old, married male patient reporting fibromyalgia for 5 years, and osteoarthritis, torn shoulder tendon, and spinal stenosis for over 20 years was referred to our clinic. His initial in-clinic recorded pain score was 8/10 on a numerical rating scale. The patient also had a history of severe obesity, sleep apnea, restless legs syndrome, and anxiety. Signs of neuropathic pain included widespread allodynia and positive DN4 score. At the time of meeting, the patient was taking several prescribed pain medications, including Percocet 5/325 mg as needed and Oxyneo 40 mg daily. Physiotherapy,

corticosteroid injections, codeine, and a number of anti-inflammatory medications were unsuccessful at achieving adequate analgesia. The patient was inexperienced with cannabis, except for intermittent use on weekends.

The patient was prescribed 1.5 g per day of a strain of cannabis containing 5% THC and 8% CBD to be administered by a vaporizer. After 2 weeks of trial, the patient reported a lack of success, and a strain of 12% THC was added to the other strain, with instructions to mix the strains in equal parts. At 60 days of follow-up, the patient's pain was lowered to a weekly average of 3/10 on a numerical rating scale, and he lowered his use of Percocet from four pills per day to three pills per week, on average.

MS-related neuropathic pain

A 67-year-old, single female patient reporting neuropathic pain secondary to MS diagnosis of over 20 years was referred to our clinic by her pain intervention physician. In-clinic pain score was recorded at 9/10 on a numeric rating scale. The patient was actively taking gabapentin 2,200 mg daily and celecoxib 200 mg daily. The patient could not tolerate the use of opiate medications, claiming dissatisfaction with their sedative effects. Failed pain interventions included IV lidocaine and lumbar radiofrequency ablation. The patient was naïve to cannabis.

The patient was prescribed 1 g per day of cannabis containing 2.5% THC and 5% CBD to be administered by a vaporizer. After failing to achieve adequate analgesia, a strain of 9% THC and 13% CBD was recommended to the patient. At 60 days of follow-up, the patient's pain subsided to a moderate 5/10 on a numeric rating scale, and she is planning to lower the dose of her other medications.

Conclusion

This review documents some of the relevant history and current research literature on medical cannabis. It draws attention to the key concerns in the Canadian medical system and provides updated treatment approaches to help clinicians work with their patients in achieving adequate pain control, reduced narcotic and other medication use (and their adverse effects), and enhanced quality of life. RCTs using large population samples are needed in order to identify the specific strains and concentrations that will work best with selected cohorts. Cannabis-based medicine is a rapidly emerging field of which all pain physicians need to be aware.

Journal of Pain Research

Publish your work in this journal

The Journal of Pain Research is an international, peer reviewed, open access, online journal that welcomes laboratory and clinical findings in the fields of pain research and the prevention and management of pain. Original research, reviews, symposium reports, hypothesis formation and commentaries are all considered for publication.

Submit your manuscript here: <https://www.dovepress.com/journal-of-pain-research-journal>

Dovepress

The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Effect of Δ -9-Tetrahydrocannabinol and Cannabidiol on Nocturnal Sleep and Early-Morning Behavior in Young Adults

Anthony N. Nicholson, MD, PhD,* Claire Turner, BSc,*
Barbara M. Stone, PhD,* and Philip J. Robson, MD†

Abstract: The effects of cannabis extracts on nocturnal sleep, early-morning performance, memory, and sleepiness were studied in 8 healthy volunteers (4 males, 4 females; 21 to 34 years). The study was double-blind and placebo-controlled with a 4-way crossover design. The 4 treatments were placebo, 15 mg Δ -9-tetrahydrocannabinol (THC), 5 mg THC combined with 5 mg cannabidiol (CBD), and 15 mg THC combined with 15 mg CBD. These were formulated in 50:50 ethanol to propylene glycol and administered using an oromucosal spray during a 30-minute period from 10 PM. The electroencephalogram was recorded during the sleep period (11 PM to 7 AM). Performance, sleep latency, and subjective assessments of sleepiness and mood were measured from 8:30 AM (10 hours after drug administration). There were no effects of 15 mg THC on nocturnal sleep. With the concomitant administration of the drugs (5 mg THC and 5 mg CBD to 15 mg THC and 15 mg CBD), there was a decrease in stage 3 sleep, and with the higher dose combination, wakefulness was increased. The next day, with 15 mg THC, memory was impaired, sleep latency was reduced, and the subjects reported increased sleepiness and changes in mood. With the lower dose combination, reaction time was faster on the digit recall task, and with the higher dose combination, subjects reported increased sleepiness and changes in mood. Fifteen milligrams THC would appear to be sedative, while 15 mg CBD appears to have alerting properties as it increased awake activity during sleep and counteracted the residual sedative activity of 15 mg THC.

is an improvement in sleep quality. This may be due to hypnotic activity in addition to the therapeutic properties of cannabinoids.¹ Indeed, early studies indicated that sleep may be modulated.^{2–8} However, these studies used various modes of administration, involved wide dose ranges, and were carried out in subjects of variable status with respect to their use of such drugs. Furthermore, the experimental designs were not amenable to analyses that could indicate the pharmacologic activity of individual substances. In some studies, extracts were used in which, although Δ -9-tetrahydrocannabinol (THC) could be measured, there were undetermined amounts of cannabidiol (CBD) and cannabinol. Nevertheless, the impression gained from these studies was that certain doses of THC, particularly with repeated ingestion, may reduce rapid eye movement (REM) activity and increase slow-wave sleep.

We have, therefore, investigated the effect on sleep of individual cannabinoids and cannabinoids in combination. The current studies with THC and CBD have been carried out using the doses that are currently under investigation for the relief of pain. The former cannabinoid is believed to be the principal psychoactive extract of cannabis, an effect mediated via cannabinoid (CB)₁ receptors. CBD may be free of such central activity but may have useful therapeutic potential arising from its reported myorelaxant and anticonvulsant properties, in addition to the attenuation of some of the effects of THC, such as euphoria and tachycardia.^{9–12} The mechanism by which CBD exerts these effects is uncertain, as it cannot be completely explained in terms of CB₁ and CB₂ receptor binding. We have studied the effect of THC alone and in combination with CBD on the sleep process and on mood, performance, and sleep latencies during the morning of the day after administration.

METHODS

Protocol

The protocol was approved by the QinetiQ Ethics Committee, and the subjects were under medical supervision

throughout the experiment. Each was provided with detailed information on the activity and potentially adverse effects of the compounds. Subjects were required to give written informed consent in the presence of the principal investigator and were informed that they could withdraw from the experiment at any time. They were warned against driving and operating machinery during the day after each experimental night.

The subjects were required to be between 18 and 35 years and weigh between 50 and 80 kg (female) and 60 and 90 kg (male) with a body mass index not greater than 30. Information on height and race were also recorded. Inclusion in the experiment required the absence of a significant medical history. Subjects were excluded if there was a family history of a schizophrenia-like illness, a personal history of psychiatric or emotional problems, or evidence of insomnia or daytime sleepiness. An intake of >14 U of alcohol per week for females and 21 U for males, smoking >5 cigarettes or equivalent a day, or ingesting >5 beverages containing caffeine a day were also exclusion criteria. A unit of alcohol is defined in the United Kingdom as being equivalent to 7.9 g or 10 mL of pure alcohol (ethanol).

Inclusion in the experiment required the absence of clinically significant findings in the medical examination and in the associated pathology tests. These included a 12-lead electrocardiogram and measurement of blood pressure, heart rate (both supine and erect), and oral temperature. Exclusion criteria included a resting blood pressure exceeding 140 mm Hg systolic or 90 mm Hg diastolic and a resting heart rate <40 per minute. Urine analysis with a drug screen, biochemistry, hematology, and screening for hepatitis B and C were carried out. The medical examination and the pathology tests were repeated at the end of the experiment.

All subjects agreed to use barrier methods of contraception with a spermicide for the duration of the experiment and for 3 months after the completion of the experiment. They agreed that if a hormonal method was being used, it would not be discontinued during the experiment. The initial screening of the subjects included, if appropriate, a urinary pregnancy test, and this was repeated before each treatment night and on completion of the experiment.

During the time between medical screening and the first experimental night, the subjects were instructed in the techniques that would be used to measure performance and memory. Subjects reached a plateau level of performance on all tests before the first experimental night.

Subjects

There were 4 females aged between 21 and 22 (mean 21.8) years and 4 males aged between 24 and 34 (mean 28.8) years. The females weighed between 57.7 and 68.3 (mean 61.3) kg and the males weighed between 70.6 and 78.9 (mean 74.7) kg. All subjects had experienced previously the

effects of cannabis, but it was determined that this was occasional and linked to social events. Furthermore, the subjects reported that they had not used cannabis for at least 30 days before the commencement of the experiment and did not use cannabis during the experiment. This was confirmed by urinary drug screen. Subjects did not have a history of drug, alcohol, tobacco, or caffeine abuse or any history of the use of a social drug other than cannabis. This was confirmed by a urine drug screen that included that for opiates, barbiturates, benzodiazepines, cocaine, and amphetamine. The alcohol intake of the subjects did not exceed 8 U/wk in the females and 20 U/wk in the males. Two subjects were smokers—1 female (3 cigarettes per day) and 1 male (up to 4 cigarettes per day).

Experiment Design

The experiment was double-blind and placebo-controlled with a 4-way crossover design in which the acute effects of two cannabinoids (THC and a combination of THC and CBD) were observed on sleep and behavior the next day. The experiment consisted an adaptation night and 4 experimental nights. At least a week separated each experimental night. Subjects were required to retire at their normal bedtime on the nights preceding and to refrain from napping or exercise during the day before each of these nights and from exercise up to 12 hours after each night. The subjects were taken to the sleep laboratory in a chauffeur-driven car.

The adaptation night was used to familiarize the subjects with the experimental situation and to confirm that the subjects had a normal sleep pattern. As far as the adaptation night was concerned, alcohol and caffeine ingestion were prohibited for 24 hours and smoking from 5 PM before the overnight sleep.

As far as the treatment nights were concerned, alcohol was prohibited for 48 hours before and for 24 hours after drug ingestion. In addition, throughout the experiment, alcohol consumption was restricted on all other days of the week to no more than 3 U/d for males and 2 U/d for females. Caffeine was prohibited for 48 hours before and for 12 hours after, and smoking was prohibited from 5 PM before and for 12 hours after each treatment night. Subjects were also required to avoid spicy foods, Chinese food, bananas, and strong cheese during the evening before the treatment night.

On each treatment night, it was ascertained whether any of the subjects had experienced adverse effects or illnesses since the previous visit. Breath alcohol levels were measured and urine samples collected for drug screening and, if appropriate, for pregnancy testing. Negative results for the alcohol, drug, and pregnancy tests were required for the subjects to continue with the experiment. Treatments were administered during a 30-minute period from 10 PM. The subjects retired to bed at approximately 11 PM (30 minutes

after completion of treatment administration) and remained in bed until approximately 7 AM the next day (8 hours after retiring). Breakfast was provided between 7:15 and 8:15 AM. At approximately 8:30 AM (10 hours after completion of treatment administration), the subjects completed subjective assessments of sleepiness and commenced a battery of performance tasks. They left the laboratory at approximately 10:30 AM in a chauffeur-driven car after a medical practitioner had discharged them.

Treatments

There were 4 treatments: THC (15 mg) and 2 combinations of THC and CBD (5 mg THC with 5 mg CBD; 15 mg THC with 15 mg CBD), together with placebo. The drugs and placebo were prepared for the experiment by GW Pharmaceuticals plc. THC and the THC/CBD combinations were formulated in 50:50 ethanol to propylene glycol and administered by means of a pump action oromucosal spray. Each actuation was 100 μ L. The 15-mg dose of THC, the 2 combinations of THC and CBD, and the placebo were each delivered by 6 actuations during a 30-minute period given at 6-minute intervals from approximately 10 PM. Subjects were trained before the study not to swallow the liquid to maximize drug absorption through the buccal mucosa. This technique of administration has been validated.¹³

Polysomnography

The subjects slept in single, light-proofed, sound-attenuated, and temperature-controlled ($18^{\circ}\text{C} \pm 2^{\circ}\text{C}$) rooms. Silver-silver chloride electrodes were used to record electroencephalograph activity from the O_1 - A_2 and C_4 - A_1 positions, together with bilateral electrooculograms and the submental electromyogram, on to EMBLA 16-channel recorders (Flaga, Iceland). The electrocardiogram and myographic activity from the anterior tibialis muscles were also recorded throughout the night. A simulated paper speed of 10 mm/s was used and the sampling rates for the various measures were as follows: electroencephalograph, 100 Hz; electrooculograms, 100 Hz; electromyogram, 200 Hz, respectively. The records were scored manually from the screen into 30-s epochs upon completion of the experiment by one analyst according to the criteria of Rechtschaffen and Kales.¹⁴ Various measures were derived from the data for subsequent statistical analysis.

Cannabinoid Plasma Levels

A blood sample was obtained at approximately 9 PM as a control for the estimation of cannabinoid plasma levels the next morning. At approximately 8:15 AM (9.75 hours after the last actuation), a blood sample was taken for the measurement of plasma levels of the cannabinoids. Samples were collected in tubes containing lithium heparin and placed immediately into ice and water to chill before being

centrifuged at $1000 \times g$ for 10 minutes at 0°C to 4°C and stored at -20°C within 30 minutes of the sampling time. The serum levels of THC, 11-hydroxy THC (a major active metabolite of THC), and CBD were determined by a high-performance liquid chromatography method. The limit of quantification of the assay was 0.1 ng/mL.

Cardiovascular Measurements

Blood pressure and heart rate were recorded using an Accutorr Plus automatic blood pressure monitor (Datascop, Paramus, NJ) before, during, and after the 30-minute period of drug administration when the subjects were seated. The next morning on waking the subjects (at approximately 7 AM), blood pressure was measured both supine and erect.

Subjective Assessments

Before the administration of the treatments, the subjects rated their level of sleepiness using the 7-point Stanford Sleepiness Scale.¹⁵ Approximately 30 minutes after awakening, the subjects assessed the quality of their sleep and their level of alertness. The extremes of the 100-mm scales were as follows: I slept *very poorly* (0) to *very well* (100); Now I feel *very sleepy* (0) to *wide awake* (100); I fell asleep *never* (0) to *immediately* (100); after I fell asleep, I slept *very badly* (0) to *very well* (100); I wanted to sleep *much more* (0) to *much less* (100). Subjects also estimated the time to sleep onset and the sleep duration. They also rated their level of sleepiness using the Stanford Sleepiness Scale.

Measurement of Next-Day Performance, Memory, and Sleepiness

After each overnight experiment, performance was measured from approximately 8:30 AM the next morning using psychomotor and cognitive tasks, together with assessments of mood, sleepiness, and fatigue, and the electroencephalographic determination of sleep latency. The tasks were presented in the following order (with elapsed time in brackets): mood assessment (0 to 1 minute), Samn-Perelli fatigue rating (1 to 2 minutes), immediate memory word recall (2 to 4 minutes), digit symbol substitution (4 to 8 minutes), 6-letter memory recall (8 to 13 minutes), multiattribute task (MAT) battery and subjective workload ratings (13 to 63 minutes), digit memory recall (63 to 66 minutes), choice reaction time (66 to 68 minutes), sustained attention (68 to 78 minutes), delayed memory word recall (78 to 79 minutes), mood assessment (79 to 80 minutes), Samn-Perelli fatigue rating (80 to 81 minutes), Stanford Sleepiness Scale (81 to 82 minutes), and sleep latency test (82 to 107 minutes).

Digit Symbol Substitution

The subjects were presented with one of a series of 30 different sheets with 200 randomized digits (0 to 9) arranged

in 10 rows on both sides of the sheet.¹⁶ In the space below each digit, they were required to insert the appropriate symbol indicated by a code at the top of the page. They were given 2 minutes for each of the 2 sides of the sheet to complete as many substitutions as possible, and the total for each session was recorded.

Multiattribute Task Battery

The MAT battery has been developed to provide a standardized test for use in laboratory studies of performance and workload.¹⁷ The battery incorporates 4 simulation tasks that aircrew would expect to perform. The MAT battery was displayed on a screen divided into 6 windows, of which 4 were tasks: system monitoring (“dials” and “lights”), tracking, communications, and resource (fuel) management, and 2 provided information about the communications and resource management tasks. Subject responses were made using keys on a standard computer keyboard, and the battery lasted 50 minutes. Response data and reaction times were recorded for all tasks except tracking, for which the root mean error score was recorded.

Choice Reaction Time

An asterisk was displayed in 1 of 4 corners of a monitor screen, and subjects were required to respond by pressing 1 of 4 buttons in the same spatial arrangement as the asterisks on the screen.¹⁸ The task was self-paced with a total of 160 asterisks presented. Response data and reaction times were recorded.

Sustained Attention

A random sequence of letters was presented one at a time on a monitor screen at a rate of 1 each second.¹⁹ Two letters (the critical stimulus) were displayed continuously at the top left-hand corner of the screen. Subjects were required to press a button whenever the letters of the critical stimulus were presented consecutively during the random sequence. Response times and the nature of the responses (correct, missed, and wrong) were recorded.

Immediate and Delayed Word Memory Recall

The immediate word memory recall task presented a list of 16 unrelated words (2-syllable nouns with a frequency of >12 per million in general usage) on a monitor screen at a rate of 1 every 3 seconds. Immediately after the presentations, subjects were given 45 seconds to recall as many of the words as possible. Delayed memory recall was tested 76 minutes later when they were again asked to recall the words within 45 seconds. The number of words recalled and the number of words correctly recalled were recorded.

Six-Letter Memory Recall

Subjects were given 15 s to memorize a set of 6 letters. Then, a series of randomly generated letters was displayed individually on a monitor, and they were required to indicate whether the letter was contained in the memory set by pressing the appropriate button.²⁰ This procedure was repeated a further 9 times, so that a total of ten 6-letter memory sets were presented during this test. Response times and the nature of the responses (correct, missed, and wrong) were recorded during this 5-minute task.

Digit Memory Recall

Series of single-digit numbers (1 to 9) were presented simultaneously above and below a horizontal line on a monitor.²⁰ Subjects were required to memorize the digit below the line, compare it with the digit above the line in the subsequent presentation, and respond by pressing the appropriate button for “same” or “different” number. The 3-minute task was self-paced with a maximum reaction time of 2 seconds per response. Response times and the nature of the responses (correct, missed, and wrong) were recorded.

Subjective Measurements

Mood and well-being were assessed using a series of twelve 100-mm visual analogue scales.²¹ The subjects assessed their level of sleepiness using the Stanford Sleepiness Scale and rated their fatigue level against 10 separate criteria, from which a score in the range 0 (*extremely fatigued*) to 20 (*extremely alert*) was calculated.²¹ Subjects also assessed their level of workload during the MAT battery when the scale was presented on the screen at 10-minute intervals by giving a rating between 1 (*workload insignificant*) and 10 (*task abandoned—unable to apply sufficient effort*).²³

Sleep Latency Test

Subjects were instructed to lie in bed and to try to fall asleep. The electroencephalograph, electrooculograms, and electromyogram were recorded as described previously. The test was ended 20 minutes after “lights out.” Subsequently, one analyst determined the latency to stage 1 (drowsy) sleep for all recordings.

Adverse Events

Adverse events whether considered to be related to the use of the drug were recorded with details of their onset and cessation, severity, and relation to treatment.

Statistical Analysis

The statistical power for the experiment was calculated using the method of Owen.²⁴ Estimates of variance from previous studies^{25,26} were used to calculate the minimum

detectable difference between the 2 drugs for a sample of sleep and psychometric tests and for 1 subjective measurement for 8 subjects with 80% power at the 5% level of significance. The order of drug ingestion was based on a Latin-square design, balanced for carryover effects.

The data were analyzed by analysis of variance as a general test at the 5% significance level. A 1-factor model (treatment) with subjects as a random factor was used for all variables except MAT battery tracking, workload ratings, mood assessment, and the Samn-Perelli fatigue rating. For these variables, a 2-factor model (treatment and "run") was used as these variables were presented at the beginning and the end of the morning test session. Significant effects in the analysis of variance of the factors were examined using Newman-Keuls.²⁷ Planned comparisons were made between the cannabinoids and placebo using Dunnett procedure, which adjusts for multiple comparisons with a control, so that the overall error rate remains at 5%.²⁸ The assumptions of analysis of variance (homogeneity of variance, normality, and additivity) were studied by considering transformations of the raw measures using the maximum likelihood method.²⁹ Each measure was examined for a possible order effect and, if significant, was included as a linear covariate in the analyses of these measures.

A principal component analysis was carried out on the subjective assessments of mood, and 2 major varimax-rotated components were identified for analysis. The first component included measures related to lethargy, inefficiency, an inability to concentrate, dullness, sleepiness, and withdrawal. The second component included measures related to anxiety, agitation, tension, irritability, and aggression.

For the sleep latency data, on those occasions when stage 1 sleep did not occur within the 20 minutes allowed (6 of the 32 sleep latency tests), an iterative extension to a standard analysis of variance procedure was used. This method follows a standard expectation/maximization algorithm for handling data censored beyond 20-minute duration, and it overcomes a downward bias, which would otherwise be created if the value was removed altogether or if it was treated as 20 minutes.³⁰

RESULTS

Sleep, Subjective Measures, Next-Day Performance, Memory, and Sleepiness

The effects of the cannabinoids on nocturnal sleep and early-morning performance, memory, and sleepiness are given in Tables 1–3. Back-transformed means corrected for bias are shown, where appropriate, together with the transformation required.

There was no difference in the subjects' ratings of sleepiness before the administration of the 4 treatments, nor were there any differences in the subjects' assessments of

sleep onset, duration, or quality following the administration of the cannabinoids.

There were no effects of 15 mg THC on sleep. In the case of the latency to rapid eye movement sleep, although the mean data with 15 mg THC appear to be increased, the statistical analysis failed to demonstrate a significant change for the group as a whole due to the variability of the data. The next day, the subjects reported increased sleepiness 30 minutes after rising, and there were decreased latencies to early-morning sleep. The subjects also reported changes in mood. Several aspects of memory were impaired. There was a reduction in the number of words remembered correctly in the immediate and delayed recall tests.

With the concomitant administration of THC and CBD, there was evidence of decreased stage 3 sleep, and at the higher dose combination (15 mg THC with 15 mg CBD), awake time was increased. At the lower dose combination (5 mg THC and 5 mg CBD), there were no changes in mood, sleepiness, fatigue, or performance the next morning. With the higher dose combination (15 mg THC and 15 mg CBD), subjects reported increased sleepiness with fatigue and changes in mood. For both combination doses, there were no changes in performance on the memory tests, except for a reduced reaction time with the lower doses in digit recall.

Blood Pressure

Inspection of the blood pressure and pulse rate recordings did not indicate changes in blood pressure or pulse rate related to the 30-minute period of drug administration. Recordings of these measures in the morning on awakening revealed postural systolic hypotension with 15 mg THC when given alone or in combination with 15 mg CBD. There were compensatory increases in pulse rate, both supine and erect.

Cannabinoid Plasma Levels

The pharmacokinetic data showed that during the evening before drug administration, the mean serum concentrations of THC, 11-hydroxy THC, and CBD were less than the limit of quantification of the assay. The serum levels of the cannabinoids the next morning were related to the dose that had been administered the previous evening. The mean serum concentrations of THC 9.75 hours after the ingestion of 5 and 15 mg THC in combination with CBD and of 15 mg THC when ingested alone were 0.405, 1.348, and 1.170 (with standard deviations of 0.359, 0.739, and 0.700) ng/mL, respectively. Similarly, the concentrations of 11-hydroxy THC 9.75 hours after the ingestion of the 2 dose combinations of THC with CBD and of 15 mg THC alone were 0.714, 2.178, and 1.663 (with standard deviations of 0.762, 1.325, and 1.293) ng/mL, respectively. The serum

concentrations of CBD following the ingestion of 5 and 15 mg CBD in combination with THC were 0.309 and 0.863 (with standard deviations of 0.187 and 0.425) ng/mL. There was no CBD detectable following the administration of THC alone.

Adverse Events

There were no serious adverse events and no adverse events that led to withdrawal of a subject. All 8 subjects reported at least one adverse event. Inspection of reported adverse events showed that the high dose combination of THC and CBD was likely to be associated with symptoms related to the nervous system.

DISCUSSION

It would appear that the cannabinoids, THC and CBD, when given in the doses and in the combinations used in the present study, are unlikely to have adverse clinical effects on sleep. THC would appear to be a sedative compound, whereas CBD would appear to have some alerting properties. The distinct activity of these compounds suggests that they could be complementary in clinical practice. The alerting activity of CBD may be particularly useful in the concomitant administration of THC and CBD when the therapeutic activity of both compounds is sought.

The present analysis did not provide evidence that 15 mg THC altered the sleep process, although inspection of

[‡] $P < 0.05$ compared with 5 mg THC and 5 mg CBD.

[§]The first component of mood included measures related to anxiety, agitation, tension, irritability, and aggression. Negative values indicate greater levels of these variables. The second component of mood included measures related to lethargy, inefficiency, an inability to concentrate, dullness, sleepiness, and withdrawal. Positive values indicate greater levels of these variables.

the data could suggest that in some individuals, the duration of slow-wave sleep may have been increased. However, there was evidence, the next morning, of increased sleepiness and changes in mood and of reduced latencies to early-morning sleep. Increased sleepiness and changes in mood the next day, but not the decreased latencies to early-morning sleep, were also seen when 15 mg THC was given with 15 mg CBD.

Modulation of slow-wave sleep was observed when 5 or 15 mg CBD was ingested with the same doses of THC, as there was a decrease in stage 3 sleep. It would appear possible that

CBD may increase slow-wave activity usually associated with stage 4, as there were no changes in the duration of stage 2 itself or in the combined duration of stage 2 and slow-wave sleep. This could be due to the activity of CBD alone or to its activity in combination with THC. It is also of interest that an increase in awake activity occurred with the ingestion of 15 mg CBD and 15 mg THC, but not with 5 mg CBD and 5 mg THC (or with 15 mg THC alone). This would suggest that CBD may have an alerting effect that is dependent on dose. The analysis did not provide any evidence that CBD reduced total sleep time for the group as a whole, but again, inspection of the data

could suggest that in some individuals, it was curtailed, together with rapid eye movement sleep.

In the present study, assessment of performance detected residual activity of the cannabinoids somewhat more than 10 hours after ingestion. At this time, impaired performance was limited to the effect of 15 mg THC on memory, and this observation is in broad accord with the published literature (reviewed by Ashton³¹) and with the studies of Curran et al.³² In the latter study, episodic memory and verbal learning were impaired only with 15 mg THC and not with 7.5 mg THC. These effects were contained within the 8-hour period after ingestion and were not present 24 hours after ingestion.

Although impaired memory was observed the next day when 15 mg THC was given alone overnight, there were no effects on memory when 15 mg THC was ingested with 15 mg CBD. This could be due to an alerting effect of CBD. Indeed, such an effect would be consistent with increased wakefulness during the night, absence of an effect on early-morning sleep latencies when the higher dose combination was ingested, and reduced reaction time in digit recall with the low dose combination. However, although the activity of 15 mg CBD may have counteracted the effects of 15 mg THC on memory, the subjective impression of sleepiness persisted, as did changes in mood. The possibility that CBD may counteract, at least partially, the activity of THC has been raised in connection with the psychologic effects of THC.¹²

Overall, these observations would suggest that the effects of overnight administration of THC and CBD on the sleep process and early-morning behavior are dependent on dose. This would accord with both the pharmacokinetic data and the recordings of blood pressure and pulse rate. The mean serum concentrations of these cannabinoids and of 11-hydroxy THC (a major active metabolite of THC) are clearly related to the administered dose. Persistent activity of the high dose cannabinoids when given alone or in combination was also evident from postural systolic hypotension with compensatory increases in pulse rate, both supine and erect, observed the next morning.

Clearly, the present studies on cannabis-related compounds have shown that overnight administration leads to dose-related serum concentrations and dose-related effects on the sleep process and early-morning activity. The studies have identified the discrete activities of THC and CBD related to their sedative and alerting properties and have explored the potential of sleep studies to establish dose combinations that are likely to provide the optimum balance of their activity.

It is suggested that combinations of THC and CBD are unlikely to prejudice any improvement in sleep brought about by the effects of these drugs in alleviating pain and other chronic symptoms. However, although 15 mg THC is

free of adverse effects of clinical significance on the sleep process, its activity is associated with residual effects. In this context, the coadministration of THC and CBD has advantages beyond the therapeutic benefits that both drugs may bring individually. An equal dose of CBD appears to counteract the residual effects of THC on daytime sleep latencies and memory, although the subjects may still report sleepiness.

ACKNOWLEDGMENTS

The study was sponsored by GW Pharmaceuticals plc. It was carried out under license obtained through the company by the principal investigator (ANN). PJR is the medical director of GW Pharmaceuticals Ltd. The authors are indebted to Ms Sue Mills and Ms Huma Syed of QinetiQ for carrying out the experimental work and for statistical analysis of the data, respectively.

The National Academies of
SCIENCES • ENGINEERING • MEDICINE

The **National Academy of Sciences** was established in 1863 by an Act of Congress, signed by President Lincoln, as a private, nongovernmental institution to advise the nation on issues related to science and technology. Members are elected by their peers for outstanding contributions to research. Dr. Marcia McNutt is president.

The **National Academy of Engineering** was established in 1964 under the charter of the National Academy of Sciences to bring the practices of engineering to advising the nation. Members are elected by their peers for extraordinary contributions to engineering. Dr. C. D. Mote, Jr., is president.

The **National Academy of Medicine** (formerly the Institute of Medicine) was established in 1970 under the charter of the National Academy of Sciences to advise the nation on medical and health issues. Members are elected by their peers for distinguished contributions to medicine and health. Dr. Victor J. Dzau is president.

The three Academies work together as the **National Academies of Sciences, Engineering, and Medicine** to provide independent, objective analysis and advice to the nation and conduct other activities to solve complex problems and inform public policy decisions. The National Academies also encourage education and research, recognize outstanding contributions to knowledge, and increase public understanding in matters of science, engineering, and medicine.

Reports document the evidence-based consensus of an authoring committee of experts. Reports typically include findings, conclusions, and recommendations based on information gathered by the committee and committee deliberations. Reports are peer reviewed and are approved by the National Academies of Sciences, Engineering, and Medicine.

Proceedings chronicle the presentations and discussions at a workshop, symposium, or other convening event. The statements and opinions contained in proceedings are those of the participants and have not been endorsed by other participants, the planning committee, or the National Academies of Sciences, Engineering, and Medicine.

For information about other products and activities of the National Academies, please visit nationalacademies.org/whatwedo.

Reviewers

This report has been reviewed in draft form by individuals chosen for their diverse perspectives and technical expertise. The purpose of this independent review is to provide candid and critical comments that will assist the institution in making its published report as sound as possible and to ensure that the report meets institutional standards for objectivity, evidence, and responsiveness to the study charge. The review comments and draft manuscript remain confidential to protect the integrity of the deliberative process. We wish to thank the following individuals for their review of this report:

Eric Bass, Johns Hopkins University
Jonathan P. Caulkins, Carnegie Mellon University
Mary D’Alton, Columbia University Medical Center
Eden Evins, Massachusetts General Hospital
Frank F. Furstenberg, Jr., University of Pennsylvania
Raul Gonzalez, Florida International University
Igor Grant, University of California, San Diego, School of Medicine
Mark Helfand, Oregon Health & Science University
David A. Kessler, University of California, San Francisco
John H. Krystal, Yale University School of Medicine
Aron Lichtman, Virginia Commonwealth University
Robin Mermelstein, University of Illinois at Chicago

Donald P. Tashkin, University of California, Los Angeles, David Geffen School of Medicine
Larry A. Walker, The University of Mississippi Medical Center
Mark A. Ware, McGill University

Although the reviewers listed above have provided many constructive comments and suggestions, they were not asked to endorse the conclusions or recommendations nor did they see the final draft of the report before its release. The review of this report was overseen by **Eric B. Larson**, Group Health Research Institute, and **Bobbie A. Berkowitz**, Columbia University Medical Center. They were responsible for making certain that an independent examination of this report was carried out in accordance with institutional procedures and that all review comments were carefully considered. Responsibility for the final content of this report rests entirely with the authoring committee and the institution.

Acknowledgments

This report reflects contributions from a number of individuals and groups. The committee takes this opportunity to recognize those who so generously gave their time and expertise to inform its deliberations.

To begin, the committee would like to thank the sponsors of this study for their guidance and support. Support for the committee's work was generously provided by the Alaska Mental Health Trust Authority; Arizona Department of Health Services; California Department of Public Health; CDC Foundation; Centers for Disease Control and Prevention; The Colorado Health Foundation; Mat-Su Health Foundation; National Highway Traffic Safety Administration; National Institutes of Health/National Cancer Institute; National Institutes of Health/National Institute on Drug Abuse; Oregon Health Authority; the Robert W. Woodruff Foundation; Truth Initiative; U.S. Food and Drug Administration; and Washington State Department of Health.

The committee greatly benefited from the opportunity for discussion with individuals who attended and presented at their open session meetings (see Appendix D). The committee is thankful for the many contributions of these individuals.

The committee could not have done its work without the support and guidance provided by the National Academies project staff: Leigh Miles Jackson, study director; Jennifer Cohen, program officer; Kelsey Geiser, research associate; R. Brian Woodbury, research associate; Sara Tharakan, research associate; Matthew Masiello, research assistant; and Marjorie Pichon, senior program assistant. The committee is also grateful to Hope R. Hare and Doris Romero for their administrative and financial

assistance on this project, and gratefully acknowledges Kathleen Stratton and Rose Marie Martinez of the Board on Population Health and Public Health Practice for the guidance they provided throughout this important study.

Many other staff within the National Academies provided support to this project in various ways. The committee would like to thank the executive office staff of the Health and Medicine Division (HMD), as well as Greta Gorman, Janice Mehler, Lauren Shern, and the staff in the HMD Office of Reports and Communication for the management of the report review process. We would like to thank Rebecca Morgan and the National Academies Research Center staff for their assistance in the committee's research efforts, and the National Academies Press staff.

We thank Steven Davenport, Tamar Lasky, Guillermo Moreno-Sanz, and Bryce Pardo for their valuable commissioned work, and we are grateful to LeAnn Locher for her creative efforts in our graphic design projects. Finally, Robert Pool is to be credited for his superb editorial assistance in preparing this report.

Preface

At the time of this report's release in January 2017, 28 states and the District of Columbia have legalized cannabis for the treatment of medical conditions. Eight of these states and the District of Columbia have also legalized cannabis for recreational use. In addition to the growing availability of legalized cannabis, there has also been a rapid expansion in the types of available cannabis products, including edibles, oils, and a variety of inhaled substances. The growing acceptance, accessibility, and use of cannabis raise important public health concerns, and there is a clear need to establish what is known and what needs to be known about the health effects of cannabis use.

The committee was tasked with conducting a comprehensive review of the current evidence regarding the health effects of using cannabis and cannabis-derived products. The study was conducted in a limited time frame in order to respond to a quickly moving landscape, but as described in the report's methods section, the amount of work that this report entailed and the volume of literature reviewed clearly indicates the substantial effort involved and the importance of this issue to the committee.

In the current report, the committee presents a rigorous and thoughtful summary of the landscape of cannabis and health and puts forth recommendations to help advance the research field and better inform public health decisions. I wish to express my deepest gratitude to my fellow committee members who worked so hard and with good grace to accomplish this task. As with other National Academies of Sciences, Engineering, and Medicine reports, the work of the committee would have been

far more difficult, if not impossible, without the support of a dedicated, knowledgeable, and very hardworking National Academies staff.

Marie C. McCormick, *Chair*
Committee on the Health Effects of Marijuana:
An Evidence Review and Research Agenda

Summary

Over the past 20 years there have been substantial changes to the cannabis policy landscape. To date, 28 states and the District of Columbia have legalized cannabis for the treatment of medical conditions (NCSL, 2016). Eight of these states and the District of Columbia have also legalized cannabis for recreational use. These landmark changes in policy have markedly changed cannabis use patterns and perceived levels of risk. Based on a recent nationwide survey, 22.2 million Americans (12 years of age and older) reported using cannabis in the past 30 days, and between 2002 and 2015 the percentage of past month cannabis users in this age range has steadily increased (CBHSQ, 2016).

Despite the extensive changes in policy at the state level and the rapid rise in the use of cannabis both for medical purposes and for recreational use, conclusive evidence regarding the short- and long-term health effects (harms and benefits) of cannabis use remains elusive. A lack of scientific research has resulted in a lack of information on the health implications of cannabis use, which is a significant public health concern for vulnerable populations such as pregnant women and adolescents. Unlike other substances whose use may confer risk, such as alcohol or tobacco, no accepted standards exist to help guide individuals as they make choices regarding the issues of if, when, where, and how to use cannabis safely and, in regard to therapeutic uses, effectively.

Within this context, in March 2016, the Health and Medicine Division

BOX S-1

Statement of Task

The National Academies of Sciences, Engineering, and Medicine (the National Academies) will appoint an ad hoc committee to develop a comprehensive, in-depth review of existing evidence regarding the health effects of using marijuana and/or its constituents.

The committee will develop a consensus report with two primary sections: (1) a section of the report will summarize what can be determined about the health effects of marijuana use and, (2) a section of the report will summarize potential therapeutic uses of marijuana. The report will also provide a background overview of the cannabinoid/endocannabinoid system, history of use in the United States, and the regulation and policy landscape. In addition, the report will outline and make recommendations regarding a research agenda identifying the most critical research questions regarding the association of marijuana use with health outcomes (both risks and therapeutic) that can be answered in the short term (i.e., within a 3-year time frame) as well as any steps that should be taken in the short term to ensure that sufficient data are being gathered to answer long-term questions (e.g., appropriate questions on large population surveillance surveys, clinical data collection or other data capture, and resolution of barriers to linkage between survey data and death/morbidity registries to enable population-level morbidity and mortality effects estimates). The committee should focus on questions and consequences with the potential for the greatest public health impact, while shedding light on the characteristics of marijuana use that impact both short- and long-term health.

In conducting its work, the committee will conduct a comprehensive review of the evidence, using accepted approaches of literature search, evidence review, grading, and synthesis. Studies reviewed regarding health risks should be as broad as possible, including but not limited to epidemiology and clinical studies, and toxicology and animal studies when determined appropriate by the committee. The committee will provide summary determinations regarding causality based on strength of evidence. Both U.S. and international studies may be reviewed based upon relevance and methodological rigor.

(formerly the Institute of Medicine [IOM]¹) of the National Academies of Sciences, Engineering, and Medicine (the National Academies) was asked to convene a committee of experts to conduct a comprehensive review of the literature regarding the health effects of using cannabis and/or its constituents that had appeared since the publication of the 1999 IOM report

¹ As of March 2016, the Health and Medicine Division continues the consensus studies and convening activities previously carried out by the Institute of Medicine (IOM).

Marijuana and Medicine. The resulting Committee on the Health Effects of Marijuana consisted of 16 experts in the areas of marijuana, addiction, oncology, cardiology, neurodevelopment, respiratory disease, pediatric and adolescent health, immunology, toxicology, preclinical research, epidemiology, systematic review, and public health. The sponsors of this report include federal, state, philanthropic, and nongovernmental organizations, including the Alaska Mental Health Trust Authority; Arizona Department of Health Services; California Department of Public Health; CDC Foundation; Centers for Disease Control and Prevention (CDC); The Colorado Health Foundation; Mat-Su Health Foundation; National Highway Traffic Safety Administration; National Institutes of Health/National Cancer Institute; National Institutes of Health/National Institute on Drug Abuse; Oregon Health Authority; the Robert W. Woodruff Foundation; Truth Initiative; U.S. Food and Drug Administration; and Washington State Department of Health.

In its statement of task, the committee was asked to make recommendations for a research agenda that will identify the most critical research questions regarding the association of cannabis use with health outcomes (both harms and benefits) that can be answered in the short term (i.e., within a 3-year time frame), as well as steps that should be taken in the short term to ensure that sufficient data are being gathered to answer long-term questions. Of note, throughout the report the committee has attempted to highlight research conclusions that affect certain populations (e.g., pregnant women, adolescents) that may be more vulnerable to potential harmful effects of cannabis use. The committee's full statement of task is presented in Box S-1.

STUDY CONTEXT AND APPROACH

Over the past 20 years the IOM published several consensus reports that focused on the health effects of marijuana or addressed marijuana within the context of other drug or substance abuse topics.² The two IOM reports that most prominently informed the committee's work were *Marijuana and Health*, published in 1982, and the 1999 report *Marijuana and Medicine: Assessing the Science Base*. Although these reports differed in scope, they were useful in providing a comprehensive body of evidence upon which the current committee could build.

The scientific literature on cannabis use has grown substantially since the 1999 publication of *Marijuana and Medicine*. The committee conducted an extensive search of relevant databases, including Medline, Embase,

² See <https://www.nap.edu/search/?year=1995&rpp=20&ft=1&term=marijuana> (accessed January 5, 2017).

BOX S-2
Health Topics and Prioritized Health Endpoints
(listed in the order in which they appear in the report)

Therapeutic effects

- Chronic pain; cancer, chemotherapy-induced nausea/vomiting; anorexia and weight loss; irritable bowel syndrome; epilepsy; spasticity related to multiple sclerosis or spinal cord injury; Tourette syndrome; amyotrophic lateral sclerosis; Huntington's disease; Parkinson's disease; dystonia; dementia; glaucoma; traumatic brain injury; addiction; anxiety; depression; sleep disorders; posttraumatic stress disorder; schizophrenia and other psychoses

Cancer

- Lung cancer; head and neck cancer; testicular cancer; esophageal cancer; other cancer

Cardiometabolic risk

- Acute myocardial infarction; stroke; metabolic dysregulation, metabolic syndrome, prediabetes, and diabetes mellitus

Respiratory disease

- Pulmonary function; chronic obstructive pulmonary disorder; respiratory symptoms (including chronic bronchitis); asthma

Immunity

- Immune function; infectious disease

the Cochrane Database of Systematic Reviews, and PsycINFO, and they initially retrieved more than 24,000 abstracts that could have potentially been relevant to this study. These abstracts were reduced by limiting articles to those published in English and removing case reports, editorials, studies by “anonymous” authors, conference abstracts, and commentaries. In the end, the committee considered more than 10,700 abstracts for their relevance to this report.

Given the large scientific literature on cannabis, the breadth of the statement of task, and the time constraints of the study, the committee developed an approach that resulted in giving primacy to recently published systematic reviews (since 2011) and high-quality primary research for 11 groups of health endpoints (see Box S-2). For each health endpoint,

Injury and death

- All-cause mortality; occupational injury; motor vehicle crash; overdose injury and death

Prenatal, perinatal, and postnatal exposure to cannabis

- Pregnancy complications for the mother; fetal growth and development; neonatal conditions; later outcomes for the infant

Psychosocial

- Cognition (learning, memory, attention, intelligence); academic achievement and educational outcomes; employment and income; social relationships and other social roles

Mental health

- Schizophrenia and other psychoses; bipolar disorders, depression; suicide; anxiety; posttraumatic stress disorder

Problem cannabis use

- Cannabis use disorder

Cannabis use and abuse of other substances

- Abuse of other substances

systematic reviews were identified and assessed for quality using published criteria; only fair- and good-quality reviews were considered by the committee. The committee's conclusions are based on the findings from the most recently published systematic review and all relevant fair- and good-quality primary research published after the systematic review. Where no systematic review existed, the committee reviewed all relevant primary research published between January 1, 1999, and August 1, 2016. Primary research was assessed using standard approaches (e.g., Cochrane Quality Assessment, Newcastle–Ontario scale) as a guide.

The search strategies and processes described above were developed and adopted by the committee in order to adequately address a broad statement of task in a limited time frame while adhering to the National

Academies' high standards for the quality and rigor of committee reports. Readers of this report should recognize two important points. First, the committee was not tasked to conduct multiple systematic reviews, which would have required a lengthy and robust series of processes. The committee did, however, adopt key features of that process: a comprehensive literature search; assessments by more than one person of the quality (risk of bias) of key literature and the conclusions; prespecification of the questions of interest before conclusions were formulated; standard language to allow comparisons between conclusions; and declarations of conflict of interest via the National Academies conflict-of-interest policies. Second, there is a possibility that some literature was missed because of the practical steps taken to narrow a very large literature to one that was manageable within the time frame available to the committee. Furthermore, very good research may not be reflected in this report because it did not directly address the health endpoint research questions that were prioritized by the committee.

This report is organized into four parts and 16 chapters. Part I: Introduction and Background, Part II: Therapeutic Effects (Therapeutic Effects of Cannabis and Cannabinoids), Part III: Other Health Effects, and Part IV: Research Barriers and Recommendations. In Part II, most of the evidence reviewed in Chapter 4 derives from clinical and basic science research conducted for the specific purpose of answering an a priori question of whether cannabis and/or cannabinoids are an effective treatment for a specific disease or health condition. The evidence reviewed in Part III derives from epidemiological research that primarily reviews the effects of smoked cannabis. It is of note that several of the prioritized health endpoints discussed in Part III are also reviewed in Part II, albeit from the perspective of effects associated with using cannabis for primarily recreational, as opposed to therapeutic, purposes.

Several health endpoints are discussed in multiple chapters of the report (e.g., cancer, schizophrenia); however, it is important to note that the research conclusions regarding potential harms and benefits discussed in these chapters may differ. This is, in part, due to differences in the study design of the reviewed evidence, differences in characteristics of cannabis or cannabinoid exposure (e.g., form, dose, frequency of use), and the populations studied. As such, it is important that the reader is aware that this report was not designed to reconcile the proposed harms and benefits of cannabis or cannabinoid use across the report's chapters. In drafting the report's conclusions, the committee made an effort to be as specific as possible about the type and/or duration of cannabis or cannabinoid exposure and, where relevant, cross-referenced findings from other report chapters.

REPORT CONCLUSIONS ON THE ASSOCIATION BETWEEN CANNABIS USE AND HEALTH

From their review, the committee arrived at nearly 100 different research conclusions related to cannabis or cannabinoid use and health. Informed by the reports of previous IOM committees,³ the committee developed standard language to categorize the weight of evidence regarding whether cannabis or cannabinoid use (for therapeutic purposes) is an effective or ineffective treatment for the prioritized health endpoints of interest, or whether cannabis or cannabinoid use (primarily for recreational purposes) is statistically associated with the prioritized health

³ *Adverse Effects of Vaccines: Evidence and Causality* (IOM, 2012); *Treatment of Posttraumatic Stress Disorder: An Assessment of the Evidence* (IOM, 2008); *Veterans and Agent Orange: Update 2014* (NASEM, 2016).

BOX S-3 Weight-of-Evidence Categories

CONCLUSIVE EVIDENCE

For therapeutic effects: There is strong evidence from randomized controlled trials to support the conclusion that cannabis or cannabinoids are an effective or ineffective treatment for the health endpoint of interest.

For other health effects: There is strong evidence from randomized controlled trials to support or refute a statistical association between cannabis or cannabinoid use and the health endpoint of interest.

For this level of evidence, there are many supportive findings from good-quality studies with no credible opposing findings. A firm conclusion can be made, and the limitations to the evidence, including chance, bias, and confounding factors, can be ruled out with reasonable confidence.

SUBSTANTIAL EVIDENCE

For therapeutic effects: There is strong evidence to support the conclusion that cannabis or cannabinoids are an effective or ineffective treatment for the health endpoint of interest.

For other health effects: There is strong evidence to support or refute a statistical association between cannabis or cannabinoid use and the health endpoint of interest.

For this level of evidence, there are several supportive findings from good-quality studies with very few or no credible opposing findings. A firm conclusion can be made, but minor limitations, including chance, bias, and confounding factors, cannot be ruled out with reasonable confidence.

continued

BOX S-3 Continued**MODERATE EVIDENCE**

For therapeutic effects: There is some evidence to support the conclusion that cannabis or cannabinoids are an effective or ineffective treatment for the health endpoint of interest.

For other health effects: There is some evidence to support or refute a statistical association between cannabis or cannabinoid use and the health endpoint of interest.

For this level of evidence, there are several supportive findings from good- to fair-quality studies with very few or no credible opposing findings. A general conclusion can be made, but limitations, including chance, bias, and confounding factors, cannot be ruled out with reasonable confidence.

LIMITED EVIDENCE

For therapeutic effects: There is weak evidence to support the conclusion that cannabis or cannabinoids are an effective or ineffective treatment for the health endpoint of interest.

For other health effects: There is weak evidence to support or refute a statistical association between cannabis or cannabinoid use and the health endpoint of interest.

For this level of evidence, there are supportive findings from fair-quality studies or mixed findings with most favoring one conclusion. A conclusion can be made, but there is significant uncertainty due to chance, bias, and confounding factors.

NO OR INSUFFICIENT EVIDENCE TO SUPPORT THE ASSOCIATION

For therapeutic effects: There is no or insufficient evidence to support the conclusion that cannabis or cannabinoids are an effective or ineffective treatment for the health endpoint of interest.

For other health effects: There is no or insufficient evidence to support or refute a statistical association between cannabis or cannabinoid use and the health endpoint of interest.

For this level of evidence, there are mixed findings, a single poor study, or health endpoint has not been studied at all. No conclusion can be made because of substantial uncertainty due to chance, bias, and confounding factors.

endpoints of interest. Box S-3 describes these categories and the general parameters for the types of evidence supporting each category. For a full listing of the committee's conclusions, please see this chapter's annex.

REPORT RECOMMENDATIONS

This is a pivotal time in the world of cannabis policy and research. Shifting public sentiment, conflicting and impeded scientific research, and legislative battles have fueled the debate about what, if any, harms or benefits can be attributed to the use of cannabis or its derivatives. The committee has put forth a substantial number of research conclusions on the health effects of cannabis and cannabinoids. Based on their research conclusions, the committee members formulated four recommendations to address research gaps, improve research quality, improve surveillance capacity, and address research barriers. The report's full recommendations are described below.

Address Research Gaps

Recommendation 1: To develop a comprehensive evidence base on the short- and long-term health effects of cannabis use (both beneficial and harmful effects), public agencies,⁴ philanthropic and professional organizations, private companies, and clinical and public health research groups should provide funding and support for a national cannabis research agenda that addresses key gaps in the evidence base. Prioritized research streams and objectives should include, but need not be limited to:

Clinical and Observational Research

- Examine the health effects of cannabis use in at-risk or under-researched populations, such as children and youth (often described as less than 18 years of age) and older populations (generally over 50 years of age), pregnant and breastfeeding women, and heavy cannabis users.
- Investigate the pharmacokinetic and pharmacodynamic properties of cannabis, modes of delivery, different concentrations, in various populations, including the dose–response relationships of cannabis and THC or other cannabinoids.
- Determine the harms and benefits associated with understudied cannabis products, such as edibles, concentrates, and topicals.
- Conduct well-controlled trials on the potential beneficial and harmful health effects of using different forms of cannabis, such

⁴ Agencies may include the CDC, relevant agencies of the National Institutes of Health (NIH), and the U.S. Food and Drug Administration (FDA).

as inhaled (smoked or vaporized) whole cannabis plant and oral cannabis.

- Characterize the health effects of cannabis on unstudied and understudied health endpoints, such as epilepsy in pediatric populations; symptoms of posttraumatic stress disorder; childhood and adult cancers; cannabis-related overdoses and poisonings; and other high-priority health endpoints.

Health Policy and Health Economics Research

- Identify models, including existing state cannabis policy models, for sustainable funding of national, state, and local public health surveillance systems.
- Investigate the economic impact of recreational and medical cannabis use on national and state public health and health care systems, health insurance providers, and patients.

Public Health and Public Safety Research

- Identify gaps in the cannabis-related knowledge and skills of health care and public health professionals, and assess the need for, and performance of, continuing education programs that address these gaps.
- Characterize public safety concerns related to recreational cannabis use and evaluate existing quality assurance, safety, and packaging standards for recreational cannabis products.

Improve Research Quality

Recommendation 2: To promote the development of conclusive evidence on the short- and long-term health effects of cannabis use (both beneficial and harmful effects), agencies of the U.S. Department of Health and Human Services, including the National Institutes of Health and the Centers for Disease Control and Prevention, should jointly fund a workshop to develop a set of research standards and benchmarks to guide and ensure the production of high-quality cannabis research. Workshop objectives should include, but need not be limited to:

- The development of a minimum dataset for observational and clinical studies, standards for research methods and design, and guidelines for data collection methods.

- Adaptation of existing research-reporting standards to the needs of cannabis research.
- The development of uniform terminology for clinical and epidemiological cannabis research.
- The development of standardized and evidence-based question banks for clinical research and public health surveillance tools.

Improve Surveillance Capacity

Recommendation 3: To ensure that sufficient data are available to inform research on the short- and long-term health effects of cannabis use (both beneficial and harmful effects), the Centers for Disease Control and Prevention, the Substance Abuse and Mental Health Services Administration, the Association of State and Territorial Health Officials, National Association of County and City Health Officials, the Association of Public Health Laboratories, and state and local public health departments should fund and support improvements to federal public health surveillance systems and state-based public health surveillance efforts. Potential efforts should include, but need not be limited to:

- The development of question banks on the beneficial and harmful health effects of therapeutic and recreational cannabis use and their incorporation into major public health surveys, including the National Health and Nutrition Examination Survey, National Health Interview Survey, Behavioral Risk Factor Surveillance System, National Survey on Drug Use and Health, Youth Risk Behavior Surveillance System, National Vital Statistics System, Medical Expenditure Panel Survey, and the National Survey of Family Growth.
- Determining the capacity to collect and reliably interpret data from diagnostic classification codes in administrative data (e.g., *International Classification of Diseases-10*).
- The establishment and utilization of state-based testing facilities to analyze the chemical composition of cannabis and products containing cannabis, cannabinoids, or THC.
- The development of novel diagnostic technologies that allow for rapid, accurate, and noninvasive assessment of cannabis exposure and impairment.
- Strategies for surveillance of harmful effects of cannabis for therapeutic use.

Address Research Barriers

Recommendation 4: The Centers for Disease Control and Prevention, National Institutes of Health, U.S. Food and Drug Administration, industry groups, and nongovernmental organizations should fund the convening of a committee of experts tasked to produce an objective and evidence-based report that fully characterizes the impacts of regulatory barriers to cannabis research and that proposes strategies for supporting development of the resources and infrastructure necessary to conduct a comprehensive cannabis research agenda. Committee objectives should include, but need not be limited to:

- Proposing strategies for expanding access to research-grade marijuana, through the creation and approval of new facilities for growing and storing cannabis.
- Identifying nontraditional funding sources and mechanisms to support a comprehensive national cannabis research agenda.
- Investigating strategies for improving the quality, diversity, and external validity of research-grade cannabis products.

ANNEX

Report Conclusions⁵*Chapter 4 Conclusions—Therapeutic Effects of Cannabis and Cannabinoids***There is conclusive or substantial evidence that cannabis or cannabinoids are effective:**

- For the treatment of chronic pain in adults (cannabis) (4-1)
- As antiemetics in the treatment of chemotherapy-induced nausea and vomiting (oral cannabinoids) (4-3)
- For improving patient-reported multiple sclerosis spasticity symptoms (oral cannabinoids) (4-7a)

There is moderate evidence that cannabis or cannabinoids are effective for:

- Improving short-term sleep outcomes in individuals with sleep disturbance associated with obstructive sleep apnea syndrome, fibromyalgia, chronic pain, and multiple sclerosis (cannabinoids, primarily nabiximols) (4-19)

There is limited evidence that cannabis or cannabinoids are effective for:

- Increasing appetite and decreasing weight loss associated with HIV/AIDS (cannabis and oral cannabinoids) (4-4a)
- Improving clinician-measured multiple sclerosis spasticity symptoms (oral cannabinoids) (4-7a)
- Improving symptoms of Tourette syndrome (THC capsules) (4-8)
- Improving anxiety symptoms, as assessed by a public speaking test, in individuals with social anxiety disorders (cannabidiol) (4-17)
- Improving symptoms of posttraumatic stress disorder (nabilone; a single, small fair-quality trial) (4-20)

⁵ Numbers in parentheses correspond to chapter conclusion numbers.

There is limited evidence of a statistical association between cannabinoids and:

- Better outcomes (i.e., mortality, disability) after a traumatic brain injury or intracranial hemorrhage (4-15)

There is limited evidence that cannabis or cannabinoids are ineffective for:

- Improving symptoms associated with dementia (cannabinoids) (4-13)
- Improving intraocular pressure associated with glaucoma (cannabinoids) (4-14)
- Reducing depressive symptoms in individuals with chronic pain or multiple sclerosis (nabiximols, dronabinol, and nabilone) (4-18)

There is no or insufficient evidence to support or refute the conclusion that cannabis or cannabinoids are an effective treatment for:

- Cancers, including glioma (cannabinoids) (4-2)
- Cancer-associated anorexia cachexia syndrome and anorexia nervosa (cannabinoids) (4-4b)
- Symptoms of irritable bowel syndrome (dronabinol) (4-5)
- Epilepsy (cannabinoids) (4-6)
- Spasticity in patients with paralysis due to spinal cord injury (cannabinoids) (4-7b)
- Symptoms associated with amyotrophic lateral sclerosis (cannabinoids) (4-9)
- Chorea and certain neuropsychiatric symptoms associated with Huntington's disease (oral cannabinoids) (4-10)
- Motor system symptoms associated with Parkinson's disease or the levodopa-induced dyskinesia (cannabinoids) (4-11)
- Dystonia (nabilone and dronabinol) (4-12)
- Achieving abstinence in the use of addictive substances (cannabinoids) (4-16)
- Mental health outcomes in individuals with schizophrenia or schizophreniform psychosis (cannabidiol) (4-21)

Chapter 5 Conclusions—Cancer

There is moderate evidence of *no* statistical association between cannabis use and:

- Incidence of lung cancer (cannabis smoking) (5-1)
- Incidence of head and neck cancers (5-2)

There is limited evidence of a statistical association between cannabis smoking and:

- Non-seminoma-type testicular germ cell tumors (current, frequent, or chronic cannabis smoking) (5-3)

There is no or insufficient evidence to support or refute a statistical association between cannabis use and:

- Incidence of esophageal cancer (cannabis smoking) (5-4)
- Incidence of prostate cancer, cervical cancer, malignant gliomas, non-Hodgkin lymphoma, penile cancer, anal cancer, Kaposi's sarcoma, or bladder cancer (5-5)
- Subsequent risk of developing acute myeloid leukemia/acute non-lymphoblastic leukemia, acute lymphoblastic leukemia, rhabdomyosarcoma, astrocytoma, or neuroblastoma in offspring (parental cannabis use) (5-6)

Chapter 6 Conclusions—Cardiometabolic Risk

There is limited evidence of a statistical association between cannabis use and:

- The triggering of acute myocardial infarction (cannabis smoking) (6-1a)
- Ischemic stroke or subarachnoid hemorrhage (6-2)
- Decreased risk of metabolic syndrome and diabetes (6-3a)
- Increased risk of prediabetes (6-3b)

There is no evidence to support or refute a statistical association between *chronic effects* of cannabis use and:

- The increased risk of acute myocardial infarction (6-1b)

*Chapter 7 Conclusions—Respiratory Disease***There is substantial evidence of a statistical association between cannabis smoking and:**

- Worse respiratory symptoms and more frequent chronic bronchitis episodes (long-term cannabis smoking) (7-3a)

There is moderate evidence of a statistical association between cannabis smoking and:

- Improved airway dynamics with acute use, but not with chronic use (7-1a)
- Higher forced vital capacity (FVC) (7-1b)

There is moderate evidence of a statistical association between the cessation of cannabis smoking and:

- Improvements in respiratory symptoms (7-3b)

There is limited evidence of a statistical association between cannabis smoking and:

- An increased risk of developing chronic obstructive pulmonary disease (COPD) when controlled for tobacco use (occasional cannabis smoking) (7-2a)

There is no or insufficient evidence to support or refute a statistical association between cannabis smoking and:

- Hospital admissions for COPD (7-2b)
- Asthma development or asthma exacerbation (7-4)

*Chapter 8 Conclusions—Immunity***There is limited evidence of a statistical association between cannabis smoking and:**

- A decrease in the production of several inflammatory cytokines in healthy individuals (8-1a)

There is limited evidence of *no* statistical association between cannabis use and:

- The progression of liver fibrosis or hepatic disease in individuals with viral hepatitis C (HCV) (daily cannabis use) (8-3)

There is no or insufficient evidence to support or refute a statistical association between cannabis use and:

- Other adverse immune cell responses in healthy individuals (cannabis smoking) (8-1b)
- Adverse effects on immune status in individuals with HIV (cannabis or dronabinol use) (8-2)
- Increased incidence of oral human papilloma virus (HPV) (regular cannabis use) (8-4)

Chapter 9 Conclusions—Injury and Death

There is substantial evidence of a statistical association between cannabis use and:

- Increased risk of motor vehicle crashes (9-3)

There is moderate evidence of a statistical association between cannabis use and:

- Increased risk of overdose injuries, including respiratory distress, among pediatric populations in U.S. states where cannabis is legal (9-4b)

There is no or insufficient evidence to support or refute a statistical association between cannabis use and:

- All-cause mortality (self-reported cannabis use) (9-1)
- Occupational accidents or injuries (general, nonmedical cannabis use) (9-2)
- Death due to cannabis overdose (9-4a)

Chapter 10 Conclusions—Prenatal, Perinatal, and Neonatal Exposure

There is substantial evidence of a statistical association between maternal cannabis smoking and:

- Lower birth weight of the offspring (10-2)

There is limited evidence of a statistical association between maternal cannabis smoking and:

- Pregnancy complications for the mother (10-1)
- Admission of the infant to the neonatal intensive care unit (NICU) (10-3)

There is insufficient evidence to support or refute a statistical association between maternal cannabis smoking and:

- Later outcomes in the offspring (e.g., sudden infant death syndrome, cognition/academic achievement, and later substance use) (10-4)

Chapter 11 Conclusions—Psychosocial

There is moderate evidence of a statistical association between cannabis use and:

- The impairment in the cognitive domains of learning, memory, and attention (acute cannabis use) (11-1a)

There is limited evidence of a statistical association between cannabis use and:

- Impaired academic achievement and education outcomes (11-2)
- Increased rates of unemployment and/or low income (11-3)
- Impaired social functioning or engagement in developmentally appropriate social roles (11-4)

There is limited evidence of a statistical association between *sustained abstinence from cannabis use* and:

- Impairments in the cognitive domains of learning, memory, and attention (11-1b)

*Chapter 12 Conclusions—Mental Health***There is substantial evidence of a statistical association between cannabis use and:**

- The development of schizophrenia or other psychoses, with the highest risk among the most frequent users (12-1)

There is moderate evidence of a statistical association between cannabis use and:

- Better cognitive performance among individuals with psychotic disorders and a history of cannabis use (12-2a)
- Increased symptoms of mania and hypomania in individuals diagnosed with bipolar disorders (regular cannabis use) (12-4)
- A small increased risk for the development of depressive disorders (12-5)
- Increased incidence of suicidal ideation and suicide attempts with a higher incidence among heavier users (12-7a)
- Increased incidence of suicide completion (12-7b)
- Increased incidence of social anxiety disorder (regular cannabis use) (12-8b)

There is moderate evidence of *no* statistical association between cannabis use and:

- Worsening of negative symptoms of schizophrenia (e.g., blunted affect) among individuals with psychotic disorders (12-2c)

There is limited evidence of a statistical association between cannabis use and:

- An increase in positive symptoms of schizophrenia (e.g., hallucinations) among individuals with psychotic disorders (12-2b)
- The likelihood of developing bipolar disorder, particularly among regular or daily users (12-3)
- The development of any type of anxiety disorder, except social anxiety disorder (12-8a)
- Increased symptoms of anxiety (near daily cannabis use) (12-9)

- Increased severity of posttraumatic stress disorder symptoms among individuals with posttraumatic stress disorder (12-11)

There is no evidence to support or refute a statistical association between cannabis use and:

- Changes in the course or symptoms of depressive disorders (12-6)
- The development of posttraumatic stress disorder (12-10)

Chapter 13 Conclusions—Problem Cannabis Use

There is substantial evidence that:

- Stimulant treatment of attention deficit hyperactivity disorder (ADHD) during adolescence is *not* a risk factor for the development of problem cannabis use (13-2e)
- Being male and smoking cigarettes are risk factors for the progression of cannabis use to problem cannabis use (13-2i)
- Initiating cannabis use at an earlier age is a risk factor for the development of problem cannabis use (13-2j)

There is substantial evidence of a statistical association between:

- Increases in cannabis use frequency and the progression to developing problem cannabis use (13-1)
- Being male and the severity of problem cannabis use, but the recurrence of problem cannabis use does not differ between males and females (13-3b)

There is moderate evidence that:

- Anxiety, personality disorders, and bipolar disorders are *not* risk factors for the development of problem cannabis use (13-2b)
- Major depressive disorder is a risk factor for the development of problem cannabis use (13-2c)
- Adolescent ADHD is *not* a risk factor for the development of problem cannabis use (13-2d)

- Being male is a risk factor for the development of problem cannabis use (13-2f)
- Exposure to the combined use of abused drugs is a risk factor for the development of problem cannabis use (13-2g)
- Neither alcohol nor nicotine dependence alone are risk factors for the progression from cannabis use to problem cannabis use (13-2h)
- During adolescence the frequency of cannabis use, oppositional behaviors, a younger age of first alcohol use, nicotine use, parental substance use, poor school performance, anti-social behaviors, and childhood sexual abuse are risk factors for the development of problem cannabis use (13-2k)

There is moderate evidence of a statistical association between:

- A persistence of problem cannabis use and a history of psychiatric treatment (13-3a)
- Problem cannabis use and increased severity of posttraumatic stress disorder symptoms (13-3c)

There is limited evidence that:

- Childhood anxiety and childhood depression are risk factors for the development of problem cannabis use (13-2a)

Chapter 14 Conclusions—Cannabis Use and the Abuse of Other Substances

There is moderate evidence of a statistical association between cannabis use and:

- The development of substance dependence and/or a substance abuse disorder for substances, including alcohol, tobacco, and other illicit drugs (14-3)

There is limited evidence of a statistical association between cannabis use and:

- The initiation of tobacco use (14-1)
- Changes in the rates and use patterns of other licit and illicit substances (14-2)

*Chapter 15 Conclusions—Challenges and Barriers in Conducting Cannabis Research***There are several challenges and barriers in conducting cannabis and cannabinoid research, including**

- There are specific regulatory barriers, including the classification of cannabis as a Schedule I substance, that impede the advancement of cannabis and cannabinoid research (15-1)
- It is often difficult for researchers to gain access to the quantity, quality, and type of cannabis product necessary to address specific research questions on the health effects of cannabis use (15-2)
- A diverse network of funders is needed to support cannabis and cannabinoid research that explores the beneficial and harmful health effects of cannabis use (15-3)
- To develop conclusive evidence for the effects of cannabis use on short- and long-term health outcomes, improvements and standardization in research methodology (including those used in controlled trials and observational studies) are needed (15-4)

Part I

Introduction and Background

1

Introduction

Over the past 20 years, significant changes have taken place in the policy landscape surrounding cannabis legalization, production, and use. To date, 28 states and the District of Columbia have legalized cannabis for the treatment of medical conditions (NCSL, 2016). Eight of these states and the District of Columbia have also legalized cannabis for recreational use. These landmark changes in policy have markedly changed cannabis use patterns and perceived levels of risk. Based on a recent nationwide survey, 22.2 million Americans (12 years of age and older) reported using cannabis in the past 30 days, and between 2002 and 2015 the percentage of past month cannabis users in this age range has steadily increased (CBHSQ, 2016).

Despite this reported rapid rise in the use of cannabis, both for medical purposes and for recreational use, conclusive evidence regarding the short- and long-term health effects of cannabis use remains elusive. While a myriad of studies have examined cannabis use in all its various forms (Calabria et al., 2010; Whiting et al., 2015, 2016; WHO, 2016), often these research conclusions are not appropriately synthesized, translated for, or communicated to policy makers, health care providers, state health officials, or other stakeholders who have been charged with influencing and enacting policies, procedures, and laws related to cannabis use. Unlike other substances whose use may confer risk, such as alcohol or tobacco, no accepted standards for the safe use or appropriate doses are available to help guide individuals as they make choices regarding the issues of if, when, where, and how to use cannabis safely and, in regard to therapeutic

tic uses, effectively (Freeman et al., 2014; Marsot et al., 2016). Moreover, studying the potential health impacts of cannabis presents its own set of unique challenges. Current challenges include the existence of certain regulations and policies that restrict access to cannabis products suited for research purposes (e.g., Schedule 1 status; regulatory approvals), the limited availability of funding for comprehensive cannabis research, and crosscutting methodological challenges. Additionally, researchers are often unable to obtain the necessary quantity, quality, or type of cannabis product to address cutting-edge public health research questions.

STUDY CHARGE

Shifting public sentiment, conflicting and impeded scientific research, and legislative battles have fueled the debate about what, if any, harms or benefits can be attributed to the use of cannabis or its derivatives. In March 2016 the Health and Medicine Division¹ of the National Academies of Sciences, Engineering, and Medicine (the National Academies) was asked to convene a committee of experts to conduct a comprehensive review of literature regarding the health consequences of using cannabis or its constituents that had appeared since the publication of the 1999 Institute of Medicine (IOM) report *Marijuana and Medicine* (IOM, 1999). In addition, the committee was asked to make recommendations for a research agenda that will identify the most critical research questions regarding the association of cannabis use with health outcomes (both harms and benefits) that can be answered in the short term (i.e., within a 3-year time frame), as well as steps that should be taken in the short term to ensure that sufficient data are being gathered to answer long-term questions. Of note, throughout this report the committee has attempted to highlight research conclusions that affect certain populations (e.g., pregnant women, adolescents) that may be at greater risk for potential adverse effects of cannabis use. The committee's full statement of task is presented in Box 1-1.

The resulting Committee on the Health Effects of Marijuana included experts in the areas of marijuana, addiction, oncology, cardiology, neurodevelopment, pulmonary, pediatric and adolescent health, immunology, toxicology, preclinical research, epidemiology, systematic review, and public health. (See Appendix E for the biographical sketches of committee members.)

In conducting its work, the committee met six times from March 2016 through December 2016. In conjunction with two of those meet-

¹ As of March 2016, the Health and Medicine Division continues the consensus studies and convening activities previously carried out by the Institute of Medicine (IOM).

BOX 1-1

Statement of Task

The National Academies of Sciences, Engineering, and Medicine (the National Academies) will appoint an ad hoc committee to develop a comprehensive, in-depth review of existing evidence regarding the health effects of using marijuana and/or its constituents.

The committee will develop a consensus report with two primary sections: (1) a section of the report will summarize what can be determined about the health effects of marijuana use and, (2) a section of the report will summarize potential therapeutic uses of marijuana. The report will also provide a background overview of the cannabinoid/endocannabinoid system, history of use in the United States and the regulation and policy landscape. In addition, the report will outline and make recommendations regarding a research agenda identifying the most critical research questions regarding the association of marijuana use with health outcomes (both risks and therapeutic) that can be answered in the short term (i.e., within a 3-year time frame) as well as any steps that should be taken in the short term to ensure that sufficient data are being gathered to answer long-term questions (e.g., appropriate questions on large population surveillance surveys, clinical data collection or other data capture, and resolution of barriers to linkage between survey data and death/morbidity registries to enable population-level morbidity and mortality effects estimates). The committee should focus on questions and consequences with the potential for the greatest public health impact, while shedding light on the characteristics of marijuana use that impact both short- and long-term health.

In conducting its work, the committee will conduct a comprehensive review of the evidence, using accepted approaches of literature search, evidence review, grading and synthesis. Studies reviewed regarding health risks should be as broad as possible, including but not limited to epidemiology and clinical studies, and toxicology and animal studies when determined appropriate by the committee. The committee will provide summary determinations regarding causality based on strength of evidence. Both U.S. and international studies may be reviewed based upon relevance and methodological rigor.

ings, the committee held half-day public information-gathering sessions which allowed the committee to hear from study sponsors, experts, and other stakeholders. These discussions helped to inform the committee's deliberations.

Sponsors of this report include federal, state, philanthropic, and non-governmental organizations. These include the Alaska Mental Health Trust Authority; Arizona Department of Health Services; California Department of Public Health; CDC Foundation; Centers for Disease Control and Prevention (CDC); The Colorado Health Foundation; Mat-Su Health Foundation; National Highway Traffic Safety Administration;

National Institutes of Health/National Cancer Institute; National Institutes of Health/National Institute on Drug Abuse; Oregon Health Authority; the Robert W. Woodruff Foundation; Truth Initiative; U.S. Food and Drug Administration; and the Washington State Department of Health.

STUDY CONTEXT AND APPROACH

Over the past 20 years the IOM has published several consensus reports that focused on the health effects of marijuana or addressed marijuana within the context of other drug or substance abuse topics.² Two IOM reports that most prominently informed the committee's work were *Marijuana and Health* (IOM, 1982), and the 1999 report *Marijuana and Medicine: Assessing the Science Base* (IOM, 1999). Although these reports differed in scope, they were useful in providing a comprehensive body of evidence upon which the current committee could build.

Marijuana and Health (IOM, 1982) was commissioned by the former Secretary of Health and Human Services and the former director of the National Institutes of Health, Joseph Califano, Jr., and Donald S. Fredrickson, respectively. The study's committee was appointed to (1) analyze the potential hazards of marijuana use on user safety and health, (2) analyze data concerning the therapeutic value of marijuana, (3) assess the federal research programs, (4) identify new research directions, and (5) draw conclusions that would assist future policy decision making. The authoring committee concluded that there was evidence indicating that marijuana has a broad range of psychological and biological effects, some of which under certain conditions are harmful to human health, but there was a substantial lack of definitive evidence to characterize the seriousness of harm. The committee's major conclusion was that "what little we know for certain about the effects of marijuana on human health—and all that we have reason to suspect—justifies serious national concern" (IOM, 1982, p. 5). The committee's major recommendation called for an intensification and more comprehensive research effort into the effects of marijuana on the health of the American people.

In 1997 the White House Office of National Drug Control Policy contracted with the IOM to conduct a scientific review of available literature to determine the potential health benefits and risks of marijuana and its constituent cannabinoids. The resulting report, *Marijuana and Medicine* (IOM, 1999), offered several conclusions and recommendations (see Box 1-2) on the effects of isolated cannabinoids, the efficacy of cannabinoid drugs, the influence of psychological effects on therapeutic effects,

BOX 1-2***Marijuana and Medicine: Assessing the Science Base (1999)***
Conclusions and Recommendations**Conclusions:**

- At this point, our knowledge about the biology of marijuana and cannabinoids allows us to make some general conclusions:
 - Cannabinoids likely have a natural role in pain modulation, control of movement, and memory.
 - The natural role of cannabinoids in immune systems is likely multifaceted and remains unclear.
 - The brain develops tolerance to cannabinoids.
 - Animal research demonstrates the potential for dependence, but this potential is observed under a narrower range of conditions than with benzodiazepines, opiates, cocaine, or nicotine.
 - Withdrawal symptoms can be observed in animals but appear to be mild compared to opiates or benzodiazepines, such as diazepam (Valium).
- The different cannabinoid receptor types found in the body appear to play different roles in normal human physiology. In addition, some effects of cannabinoids appear to be independent of those receptors. The variety of mechanisms through which cannabinoids can influence human physiology underlies the variety of potential therapeutic uses for drugs that might act selectively on different cannabinoid systems.
- Scientific data indicate the potential therapeutic value of cannabinoid drugs, primarily tetrahydrocannabinol (THC), for pain relief, control of nausea and vomiting, and appetite stimulation; smoked marijuana, however, is a crude THC delivery system that also delivers harmful substances.
- The psychological effects of cannabinoids, such as anxiety reduction, sedation, and euphoria, can influence their potential therapeutic value. Those effects are potentially undesirable for certain patients and situations and beneficial for others. In addition, psychological effects can complicate the interpretation of other aspects of the drug's effect.
- Numerous studies suggest that marijuana smoke is an important risk factor in the development of respiratory disease. A distinctive marijuana withdrawal syndrome has been identified, but it is mild and short lived. The syndrome includes restlessness, irritability, mild agitation, insomnia, sleep disturbance, nausea, and cramping.
- Present data on drug use progression neither support nor refute the suggestion that medical availability would increase drug abuse. However, this question is beyond the issues normally considered for medical uses of drugs and should not be a factor in evaluating the therapeutic potential of marijuana or cannabinoids.

continued

BOX 1-2 Continued**Recommendations:**

- Research should continue into the physiological effects of synthetic and plant-derived cannabinoids and the natural function of cannabinoids found in the body. Because different cannabinoids appear to have different effects, cannabinoid research should include, but not be restricted to, effects attributable to THC alone.
- Clinical trials of cannabinoid drugs for symptom management should be conducted with the goal of developing rapid-onset, reliable, and safe delivery systems.
- Psychological effects of cannabinoids such as anxiety reduction and sedation, which can influence medical benefits, should be evaluated in clinical trials.
- Studies to define the individual health risks of smoking marijuana should be conducted, particularly among populations in which marijuana use is prevalent.
- Clinical trials of marijuana use for medical purposes should be conducted under the following limited circumstances: trials should involve only short-term marijuana use (less than 6 months), should be conducted in patients with conditions for which there is reasonable expectation of efficacy, should be approved by institutional review boards, and should collect data about efficacy.
- Short-term use of smoked marijuana (less than 6 months) for patients with debilitating symptoms (such as intractable pain or vomiting) must meet the following conditions:
 - failure of all approved medications to provide relief has been documented,
 - the symptoms can reasonably be expected to be relieved by rapid-onset cannabinoid drugs,
 - such treatment is administered under medical supervision in a manner that allows for assessment of treatment effectiveness,
 - and involves an oversight strategy comparable to an institutional review board process that could provide guidance within 24 hours of a submission by a physician to provide marijuana to a patient for a specified use.

SOURCE: IOM, 1999.

physiological risks, marijuana dependence and withdrawal, marijuana as a “gateway drug,” and the use of smoked marijuana.

The scientific literature on cannabis use has grown substantially since the publication of *Marijuana and Medicine* in 1999. The current committee conducted an extensive search of relevant databases, including Medline, Embase, the Cochrane Database of Systematic Reviews, and PsycINFO,

FIGURE 1-1 Summary of the committee’s process.

and they initially retrieved more than 24,000 abstracts for articles published since the 1999 report that could potentially be relevant to this study. These abstracts were reduced by limiting articles to those published in English and removing case reports, editorials, studies by “anonymous” authors, conference abstracts, and commentaries. In the end, the committee considered more than 10,700 abstracts for their relevance to this report. (See Appendix B for details.)

The methodological approach taken by the committee to conduct this comprehensive literature review and meet the objectives outlined in the Statement of Task is detailed in Appendix B and briefly described here. Given the large scientific literature on cannabis, the breadth of the statement of task, and the time constraints of the study, the committee developed an approach that resulted in giving primacy to recently published systematic reviews (since 2011) and high-quality primary research that studied 1 or more of 11 groups of health endpoints (see Figure 1-1 and Box 1-3). For each health endpoint, systematic reviews were identified and assessed for quality using methods adapted from published criteria (Whiting et al., 2016); only reviews that were assessed by the committee as being of good or fair quality were considered in this comprehensive review. The committee’s conclusions are based on the findings from the most recently published systematic review and all relevant primary literature that was determined to be fair and good quality that was published after the most recent systematic review. Where no systematic review existed, the committee reviewed all relevant primary research from January 1, 1999, through August 1, 2016. Primary research was evaluated using global assessments of the quality of available studies guided by standard approaches and methodologies (Cochrane Quality Assessment [Higgins et al., 2011], Newcastle–Ontario scale [Wells et al., 2014]). Any deviations from this approach are noted in the relevant chapters. For a comprehensive description of the committee’s approach to evaluating the available literature, please refer to Appendix B.

BOX 1-3
Health Topics and Prioritized Health Endpoints
(listed in the order in which they appear in the report)

Therapeutic effects

- Chronic pain; cancer, chemotherapy-induced nausea/vomiting; anorexia and weight loss; irritable bowel syndrome; epilepsy; spasticity related to multiple sclerosis or spinal cord injury; Tourette syndrome; amyotrophic lateral sclerosis; Huntington's disease; Parkinson's disease; dystonia; dementia; glaucoma; traumatic brain injury; addiction; anxiety; depression; sleep disorders; posttraumatic stress disorder; schizophrenia and other psychoses

Cancer

- Lung cancer; head and neck cancer; testicular cancer; esophageal cancer; other cancer

Cardiometabolic risk

- Acute myocardial infarction; stroke; metabolic dysregulation, metabolic syndrome, prediabetes, and diabetes mellitus

Respiratory disease

- Pulmonary function; chronic obstructive pulmonary disorder; respiratory symptoms (including chronic bronchitis); asthma

Immunity

- Immune function; infectious disease

Informed by the reports of previous IOM committees,³ the committee developed standard language to categorize the weight of evidence regarding whether cannabis or cannabinoid use (for therapeutic purposes) is an effective or ineffective treatment for the prioritized health endpoints of interest, or whether cannabis or cannabinoid use (primarily for recreational purposes) is statistically associated with the prioritized health endpoints of interest. Box 1-4 describes these categories and the general parameters for the types of evidence supporting each category. The committee used these weight-of-evidence categories in their conclusions.

³ *Adverse Effects of Vaccines: Evidence and Causality* (IOM, 2012); *Treatment of Posttraumatic Stress Disorder: An Assessment of the Evidence* (IOM, 2008); *Veterans and Agent Orange: Update 2014* (NASEM, 2016).

Injury and death

- All-cause mortality; occupational injury; motor vehicle crash; overdose injury and death

Prenatal, perinatal, and postnatal exposure to cannabis

- Pregnancy complications for the mother; fetal growth and development; neonatal conditions; later outcomes for the infant

Psychosocial

- Cognition (learning, memory, attention, intelligence); academic achievement and educational outcomes; employment and income; social relationships and other social roles

Mental health

- Schizophrenia and other psychoses; bipolar disorders, depression; suicide; anxiety; posttraumatic stress disorder

Problem cannabis use

- Cannabis use disorder

Cannabis use and abuse of other substances

- Abuse of other substances

The search strategies and processes described above were developed and adopted by the committee in order to adequately address a broad statement of task in a limited time frame while adhering to the National Academies high standards for the quality and rigor of committee reports.

First, the committee was not tasked with conducting multiple systematic reviews, which would have implied a lengthy and robust series of processes. The committee adopted key features of that process; however, a comprehensive literature search; assessments by more than one person of the quality (risk of bias) of key literature and the conclusions; pre-specification of the questions of interest before conclusions were formulated; standard language to allow comparisons between conclusions; and

BOX 1-4
Weight-of-Evidence Categories

CONCLUSIVE EVIDENCE

For therapeutic effects: There is strong evidence from randomized controlled trials to support the conclusion that cannabis or cannabinoids are an effective or ineffective treatment for the health endpoint of interest.

For other health effects: There is strong evidence from randomized controlled trials to support or refute a statistical association between cannabis or cannabinoid use and the health endpoint of interest.

For this level of evidence, there are many supportive findings from good-quality studies with no credible opposing findings. A firm conclusion can be made, and the limitations to the evidence, including chance, bias, and confounding factors, can be ruled out with reasonable confidence.

SUBSTANTIAL EVIDENCE

For therapeutic effects: There is strong evidence to support the conclusion that cannabis or cannabinoids are an effective or ineffective treatment for the health endpoint of interest.

For other health effects: There is strong evidence to support or refute a statistical association between cannabis or cannabinoid use and the health endpoint of interest.

For this level of evidence, there are several supportive findings from good-quality studies with very few or no credible opposing findings. A firm conclusion can be made, but minor limitations, including chance, bias, and confounding factors, cannot be ruled out with reasonable confidence.

MODERATE EVIDENCE

For therapeutic effects: There is some evidence to support the conclusion that cannabis or cannabinoids are an effective or ineffective treatment for the health endpoint of interest.

declarations of conflict of interest via the National Academies' conflict-of-interest policies.

Second, there is a possibility that some literature was missed because of the practical steps taken to narrow a very large literature to one that was manageable within the time frame available to the committee. Furthermore, some very good research may not have been reviewed in this report because it did not directly address the specific health endpoint questions formulated by the committee.

For other health effects: There is some evidence to support or refute a statistical association between cannabis or cannabinoid use and the health endpoint of interest.

For this level of evidence, there are several supportive findings from good- to fair-quality studies with very few or no credible opposing findings. A general conclusion can be made, but limitations, including chance, bias, and confounding factors, cannot be ruled out with reasonable confidence.

LIMITED EVIDENCE

For therapeutic effects: There is weak evidence to support the conclusion that cannabis or cannabinoids are an effective or ineffective treatment for the health endpoint of interest.

For other health effects: There is weak evidence to support or refute a statistical association between cannabis or cannabinoid use and the health endpoint of interest.

For this level of evidence, there are supportive findings from fair-quality studies or mixed findings with most favoring one conclusion. A conclusion can be made, but there is significant uncertainty due to chance, bias, and confounding factors.

NO OR INSUFFICIENT EVIDENCE TO SUPPORT THE ASSOCIATION

For therapeutic effects: There is no or insufficient evidence to support the conclusion that cannabis or cannabinoids are an effective or ineffective treatment for the health endpoint of interest.

For other health effects: There is no or insufficient evidence to support or refute a statistical association between cannabis or cannabinoid use and the health endpoint of interest.

For this level of evidence, there are mixed findings, a single poor study, or health endpoint has not been studied at all. No conclusion can be made because of substantial uncertainty due to chance, bias, and confounding factors.

Special Considerations for the Report

Biological Plausibility

After careful consideration, the committee chose not to attempt to review basic, nonhuman research in order to attempt to bolster evidence for identified health outcomes from cannabis exposure. This policy was, in part, dictated by the time constraints available for crafting this report. Also, while basic research is in the end critical for understanding health outcome mechanisms and suggesting new and innovative interventions,

it often cannot explain the large number of null findings, the frequent variation among human study outcomes, the adverse clinical effects seen in some studies, nor the diversity in host susceptibility to cannabis exposure. Given the methodologic variation in the studies reviewed, as well as potential deficiencies in study design and execution, the committee focused its attention and energy on identifying high-quality studies with the best information and lowest risk of bias as the way to ensure that report findings and conclusions were as informative and relevant as possible. In those instances where cannabis-disease associations seemed relatively secure and evidence-based, the committee believed that the findings would have clinical and public health importance even in the absence of supporting basic studies. Similarly, for those experimental studies where causation could be more explicitly determined—mostly in the area of therapeutics—these findings, if sufficiently robust and replicable, were deemed to stand on their own whether or not bolstered with mechanistic or biologically plausible underpinnings.

Considerations of Observational Studies

The vast majority of the systematic reviews, meta-analyses, and primary literature reviewed in Part III: Other Health Effects consists of observational studies. This is in contrast to the literature base in other fields such as therapeutics (discussed in Part II: Therapeutic Effects). As such, it was not possible to restrict the literature reviews to those that synthesized evidence from randomized clinical trials (RCTs). The methodology used for systematic reviews and meta-analysis originates in the synthesis of data from RCTs, where methodology is highly standardized and structured. The synthesis of observational studies presents some challenges that have not been fully met, arising, in part, out of the greater variety in study design.

Exposure measurement is always an additional concern when evaluating comprehensive reviews of observational studies. Assessment of cannabis exposure is particularly challenging because of its illegal status (in most settings) and the reliance on self-report. Inherent difficulties in accurately assessing the exposure in terms of dose, specific type of cannabis product used, mode of intake, duration, frequency, and other variables result in the variability in definitions used to operationalize cannabis exposure. Additionally, observational studies often have to contend with confounders related to polysubstance use, which obscures the ability to answer questions about the effects of “cannabis only” on the health effects. Moreover, in some cases, samples included different populations (i.e., adolescents versus adults), cannabis-use history (i.e., chronic versus

acute), and patterns of use (i.e., frequency, dose, quantity)—all of which provide mixed or inconsistent evidence as to the effects of cannabis on a specific outcome. Additional limitations include a lack of longitudinal assessments and small study cohorts.

There is also a concern about the broad reporting standards across cannabis research fields. For example, several systematic reviews on cognition discussed in the report's Psychosocial chapter did not consistently describe the methods for scoring the evidence for each endpoint. That is, the reviews include scores of the strength and consistency of the evidence for each outcome, but they provided less information about issues such as study design and statistical analyses. As a result, the committee found that the reviews did not include the conventional data generally found within quantitatively-based systematic examinations of a topic, or such as would be found in meta-analytic reviews. Reasons for this may include variations in study methodologies, instrumentation, populations, or research designs.

Despite these special considerations regarding the use of systematic reviews, meta-analyses, and primary literature of observational studies, the committee determined that using recent good- or fair-quality systematic reviews was the most appropriate approach to adequately address the committee's broad statement of task and comprehensive, prioritized research questions while maintaining a high standard for quality and rigor. For additional information on these considerations, please see Box 11-2 in Chapter 11 (Psychosocial) and Box 12-2 in Chapter 12 (Mental Health).

Comparing Harms and Benefits of Cannabis Use

Several health endpoints are discussed in multiple chapters of the report (e.g., cancer, schizophrenia); however, it is important to note that the research conclusions regarding potential harms and benefits discussed in these chapters may differ. This is, in part, due to differences in the study design of the reviewed evidence, differences in characteristics of cannabis or cannabinoid exposure (e.g., form, dose, frequency of use), and the populations studied. As such, it is important that the reader is aware that this report was not designed to reconcile the proposed harms and benefits of cannabis or cannabinoid use across the report's chapters. In drafting the report's conclusions, the committee made an effort to be as specific as possible about the type and/or duration of cannabis or cannabinoid exposure and, where relevant, cross-referenced findings from other report chapters.

Key Definitions

The terms “marijuana” and “cannabis” are often used interchangeably, particularly within the United States; however, these are two separate entities. Cannabis is a broad term that can be used to describe organic products (e.g., cannabinoids,⁴ marijuana,⁵ hemp⁶) derived from the *Cannabis sativa* plant. These products exist in various forms and are used for a number of different purposes (e.g., medical, industrial, recreational). Given its broad potential, the all-encompassing word “cannabis” has been adopted as the standard terminology within scientific and scholarly communities. The committee uses the term “cannabis” rather than “marijuana” throughout this report.

The committee notes the existence of “cannabimimetic agents” (often referred to as “K2” or “Spice”) which are made up of dried plant matter sprayed with synthetic chemicals that mimic the effect of THC by interacting with cannabinoid receptors in the brain (King, 2014). At the request of the study sponsors, nontherapeutic synthetic cannabinoids are not considered in this study.

REPORT ORGANIZATION

This report is organized into four parts and 16 chapters. Part I: Introduction and Background (Chapters 1–3) provides an overview of the origin, purpose, and organization of the report, as well as essential information on cannabis and cannabis-derived medications and products, and the history and current state of federal and state cannabis policy. In addition to this Introduction (Chapter 1), Chapter 2 (Cannabis) reviews the biology of cannabis and its constituent compounds, exploring the biochemistry of the marijuana plant, its derivatives, and the different routes of administration. Additionally, this chapter provides an overview of synthetic versions of cannabis, including U.S. Food and Drug Administration–approved medicinal synthetics and manufactured cannabis (street drugs such as K2, Spice). Chapter 3 (Cannabis: Prevalence of Use, Regulation, and Current Policy Landscape) provides an overview of cannabis use in the United States and reviews policy related to cannabis legislation.

⁴ Cannabinoids are a group of active chemical compounds found in cannabis. Among the more than 100 different types of cannabinoids are tetrahydrocannabinol (THC) and cannabidiol (CBD) (Small, 2015).

⁵ In general, marijuana refers only to parts of the plant or derivative products that contain substantial levels of tetrahydrocannabinol (THC), the chemical compound that is found in the highest concentrations in the cannabis plant and which is primarily responsible for the plant’s intoxicative qualities (Small, 2015).

⁶ Under U.S. law, cannabis plants with very low levels of THC (not more than 0.3 percent) are not considered marijuana but instead “industrial hemp” (Small, 2015).

Part II: Therapeutic Effects (Chapter 4—Therapeutic Effects of Cannabis and Cannabinoids) discusses the health effects of cannabis and cannabinoids used for therapeutic purposes in relation to the most commonly reported conditions for medical cannabis use (in states where usage is legal), as well as the current qualifying ailments recognized by state medical marijuana programs. Most of the evidence reviewed in this chapter derives from clinical and basic science research conducted for the specific purpose of answering an a priori question of whether cannabis and/or cannabinoids are an effective treatment for a specific disease or health condition. The vast majority of these studies examined the potential therapeutic effect of cannabinoids (e.g., FDA-approved synthetics) rather than smoked cannabis.

Part III: Other Health Effects (Chapters 5–14) discusses the health effects of cannabis and/or cannabis-derived products used for primarily recreational and other nontherapeutic purposes. Most of the evidence reviewed in Part III derives from epidemiological research primarily focusing on smoked cannabis. It is of note that several of the prioritized health conditions discussed in Part III are also reviewed in Part II, albeit from the perspective of effects associated with using cannabis for primarily recreational, as opposed to therapeutic, purposes. A bulleted list of chapter highlights are included in the introduction of the chapters in Part II and Part III of the report.

Within Part III, the effects of cannabis use on cancer incidence are discussed in Chapter 5. Chapter 6 addresses cardiometabolic risks of cannabis use, including effects on acute myocardial infarction, stroke, and metabolic effects—metabolic dysregulation, metabolic syndrome, prediabetes, and diabetes mellitus. Respiratory disease—pulmonary function, chronic obstructive pulmonary disease, respiratory symptoms including chronic bronchitis, and asthma—are discussed in Chapter 7. Immunity and infection are discussed in Chapter 8. The effects of cannabis use on overall mortality, overdose death, employment injuries, and motor vehicle crashes are reviewed in Chapter 9 (Injury and Death). Prenatal, perinatal, and neonatal effects are discussed in Chapter 10. Psychosocial effects, including the effects of cannabis on learning, memory, attention, academic achievement, employment and income, and social relationships and social roles are discussed in Chapter 11, and mental health conditions, including schizophrenia and other psychosis, bipolar disorder, depression, suicide, anxiety, and posttraumatic stress disorder are discussed in Chapter 12. Chapter 13 discusses problem cannabis use, including cannabis use disorder, and the abuse of other substances is discussed in Chapter 14.

Part IV: Research Barriers and Recommendations (Chapters 15–16) reviews the regulatory barriers and methodological challenges that hinder cannabis research, and recommends the actions necessary to successfully

implement a comprehensive cannabis research agenda. Chapter 15 provides an overview of barriers to studying cannabis, including regulatory, policy, and financial, as well as of methodological challenges, and Chapter 16 outlines the committee's proposed research agenda, detailing both short-term and long-term objectives.

Appendixes A–E contain the report glossary, details about the committee's search strategy, systematic reviews considered in this report, open session agendas, and biographical sketches of committee and staff members.
